1.01 Deep Earth Seismology: An Introduction and Overview 1
AM Dziewonski and BA Romanowicz

1.02 Theory and Observations - Instrumentation for Global and Regional Seismology 29
JM Steim

1.03 Theory and Observations - Earth's Free Oscillations 79
JH Woodhouse and A Deuss

1.04 Theory and Observations: Normal Mode and Surface Wave Observations 117
G Laske and R Widmer-Schnidrig

1.05 Theory and Observations: Body Waves, Ray Methods, and Finite-Frequency Effects 169
J Virieux and G Lambaré

1.06 Theory and Observations: Forward Modeling: Synthetic Body Wave Seismograms 201
VF Cormier

1.07 Theory and Obeservations - Forward Modeling and Synthetic Seismograms, 3D Numerical Methods 231
J Tromp

1.08 Theory and Observations - Seismology and the Structure of the Earth: Teleseismic Body-Wave Scattering and Receiver-Side Structure 253
MG Bostock

1.09 Theory and Observations - Seismic Anisotropy 277
V Maupin and J Park

1.10 Theory and Observations - Seismic Tomography and Inverse Methods 307
C Thurber and J Ritsema

1.11 Crust and Lithospheric Structure - Global Crustal Structure 339
WD Mooney

1.12 Crust and Lithospheric Structure - Seismic Imaging and Monitoring with Ambient Noise Correlations 391
M Campillo and P Roux

1.13 Crust and Lithospheric Structure - Seismic Structure of Mid-Ocean Ridges 419
RA Dunn

1.14 Crust and Lithospheric Structure - Hot Spots and Hot-Spot Swells 453
M McNutt and DW Caress

1.15 Crust and Lithospheric Structure - Active Source Studies of Crust and Lithospheric Structure 479
A Levander, CA Zelt, and WW Symes

1.16 Crust and Lithospheric Structure - Natural Source Portable Array Studies of the Continental Lithosphere 513
DE James

1.17 Crustal and Lithospheric Structures Between the Alps and East European Craton from Long-Range Controlled Source Seismic Experiments 557
A Guterch, M Grad, G Randy Keller, and E Brückl

1.18 Crust and Lithospheric Structure - Seismological Constraints on the Lithosphere-Asthenosphere Boundary 587
KM Fischer

1.19 Deep Earth Structure - Upper Mantle Structure: Global Isotropic and Anisotropic Elastic Tomography 613
J-P Montagner

1.20 Deep Earth Structure - Subduction Zone Structure in the Mantle Transition Zone 641
Y Fukao and M Obayashi

1.21 Deep Earth Structure - Transition Zone and Mantle Discontinuities 655
R Kind and X Li

1.22 Deep Earth Structure: Lower Mantle and D″ 683
T Lay

1.23 Deep Earth Structure: The Earth's Cores 725
A Souriau and M Calvet

1.24 Deep Earth Structure: Seismic Scattering in the Deep Earth 759
PM Shearer

1.25 Deep Earth Structure: *Q* of the Earth from Crust to Core 789
BA Romanowicz and BJ Mitchell

1.26 Constraints on Seismic Models from Other Disciplines - Constraints from Mineral Physics on Seismological Models 829
L Stixrude and R Jeanloz

1.27 Constraints on Seismic Models from Other Disciplines - Constraints on 3-D Seismic Models from Global Geodynamic Observables: Implications for the Global Mantle Convective Flow 853
AM Forte, NA Simmons, and SP Grand

PREFACE

The *Treatise on Geophysics* is a comprehensive and in-depth study of the physics of the Earth and of terrestrial-like planets residing both within and outside our solar system. Its breadth and detail of coverage are beyond what any single geophysics text can provide. The first edition of the *Treatise on Geophysics* was published in 2007, nearly a decade ago. Of course, there is much progress in science in that length of time and the field of geophysics has grown rapidly and developed new lines of inquiry. Accordingly, we have brought the *Treatise on Geophysics* up-to-date with this second edition. The new edition will continue to provide students and professionals with fundamental and state-of-the-art discussion of all aspects of geophysics. In this new edition, the reader will find updates to all the chapters contained in the first edition and new chapters that discuss topics missing from the first edition. In a few instances, chapters from the first edition have simply been reprinted in order to avoid gaps in coverage. Chapters that emphasized fundamental physics often required little updating.

A highlight of the second edition is a new volume on Resources in the Near-Surface Earth. The new volume discusses the role of geophysics in the exploitation and conservation of natural resources and the assessment of degradation of natural systems by pollution. The near surface is a zone where humans and natural systems interact. Understanding the effects of human impacts is a challenge particularly for the long term.

There are four new chapters in the volume on Deep Earth Seismology. One of them describes progress in seismic instrumentation in the last 30 years in the era of broadband digital sensor and recording systems. Another one addresses a new approach for the determination of crust and uppermost mantle structure, based on ambient noise cross-correlations. This has revolutionized the field, since it allows the study of regional structure at high resolution in areas where there are no earthquakes. The third new chapter is devoted to recent advances in characterizing the lithosphere–asthenosphere boundary under both oceans and continents. Finally, the last new chapter discusses the morphology of subducted slabs in the Earth's transition zone.

The Mineral Physics volume has new chapters on dynamic (shock-wave) compression methods, and on the mineralogy of the upper mantle and the D″ layer focusing on post-perovskite, and extrasolar super-Earths.

New material in the Geodesy volume expands the temporal resolution and latency of geodetic measurements to high-rate, real-time measurements and increases the spatial resolution to meter size pixels with optical and radar imaging systems. Application areas are extended with new material on the uses of Earth gravity measurements.

The Earthquake Seismology volume has a new chapter on rock mechanics that is a comprehensive account of modern rock mechanics with emphasis on the variation of frictional properties of rocks during an earthquake cycle. Many chapters have considerable updates reflecting the lessons from significant recent earthquakes (e.g., the 2011 Tohoku-Oki earthquake and the 2013 Okhotsk deep earthquake), new observations on slow slips and triggered earthquakes, and developments of new methods (e.g., back projection method). Some chapters are updated (e.g., paleoseismology and strong ground motion) with substantial new material.

Chapters in the Geomagnetism volume have been updated to include recent advances in the acquisition of larger data sets and higher quality data and in the construction of more reliable and sophisticated models. Improvements in data have occurred in areas such as magnetic anomalies, paleointensities, and planetary magnetism. Improvements in models of the present day field include so-called comprehensive models and models that incorporate data assimilation.

The Crustal and Lithosphere Dynamics volume has new contributions on mountain building and landscape evolution.

The Mantle Dynamics volume contains new chapters on the generation of plate tectonics from mantle convection and the core–mantle boundary region.

The Core Dynamics volume features a comprehensive update of this rapidly changing subject, including new chapters on turbulence and waves in the fluid outer core.

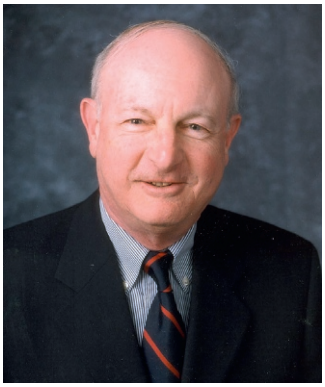
The volume on the Evolution of the Earth presents a new assessment on the role of volatiles in Earth evolution.

There are new chapters in the Physics of Terrestrial Planets and Moons volume on planetary atmospheres, planetary tectonics, extrasolar planets and asteroids and comets. The study of extrasolar planets has had explosive growth in the last decade and new spacecraft missions have significantly enhanced our knowledge of solar system planets and moons.

Finally, this is an opportunity for me to thank and acknowledge the editors of the individual volumes for their hard work, patience, dedication, and commitment in bringing this new edition of the Treatise to fruition. I am also indebted to Gemma Tomalin of Elsevier for her care and attention to the organization and production of the Treatise and to Deepa Arumugam for her careful coordination of the proofs from the copyeditor and typesetter. Of course, the authors of the individual chapters are the ones who are responsible for the excellence of the Treatise. We have all had some ups and downs in the process of producing the second edition of the Treatise but the final product is one that we can all view with pride.

Gerald Schubert
Editor-in-Chief

EDITOR-IN-CHIEF



Gerald Schubert is Distinguished Professor Emeritus in the Department of Earth, Planetary and Space Sciences at the University of California, Los Angeles. His research interests encompass the physics of the interiors and atmospheres of the Earth, the Moon, and the other moons and planets of the solar system. He is co-author with Donald Turcotte of *Geodynamics* (ed. 3, Cambridge University Press, 2014) and with Turcotte and Peter Olson of *Mantle Convection in the Earth and Planets* (Cambridge University Press, 2001). He is the author of over 540 research papers. He has participated in a number of NASA's planetary missions, including Apollo, Pioneer Venus, Magellan, and Galileo, and has been editor and editorial board member of many journals, including *Icarus*, *Journal of Geophysical Research*, *Geophysical Research Letters*, and *Annual Reviews of Earth and Planetary Sciences*. Professor Schubert is a Fellow of the American Geophysical Union and a recipient of the Union's James B. MacElwane medal and the Harry H. Hess medal. He is a member of the National Academy of Sciences and the American Academy of Arts and Sciences.

Applications of seismology to the study of the Earth's interior are only a little over 100 years old. Its tools in determining the properties of inaccessible Earth are the most powerful among all geophysical methods. The principal reasons are the availability of natural (earthquakes) or controlled (explosions and vibrators) sources of elastic waves and their relatively low attenuation with distance. Seismological methods span some six orders of magnitude in frequency, and the depth of an investigated structure may range from a few meters in engineering applications to the center of the Earth. Progress in seismology has been achieved through developments on several fronts: theory, instrumentation, and its deployment, as well as computational resources.

Even though the studies of earthquakes and the Earth's structure are closely related, the two subjects are often discussed separately. This volume is devoted to the Earth's structure and Volume 4 to studies of earthquakes. Nevertheless, the relationship is intimate. For example, it is possible to formulate an inverse problem in which earthquake locations are sought simultaneously with the parameters of the Earth's structure, including three-dimensional (3-D) models (see Chapter 1.10).

In the past 25 years, important progress has been made on several fronts: (1) the development of broadband digital instrumentation (see Chapter 1.02), which has allowed the construction of digital seismic databases of unprecedented quality at both the global and the regional scales; (2) the development of powerful data analysis tools, made possible by ever more efficient computer technology; and (3) theoretical progress in the forward and inverse computation of the effects of strong lateral heterogeneity on seismic-wave propagation. The combination of these factors has led to much improved images of structure at the global and regional scale, often helped by the inclusion of constraints from other types of data, primarily from the fields of mineral physics and geodynamics. This volume is thus divided into four parts. The first part principally covers seismic instrumentation, theoretical developments, and seismic data analysis techniques. Chapter 1.03 discusses the state of the art in the computation of the Earth's normal modes, while Chapter 1.04 describes progress in the measurements of normal-mode and long-period surface waves. Two chapters are devoted to the computation of synthetic seismograms in the presence of lateral heterogeneity, suitable for the case of body waves (see Chapters 1.05 and 1.06). Significant progress has recently been made in the computation of synthetic seismograms in a 3-D Earth using numerical methods. A review is given in Chapter 1.07. With the deployment of dense regional arrays of broadband seismometers, another area of rapid progress has been that of the adaptation of methodologies first developed in exploration seismology to the case of fine structure imaging of the crust and upper mantle at larger scale. These approaches are described in Chapter 1.08 for passive-source applications and in Chapter 1.15 for the case of active sources. The realization of the importance of anisotropy in the Earth has led to theoretical and methodological developments (see Chapters 1.09 and 1.18). Note that the issue of anisotropy is also discussed in Chapter 1.19 in the context of the inversion of surface-wave data. Inverse methods, in particular in the context of global and regional tomography, are discussed in Chapter 1.10.

In the second part of Volume 1, reviews of the status of our knowledge on the structure of the Earth's shallow layers are presented, starting with a global review of the Earth's crustal structure (see Chapter 1.11). During the last decade, there has been rapid development in using the Earth's noise as a source of the signal. A review of these developments is presented in Chapter 1.12. Two chapters discuss regional structure in the oceans: Chapter 1.13 for mid-ocean ridges and Chapter 1.14 for hot-spot swells. Chapter 1.18 presents results of studying anisotropy in subduction zones with particular attention devoted to the flow-induced preferential orientation of olivine crystals. Finally, two chapters are devoted to the results of regional experiments: upper-mantle studies using data from portable broadband experiments (see Chapter 1.16) and crustal studies, specifically in Europe, from high-resolution long-range active-source experiments (see Chapter 1.17).

The third part of this volume concerns the Earth's deep structure, divided into its main units: the upper mantle (see Chapter 1.19); the transition zone and upper-mantle discontinuities (see Chapter 1.21); regional tomography of

subducted slabs, with particular attention given their stagnation at the bottom of the transition zone (Chapter 1.20); the lower mantle; and the highly complex D″ region at the base of the mantle (Chapter 1.22) as well as the Earth's core (see Chapter 1.23). Chapter 1.24 is devoted to the subject of scattering in the Earth and Chapter 1.25 to that of attenuation. Finally, the fourth part of this volume comprises two chapters, in which constraints on the Earth's structure from fields other than seismology, mineral physics (see Chapter 1.26) and geodynamics (see Chapter 1.27), are discussed.

This volume addresses various aspects of 'structural seismology' and its applications to other fields of Earth sciences. Not all the subjects are covered in comparable detail, even though the completeness of the coverage was the initial objective of the editors. Compared to the 2007 edition of Volume 1 of *Treatise on Geophysics*, this edition contains four new (Chapters 1.02, 1.12, 1.18, and 1.20). Most of the other chapters have been significantly updated, except Chapters 1.14, 1.15, and 1.16, which are reprinted 'as is' from the 2007 edition.

In what follows, we briefly describe the developments in seismology from the end of the nineteenth century until the present, with the main emphasis on the development of instrumentation and its deployment, because seismology is a data-driven science. An account of the history of seismology can be found, among others, in Agnew et al. (2002). We also present our point of view, which some may consider controversial, specifically on current issues in global tomography and interpretation of the 3-D models not discussed in any of the chapters. We justify bringing these issues forward because of our belief that interpretation of tomographic results in terms of mantle dynamics does not match the robustness of models built using data that have good resolution at all depths in the mantle.

1.01.1 Developments from the Late Nineteenth Century until the Early 1950s

The theoretical beginnings of seismology may be traced to the eighteenth- and nineteenth-century studies of elasticity and propagation of elastic waves in solids. Lord Kelvin provided the first numerical estimate of the period of the fundamental vibrational mode ($_0S_2$) in 1863, but the development of the proper theory for a homogeneous sphere had to wait nearly 50 years (Love, 1911). Lord Rayleigh solved the problem of propagation of surface waves in an elastic half-space in 1877.

This preceded the first mechanical seismographs, which were developed in the 1880s. Originally, the seismographs had very low sensitivity and were used for the recording of local earthquakes. The history of global seismology begins with the recording of an earthquake in Japan on 19 April 1889 by von Rebeur-Paschwitz. He associated a disturbance recorded on a tiltmeter, used to study the Earth's tides, with the reports of a great earthquake in Japan. Figure 1 shows a copy of this recording as published in *Nature* (von Rebeur-Paschwitz, 1889, 1895).

The early seismographs were mechanical pendulums with no damping, other than friction. Their magnifications (the ratio of the amplitude on a seismogram to the actual ground motion) were very low, and because of the lack of damping, the records were very oscillatory and it was difficult to distinguish the arrivals of different phases. An improved mechanical

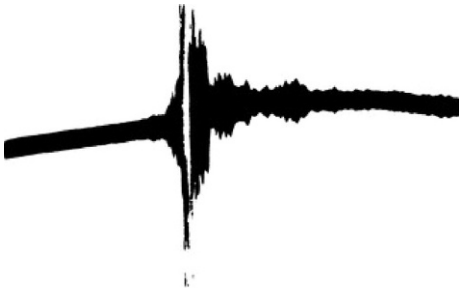

Figure 1 The historical first recording of a teleseismic event: an earthquake in Japan recorded in Potsdam on a tiltmeter designed by von Rebeur-Paschwitz. The early seismograms had difficulty with damping the pendulum motion and made phase identification difficult. Reproduced from von Rebeur-Paschwitz (1895) Horizontalpendal-Beobachtungen auf der Kaiserlichen Universitats-Sternwarte zu Strassburg 1892–1894. *Gerlands Beiträge zur Geophysik* 2: 211–536.

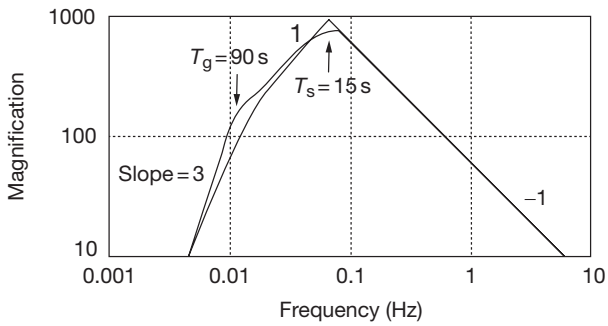

Figure 2 Plot of the ground-motion (amplitude) response of a World-Wide Standardized Seismograph Network (WWSSN) station with a seismograph free period (T_s) of 15 s and galvanometer with a free period (T_g) of 90 s. The segment between these two periods has a flat velocity response, characteristic of broadband seismometers. The response in modern instruments is shaped electronically; a typical FDSN station has a flat velocity response from 5 Hz to 360 s. Reproduced from Wielandt E (2002) Seismic sensors and their calibration. In: Bormann IP (ed.) *IASPEI New Manual of Seismological Observatory Practice*, vol. I, pp. 1–46. Potsdam: GeoForschungsZentrum Potsdam, Chapter 1.06.

seismograph with controlled damping was built by Wiechert in 1904. Soon afterward, Galitzin (1914) developed an electromagnetic seismograph system, where the motion of the seismometer's pendulum generated an electric current by motion of a coil in the magnetic field. This current was, in turn, carried to a galvanometer; the rotation of the galvanometer's coil in a magnetic field was recorded on photographic paper by a beam of light reflected from a mirror attached to the coil. The response of the system depended on the sensitivity and free period of the seismometer and of the galvanometer and their damping. While the system was more complex, it allowed for much more flexibility in selecting a desired response. Figure 2 shows the response of the seismograph–galvanometer system and gives an idea of the way it could be shaped by the choice of different free periods of the system's components. With gradual improvements, the seismometer–galvanometer system, recording on photographic paper, was commonly used during the following 60–70 years, when it was gradually replaced by digital systems (see Chapter 1.02).

With the improvement of the recording systems technology, phase identification became easier, and it was possible to identify P-arrivals (primary) corresponding to compressional waves, S-arrivals (secondary) corresponding to shear waves, and L-arrivals, sometimes called 'the main phase,' corresponding to surface waves. The surface waves caused some confusion because there was also a transverse motion, not predicted by Rayleigh. It was not until 1911 that Love showed that transversely polarized surface waves can propagate in a layered Earth.

Progress in the first decade of the twentieth century was rapid. Some classical problems such as computation and inversion of travel times for the velocity structure were solved by (Benndorf, 1905, 1906; Herglotz, 1907; Knott, 1899; Wiechert, 1907; Zöppritz, 1907) independently developed equations for the amplitude of reflected and transmitted waves at the boundary between two elastic media.

As regards the Earth's structure, there was a paper by Oldham (1906), in which he proposed the existence of the Earth's core, although there has been some confusion in identification of phases: what he thought to be a delayed S-wave was actually an SS (e.g., Schweitzer, 2007). Gutenberg (1913) properly identified reflections from the core–mantle boundary (CMB) and determined the radius of the core quite accurately, and Jeffreys (1926) showed that the core is liquid. Mohorovičić (1910) discovered the boundary between the crust and the upper mantle, thus beginning the era of studies of the crust and lithosphere, which greatly accelerated after World War II.

The first global seismographic networks (GSNs) were established in the early years of the twentieth century. The first one was deployed by John Milne in various countries of the British Commonwealth with the support of the British Association for the Advancement of Science and eventually consisted of 30 stations (Adams et al., 2002). The Jesuit Network was established soon afterward, with a particularly large number of instruments in the United States, but also including stations on all continents (Udias and Stauder, 2002). With a global coverage sufficient to locate large earthquakes, informal bulletins were published using the location method developed by Geiger (1910, 1912), which (with many modifications) is still used today. In 1922, the International Seismological Summary (ISS), with international governance, was established under Professor Turner of the University of Oxford with the charge to produce 'definitive global catalogs' from 1918 onward.

The slow progress in unraveling the Earth's structure culminated in the 1930s with the discovery of the inner core by Lehmann (1936) and the compressional velocity, shear velocity, and density models by Gutenberg (1913), Jeffreys (1926), and Bullen (1940). The Gutenberg and Jeffreys velocity models are shown in **Figure 3**; except for the details of the upper-mantle structure, these models are very similar to the modern ones. The low-velocity zone above the inner–outer core boundary in the model of Jeffreys illustrates the sometimes unfortunate tendency of seismologists to introduce physically implausible features in the model in order to match the data; Jeffreys needed to add a 2 s delay to match the inner-core travel times and accomplished it by inserting this feature, which is impossible to reconcile with the chemical and physical properties of materials in this depth range (Birch, 1952). The other important difference between the models of Jeffreys and Gutenberg was the existence of a low-velocity zone in the depth range 100–200 km in the upper mantle. There were very hot debates on this issue; it can now be explained by the fact that they used data from tectonically different regions; there is a pronounced low-velocity zone in the western United States, but not under the Eurasian shield regions.

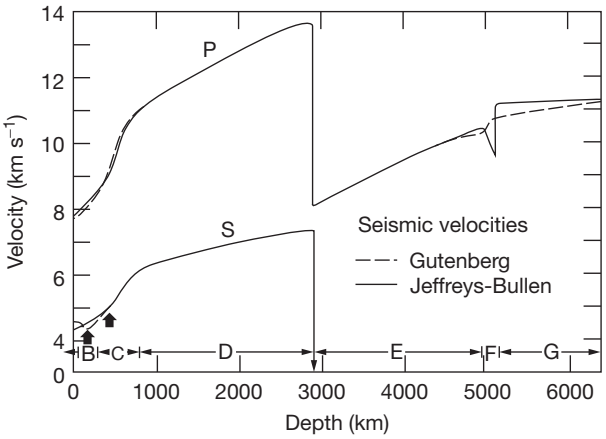

Figure 3 Comparison of the seismic velocity models of Gutenberg and Jeffreys, both built in the 1930s. The principal difference between the models is the presence of the low-velocity zone in the Gutenberg model and the structure near the inner–outer core boundary where the low-velocity zone in the Jeffreys model is erroneous and the velocity increase in the inner core is larger than in the Gutenberg model. With the exception of the transition zone (400–650 km depth), the modern models are not very different. Reproduced from Anderson DL (1963) Recent evidence concerning the structure and composition of the Earth's mantle. *Physics and Chemistry of the Earth* 6: 1–129.

With internal reflections and conversions of waves at the boundaries, seismologists developed a system of phase identification that reflects a combination of the types of waves (P or S), the region in which they propagate (K and I for the P-waves in the outer and inner core, respectively; PKIKP designates a phase that travels as P in the mantle, P in the outer core, and P in the inner core) and the boundary at which they were reflected (c for CMB and i for the inner–outer core boundary). A shear wave reflected once from the free surface at the midpoint of its path is designated by SS; higher multiple reflections, like SSS or SSSSS, can be observed by sampling a large volume of the Earth along their paths. For earthquakes with a finite focal depth, the P- and S-waves traveling upward from the source have designation of p or s; following reflection at the surface, they represent the so-called depth phases (e.g., pP and sP); the travel-time difference between the arrival of pP and P strongly depends on focal depth.

Figure 4 shows examples of various seismic phases, and **Figure 5** is the graphic representation of the travel times as a function of distance computed by Jeffreys and Bullen (1940) for the model of Jeffreys (1939). It is remarkable that this set of tables, including predictions for different focal depths, was calculated using a manual mechanical calculator! The data used by Jeffreys were extracted from the ISS, the precursor of the International Seismological Centre (ISC), which (with international financial support and governance) resumed the ISS role in 1964 and continues until today.

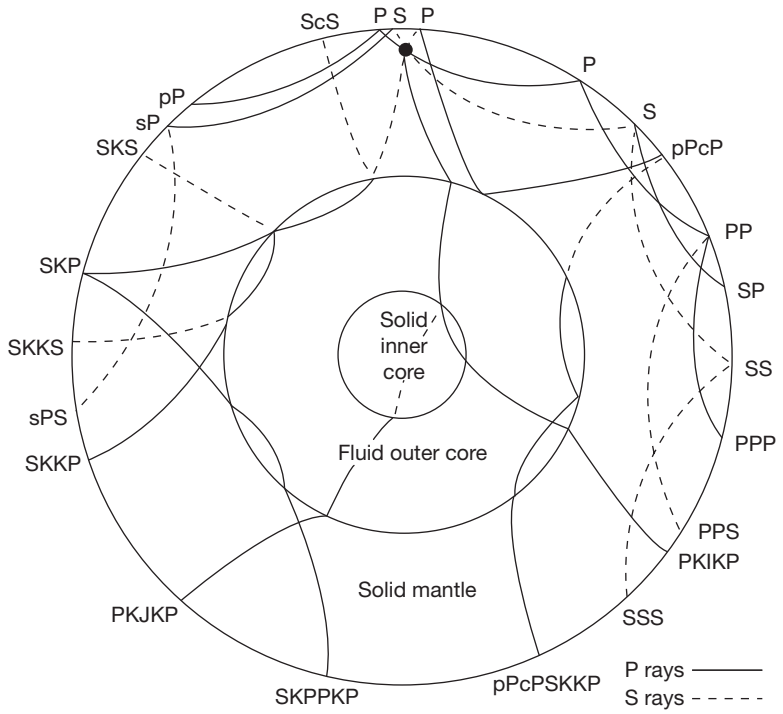

Figure 4 Examples of seismic rays and their nomenclature. The most commonly identified phases used in earthquake location are the first arriving phases: P and PKIKP. Reproduced from Stein S and Wysession M (2003) *An Introduction to Seismology, Earthquakes and Earth Structure*. Oxford: Blackwell, ISBN: 0865420785.

Bullen (1949) divided the Earth into a number of concentric shells, designated by letters from A to F; in this division, the lower mantle was designated by the letter D″. when Bullen recognized that the deepest 150 km of the lower mantle had an anomalously flat velocity gradient, he divided the region D into D′ and D″. More recently, and not entirely correctly, D″ came to signify the structure in the deepest 300 km, or so, of the lower mantle, which is characterized by a still-growing collection of structural and compositional complexities (see **Chapter 1.22**).

It was recognized relatively early that the dispersion of surface waves was different in the continents than in the oceans, with an indication that the oceanic crust was significantly thinner. Computing the dispersion of surface waves was algebraically and numerically difficult; the correct formulas for the dispersion of Rayleigh waves in a layer over a half-space were formulated by Stoneley (1928), and the case of the two layers over a half-space could be solved only for a very specific set of parameters.

1.01.2 Developments from 1950s to the Early 1980s

It must have been frustrating for seismologists not to be able to use information about the Earth's structure contained in the most prominent features of the seismograms: the dispersed surface waves. This changed when Haskell (1953) adapted to the case of elastic media the method first proposed by Thomson (1950) in the acoustics case. The approach made it possible to compute dispersion of surface waves (Rayleigh and Love) in a layered medium with an arbitrary number of layers over a half-space. It involved multiplication of matrices, one for each layer, changing the wave number for a fixed frequency such as to match the boundary conditions (vanishing of stresses) at the free surface. Because of the enormous amount of calculations to be performed, it required application of an electronic computer, and its application opened yet a new era in seismology. The Haskell's matrix method has been adapted to other problems in seismology, such as calculation of synthetic seismograms using the 'reflectivity method' (Fuchs and Müller, 1971). Electronic computers were at first very expensive and rare, and it was not until the 1960s that they became generally available at universities (Haskell worked at the Air Force Cambridge Research Laboratories).

Surface-wave dispersion began to be studied intensively in the 1950s principally at the Lamont Geological Observatory of Columbia University, primarily by Ewing and Press, who observed mantle waves in the 1952 Kamchatka earthquake, identifying arrivals from R6 to R15 (see **Chapter 1.04**) and measuring their group velocities up to a period of 500 s (Ewing and Press, 1954). Regional measurements of surface-wave dispersion were initiated by Press (1956). A monograph by Ewing et al. (1957) summarizes the state of the knowledge on seismic-wave propagation in layered media at that time. Ewing and Press also developed a true long-period seismograph, which was capable of recording mantle waves even for moderately sized earthquakes. This instrument was deployed at 10 globally distributed International Geophysical Year network stations operated by Lamont.

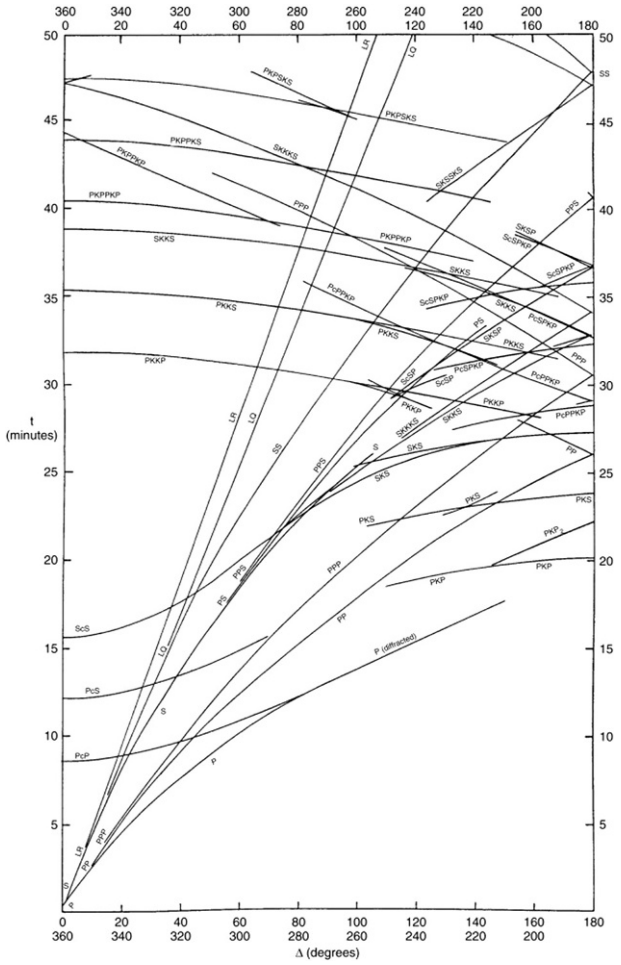

Figure 5 Travel times of seismic phases for the surface focus as computed by Jeffreys and Bullen (1940). Reproduced from Jeffreys H and Bullen KE (1940) *Seismological Tables*, p. 50. London: British Association for the Advancement of Science.

It is not often that a mistake leads to favorable results, but this was the case with the free oscillations of the Earth. Benioff (1958) reported an oscillation with a period of 57 min seen in the record of the 1952 Kamchatka earthquake. Even though this observation was eventually attributed to an artifact in the functioning of the instrument, it stimulated the theoretical and computational research needed to calculate eigenfrequencies for a realistic Earth model. Some of the calculations preceded Benioff's report (Jobert, 1956, 1957), but the efforts of Pekeris and Jarosch (1958) and Takeyuchi (1959) were clearly motivated to explain the observed period. These calculations, using the variational approach and the Jeffreys–Bullen Earth model, predicted the period of ${}_0S_2$ to be 52 min and that of ${}_0T_2$ 43.5 min. Neither was close enough to Benioff's 'observation.' The modern approach was developed by Alterman et al. (1959), who recast the system of three second-order partial differential equations into a system of six first-order differential equations, thus removing the need for differentiation of the elastic constants, and allowed the use of standard numerical methods to obtain the solution. Tests using the Gutenberg and the Jeffreys–Bullen models showed that they predict very similar free oscillation periods for the gravest modes but differ at shorter periods by 1–2%.

When the greatest instrumentally recorded earthquake of 20 May 1960 occurred in Chile, seismologists had all the tools (theory, computers, and instrumentation) needed to measure and interpret its recordings. Three back-to-back papers in a 1961 issue of the *Journal of Geophysical Research* reported the first correct measurements of free oscillation periods: Benioff et al., Ness et al. (1961), and Alsop et al. (1961). The observations were made on strainmeters in Isabella, Ñaña, and Ogdensburg; seismographs at Pasadena; and a gravimeter at the University of California, Los Angeles (UCLA). All three studies agreed in mode identification and found that their periods were very close to those predicted by the existing Earth models (Pekeris et al., 1961a). More detailed studies of the spectra revealed that they are split; the effect of the Earth's rotation was shown to explain this effect (Backus and Gilbert, 1961; Pekeris et al., 1961b). Thus, normal-mode seismology was born. Progress in the theory, particularly considering the effect of lateral heterogeneities and mode coupling, would extend over decades to come. First attempts at inversion of normal-mode data were not particularly successful; the density model of Landisman et al. (1965) was flat throughout the lower mantle, implying either a strong radial heterogeneity or an immensely superadiabatic temperature gradient.

Backus and Gilbert (1967), Backus and Gilbert (1968), and Backus and Gilbert (1970) provided the formal background for consideration of geophysical inverse problems, and even though their own experiments with inversion of normal-mode periods for the velocities and density, using a subset of normal-mode data, were discouraging (two very different models were found fitting the data nearly exactly; Backus and Gilbert, 1968), the idea of resolving kernels and trade-offs became part of the geophysical terminology.

Because seismic methods were considered essential in discriminating between earthquakes and nuclear explosions (Berkner et al., 1959), an intensive observational program, called Vela Uniform, was initiated. One of its components of great significance to studies of the Earth's interior was the World-Wide Standardized Seismograph Network (WWSSN), consisting of a set of three-component short-period and three-component long-period seismographs, with identical responses, except for magnification, which depended on local noise levels. At its peak, the WWSSN consisted of 125 stations (**Figure 6**), with distribution limited by geography and politics: there were no stations in the Soviet Union, China, and poorly developed areas in Africa and South America. The novel aspect of WWSSN was its standardized response and centralized system of distribution of copies of seismograms. Individual stations were sending the original seismograms to a central location, where they were microfilmed, using a very high-resolution camera, and then returned to the stations. A seismologist could request copies of seismograms for a particular date and receive them as either microfilm chips or photographic enlargements to the original size. Several larger institutions had a blanket order on all the records. This data accessibility represented major progress with respect to the earlier procedures, where one had to request copies of seismograms from individual stations, which greatly limited and delayed the research. WWSSN functioned for 20–25 years,

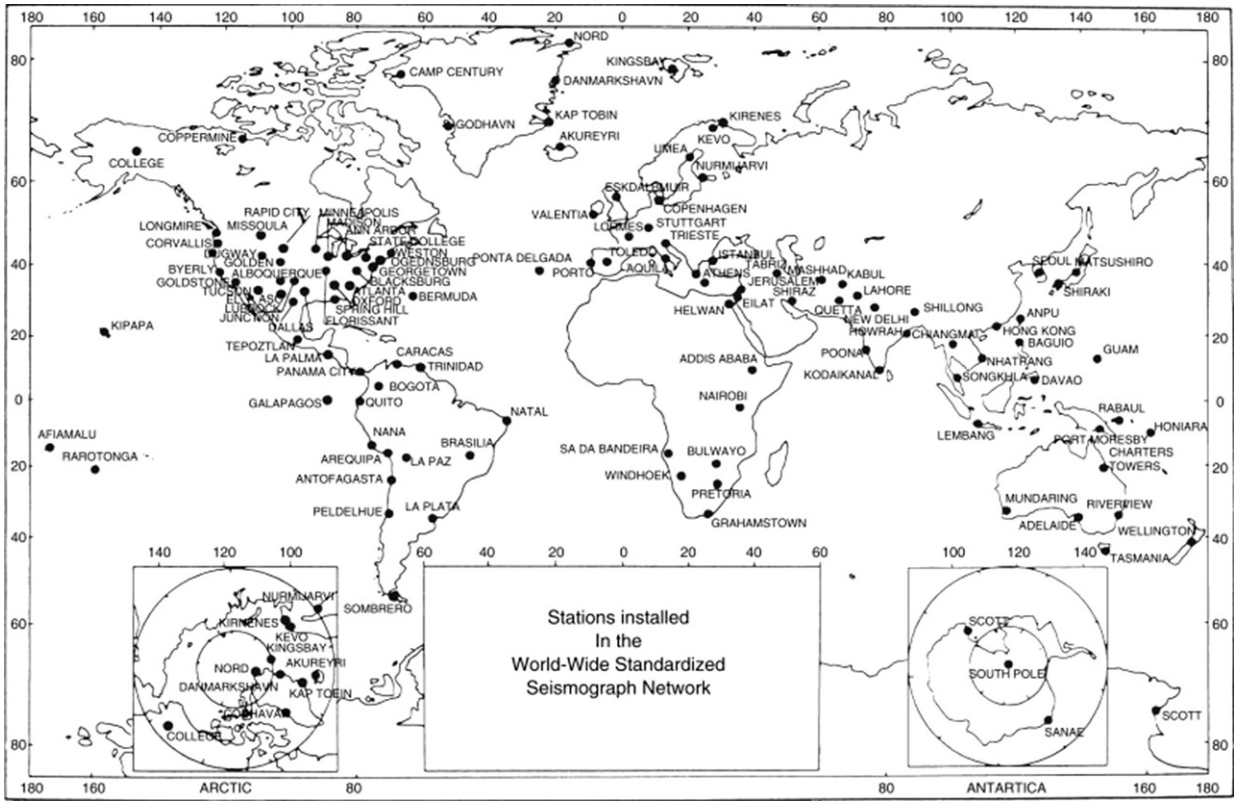

Figure 6 Map of the stations of WWSSN established in the early 1960s, following recommendations of Berkner et al. (1959). Courtesy of US Geological Survey.

slowly declining in the quality and number of stations; it ceased functioning in the late 1980s when data from new digital stations became available.

Another development of the 1960s was the introduction to seismology of digital recording, greatly facilitating research and the development of massive, computerized data-processing methods. One such facility, the large aperture seismic array (LASA), shown in Figure 7, was built in the mid-1960s in Montana. It consisted of six 'rings,' for a total of 21 subarrays, each with 25 short-period seismometers emplaced in boreholes, to improve the signal-to-noise ratio. The data were telemetered in real time to a central location in Billings, Montana, where they were processed for detection of a signal. Major scientific discoveries were made with this tool, particularly when weak signals were involved, for example, observations of reflections from the inner core. In practical terms, the array did not meet the expectations; the site response across this 200 km aperture array varied so much that the signals had limited coherency and signal enhancement by stacking was not as effective as expected. A somewhat smaller array was installed a few years later in Norway (NORSAR); elements of this array are still active and have been upgraded recently to modern, high-dynamic-range band–band response. Most of the arrays of the International Monitoring System (IMS) used for seismic discrimination purposes have an aperture of only several kilometers; because on that scale, the coherency at 1 Hz frequency can be achieved.

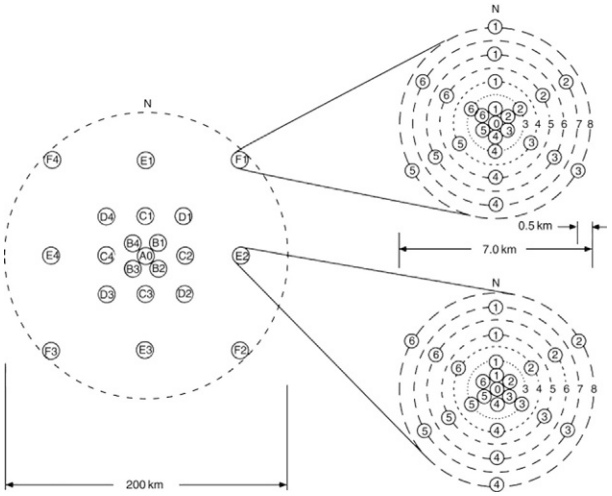

Figure 7 Configuration of the large aperture seismic array (LASA) and an expanded view of two of its subarrays. Reproduced from Stein S and Wysession M (2003) *An Introduction to Seismology, Earthquakes and Earth Structure*. Oxford: Blackwell, ISBN: 0865420785.

One of the important results obtained from the analysis of array data was the detection of upper-mantle discontinuities (Johnson, 1967), confirming the result predicted by experimental petrology that there should be two discontinuities at

pressures and temperatures corresponding to depths of about 400 and 650 km, respectively (Birch, 1952).

Surface-wave studies blossomed in the 1960s. At first, measurements of dispersion involved rather simple 'analog' methods, such as the peak-and-trough approach to measuring phase and group velocities. Some very important results were obtained in this way, such as the Canadian Shield study of Brune and Dorman (1963). Digital analysis, however, was soon to take over. Manual digitization of analogue recordings, WWSSN data in particular, became easier, and with increasing availability of computers and decreasing cost of computations, various techniques were developed, for the most part involving applications of the Fourier transform. With the development of the fast Fourier transform (FFT) algorithm (Cooley and Tukey, 1965), the cost of time-series analysis declined dramatically; a review by Dziewonski and Hales (1972) summarizes the state of the art at the beginning of the 1970s. Some of these methods, such as the multiple filtration technique to measure group velocity dispersion, residual dispersion measurements, and time-variable filtration, are still in use today. The 1960s have also seen the first studies of intrinsic attenuation by Anderson and Archambeau (1964), who developed partial derivatives (kernels) for Q from mantle-wave attenuation. Also, the first studies of lateral heterogeneity were conducted using the 'pure path' approach (Toksöz and Anderson, 1966).

Seismic experiments with controlled sources were conducted in a multi-institutional mode. One of the largest experiments was 'Early Rise' carried out in the July of 1966. A series of 38 explosions in Lake Superior of up to 5 tons of outdated torpedoes were used as the source of signals recorded by hundreds of seismometers – deployed by 12 governmental and academic groups – spreading radially in all directions. Signals were recorded as far as 2500 km, reaching teleseismic distances and providing a detailed profile of P velocity under a continental upper mantle (Green and Hales, 1968). A detailed review of crustal and upper-mantle studies with controlled sources is provided in **Chapter 1.11**.

With a large new data set, particularly measurements of previously unreported periods of long-period overtones provided by the analysis of free oscillations generated by the 1964 Alaskan earthquake and recorded at WWSSN stations (Dziewonski and Gilbert, 1972, 1973), studies of 1-D structure entered a new era. The resolution of this data set was sufficient to constrain the density profile in the mantle and the core; this turned out to be quite consistent with the behavior, in the lower mantle and outer core, of a homogeneous material under adiabatic compression. Jordan and Anderson (1974) were the first to combine the normal-mode and travel-time data, including differential travel-time data.

Numerous additional overtone data were obtained by Mendiguren (1973) and Gilbert and Dziewonski (1975) by introducing phase equalization techniques, such as 'stacking' and 'stripping.' These methods require the knowledge of the source mechanism to predict the proper phase for each seismogram to be considered; this in itself turned out to be a challenging inverse problem. Dziewonski and Gilbert (1974) derived the spectrum of all six components of the moment-rate tensor as a function of time for two deep earthquakes (Brazil, 1963; Colombia, 1970). For both events, they detected a precursive isotropic component. Eventually, this turned out to be an artifact of coupling between toroidal and spheroidal (Russakoff et al., 1998) modes, but the requisite theory to consider this effect was not available until 1984. Gilbert and Dziewonski (1975) presented two models based on measurements of eigenfrequencies of 1064 modes and mass and moment of inertia for a total of 1066 data. They derived two models 1066A and 1066B, with the first being smooth through the transition zone and the latter including the 400 and 660 km discontinuities; both models fit the data equally well.

At the 1971 General Assembly of the International Union of Geodesy and Geophysics (IUGG) in Moscow, the need for a reference Earth model was stated, and a Standard Earth Model Committee formed under the chairmanship of Keith Bullen. The Committee appointed several subcommittees, including one for the radius of the CMB: there were discrepancies on the order of 10 km at the time. The value recommended by the subcommittee was 3484 km (Dziewonski and Haddon, 1974), which – within 1 km – withstood the trial of time. Hales et al. (1974) proposed that the seismic velocities and density in the standard Earth model should be described by a low-order polynomial, with discontinuities at the appropriate depths. Dziewonski et al. (1975) constructed such a model, named parametric Earth model (PEM), which satisfied the normal-mode, travel-time, and surface-wave data. The novelty of this model was that, in a single inversion, different structures were obtained for the continental and oceanic crust and upper mantle. The normal-mode periods predicted by these two models (PEM-O and PEM-C) averaged in 2/3 and 1/3 proportion were constrained to match the observed periods and teleseismic travel times but separate data sets for continental and oceanic surface-wave dispersion. The differences between these two models ceased at the 400 km discontinuity, at which depth they became identical with the average Earth model, PEM-A.

The drawback of the PEM and all the previous models was that they did not consider the physical dispersion due to anelastic attenuation. For a signal propagating in an attenuating medium to be causal, the wave with higher frequencies must propagate with higher velocities. Thus, waves with a frequency of 1 Hz will propagate more rapidly than waves at a frequency of 1 mHz. In order to reconcile the seismic data that span 3.5 orders of magnitude, it is necessary to consider the frequency dependence of elastic parameters. This was pointed out by Liu et al. (1976). The Preliminary Reference Earth Model (PREM) constructed by Dziewonski and Anderson (1981), following the idea of parametric representation, considered the frequency dependence using the assumption that Q is constant in the band from 0.3 mHz to 1 Hz.

This necessitated obtaining the radial profiles of Q_μ and Q_κ; fortunately, there were new measurements available of normal-mode and surface-wave Q (Sailor and Dziewonski, 1978) such that a formal inversion for Q could be conducted simultaneously with the inversion for the velocities and density. It was recognized earlier that to explain the observed attenuation of radial modes, which contain a very high percentage of compressional energy (97.5% for ${}_0S_0$), it was necessary to introduce a finite bulk attenuation; Anderson and Hart (1978) preferred to place it in the inner core, and Sailor and

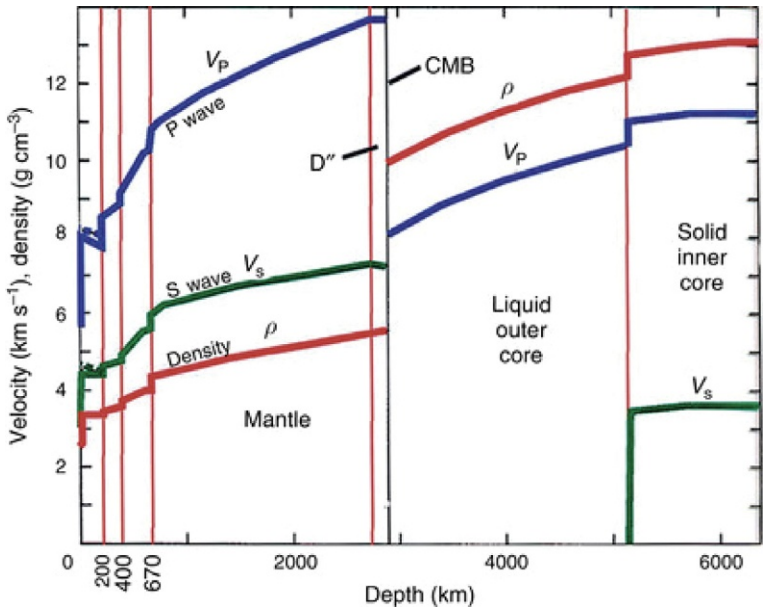

Figure 8 The Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981). In addition to the distribution of seismic velocities and density, PREM contains also the distribution of attenuation of the shear and compressional energy. From the website of Ed Garnero.

Dziewonski (1978) thought that Q_κ is finite in the upper mantle; unfortunately, the radial modes do not have the requisite depth resolution. **Figure 8** shows the seismic velocities and density as a function of radius; the attenuation in PREM is discussed in **Chapter 1.25**. Another novel aspect of PREM was its radial anisotropy between the Moho and 220 km depth. This feature, at first suspected to be an artifact of the nonlinearity of the inverse problem, has been confirmed by global tomographic studies (e.g., Ekström and Dziewonski, 1998). The PREM model remains to this day a widely used 1D reference model for seismological studies based on long period data. For P wave studies, especially those concerning core sensitive phases, model AK135 (Kennett et al., 1995), which was built to constrain a global dataset of travel times from the ISC bulletins, is often preferred as a 1D reference model. It is to be noted, however, that this model includes a 36 km continental crust, and cannot be used for waveform modeling outside of continental areas.

The 1970s have also seen the beginning of seismic tomography; two studies published simultaneously (Aki et al., 1977; Dziewonski et al., 1977) addressed the problem on different scales: regional and global. Aki et al. solved for 3-D velocity structure under the NORSAR array, while Dziewonski et al. obtained a very low-resolution model of 3-D velocity perturbations in the entire mantle and showed significant correlation between velocity anomalies in the lowermost mantle and the gravest harmonics of the gravity field. The study of Dziewonski et al. (1977) was motivated by a paper by Julian and Sengupta (1973) who noticed that travel times for rays bottoming in the same region of the mantle tend to show similar residuals. They interpreted this result qualitatively as the evidence of lateral velocity variations; no modeling was presented in that paper. The first continental-scale 3-D model of the upper mantle, under North America, was published by Romanowicz (1979).

Two digital seismographic networks were established in the mid-1970s. One was the International Deployment of Accelerometers (IDA; Agnew et al., 1976, 1986), consisting of 18 globally distributed LaCoste–Romberg gravimeters with a feedback system that allowed digitization of the signal. It was designed to record very long-period waves, including the gravest modes of free oscillations of the Earth: one sample was taken every 20 s (later changed to 10 s). Only the vertical component of acceleration was recorded and the word length was 12 bits; the dynamic range was, therefore, rather limited but still considerably greater than that of analogue recordings. The sensitivity was set such that the scale was saturated for the first surface-wave arrivals for events with magnitude 7.0, or so, depending on the station's distance from the source and radiation pattern. The IDA network was operated by the Scripps Institution of Oceanography, and the centrally collected data were freely distributed to the academic community. This later became the future standard in global seismology. An early illustration of the power of such a global array was the analysis of the splitting of the gravest modes of free oscillations generated by the 1977 Sumbawa earthquake (Buland et al., 1979; M_w only 8.4).

The other network consisted originally of nine installations called Seismic Research Observatories (SROs) and five Abbreviated Seismic Research Observatories (ASROs). The SROs used borehole instruments, with significantly suppressed wind-generated noise levels, particularly on horizontal components. The ASROs were placed in underground tunnels or mine shafts and the seismographs were protected from the effects of changing pressure and temperature. The instrumentation is described by Peterson et al. (1976). This network was designed for monitoring the Nuclear Test Ban Treaty and high sensitivity was the main objective. In order to increase the dynamic range, the signal was sharply band-pass-filtered, so that at very long periods (>200 s), the response to acceleration was falling as ω^{-3}, while it was flat for the IDA instruments.

Even so, the SRO and ASRO stations were able to produce useful mantle-wave records for events with magnitude greater than about 6.5. Later, the network was augmented by 10 WWSSN stations, with the analogue output amplified and digitized at 16-bit analog to digital converters. The entire system was called Global Digital Seismographic Network (GDSN). There was no general data distribution system, but data for selected dates were available upon request from the Albuquerque Seismological Laboratory.

Until then, a seismic station typically comprised a set of seismometers with either 'long-period' or 'short-period' responses, or sometimes, as was the case for the WWSSN, one of each. This setup was designed at the time of analogue recording to avoid the microseismic noise peak around 6–7 s period, which would have made it impossible to digitize all but the largest earthquake signals. With digital recording, and the possibility of filtering out the microseismic noise by post-processing, this traditional instrument design became unnecessary.

A very important development in seismic instrumentation took place in Germany in the mid-1970s. An array of a new kind of instruments with digital recording was deployed near Gräfenberg (Harjes and Seidl, 1978). It used a novel feedback seismograph (Wielandt and Streckeisen, 1982). The system was rapidly recognized for its linearity and large dynamic range within a wide band of frequencies – hence the name 'broadband.' The Gräfenberg array's central station had been colocated with the SRO borehole station GRFO, and the comparisons were very favorable for the broadband instruments, which were capable of reproducing different narrowband responses using a single data stream. This type of instrumentation became the pattern for future developments (e.g., **Chapter 1.02**).

In addition to the developments in instrumentation, the late 1970s saw important theoretical developments, related to the asymptotic properties and coupling of the normal modes. Examples of such developments are papers by Woodhouse and Dahlen (1978), Jordan (1978), and Woodhouse and Girnius (1982).

1.01.3 From 1980 to Present: The Era of Tomography and Broadband Digital Seismic Networks

The data from both global networks of the 1970s led to results that demonstrated the need for development of a global network that would better satisfy the needs of basic research in seismology; three studies are noteworthy. A robust method, which uses entire segments of (digital) seismograms, was developed to obtain reliable mechanisms of earthquakes with magnitude 5.0 and above (Dziewonski et al., 1981; Ekström et al., 2005). In addition, the method refines the location of the source, which for an event of finite size need not be identical with the hypocenter determined from the first arrivals of the P-waves. This topic is discussed at length in **Chapter 4.16**. The reason why the subject is brought up here is that in most aspects of using waveform analysis for the purpose of drawing inferences about the Earth's structure, it is necessary to know the source mechanism. The so-called 'centroid moment tensor' method has now been applied to over 40 000 earthquakes from 1976 till present, and this catalog is available online (http://www.globalcmt.org).

Masters et al. (1982) measured center frequencies of spectral peaks of the fundamental spheroidal mode from hundreds of IDA records and discovered that there are spatially distinct patterns in the frequency shifts when plotted at locations of the poles of the great circles corresponding to the paths between the source and the receiver. By fitting spherical harmonics (even degrees only, because of the symmetry), these authors realized that the pattern is dominated by spherical harmonics of degree 2, an observation also made from great-circling surface waves by Souriau and Souriau (1983). **Figure 9** shows the pattern of the shifts of spectral peaks and zero line of the best-fitting spherical harmonics of degree 2 for four groups of ${}_0S_\ell$ modes with different ranges of degree ℓ. Note that the modes with the lowest ℓ show a different pattern than the remaining three groups. Our current understanding of this fact is that the low-ℓ modes sample deeper structure (lower mantle) than the higher-ℓ groups that predominantly sample the upper mantle. The authors performed a parameter search, in which they changed the radii of a shell in which the anomaly is located. The best variance reduction was for the anomaly placed in the transition zone. The lasting importance of this chapter is that it demonstrated that heterogeneity of very large wavelength and sizeable amplitude ($\pm 1.5\%$) exists in the Earth's interior.

Following the development of a waveform-fitting technique that allowed the simultaneous measurement of phase velocity and attenuation along a great-circle path (Dziewonski and Steim, 1982), Woodhouse and Dziewonski (1984) developed an approach to the interpretation of waveforms that could extract both the even and the odd harmonic coefficients of lateral heterogeneity as a function of depth. This method involves the 'path average approximation,' sometimes called PAVA. The seismograms are represented as a sum of all normal modes (spheroidal and toroidal) up to a certain frequency ω_{max}. For a given great circle, each mode is assumed to be affected by the average deviation from reference structure along the great-circle path (which is sensitive only to even-order harmonics) and along the minor-circle path (sensitive to both even and odd harmonics). The effect of the great-circle path can be modeled by a shift in eigenfrequency of the mode; the effect of the minor-arc structure is modeled by a fictitious shift of the epicentral distance for that mode; this shift depends on both even and odd parts of the structure. Woodhouse and Dziewonski (1984) processed about 2000 mantle-wave seismograms from the GDSN and IDA networks and obtained a model of the upper mantle (Moho – 670 km), M84C, using as basis functions spherical harmonics up to degree 8 for horizontal variations and Legendre polynomials as a function of radius up to degree 3. **Figure 10** shows a map of shear velocity anomalies at a depth of 100 km; there was no a priori information used on the location of the plate boundaries. Corrections were made for crustal thickness, recognizing only the continental and oceanic structure. An experimental model, M84A, obtained without applying crustal corrections, showed that not taking crustal thickness into account may result in mapping artificial anomalies at depths as large as 300 km. Model M84C had a strong degree-2 anomaly in the transition zone, confirming the results of Masters et al. (1982).

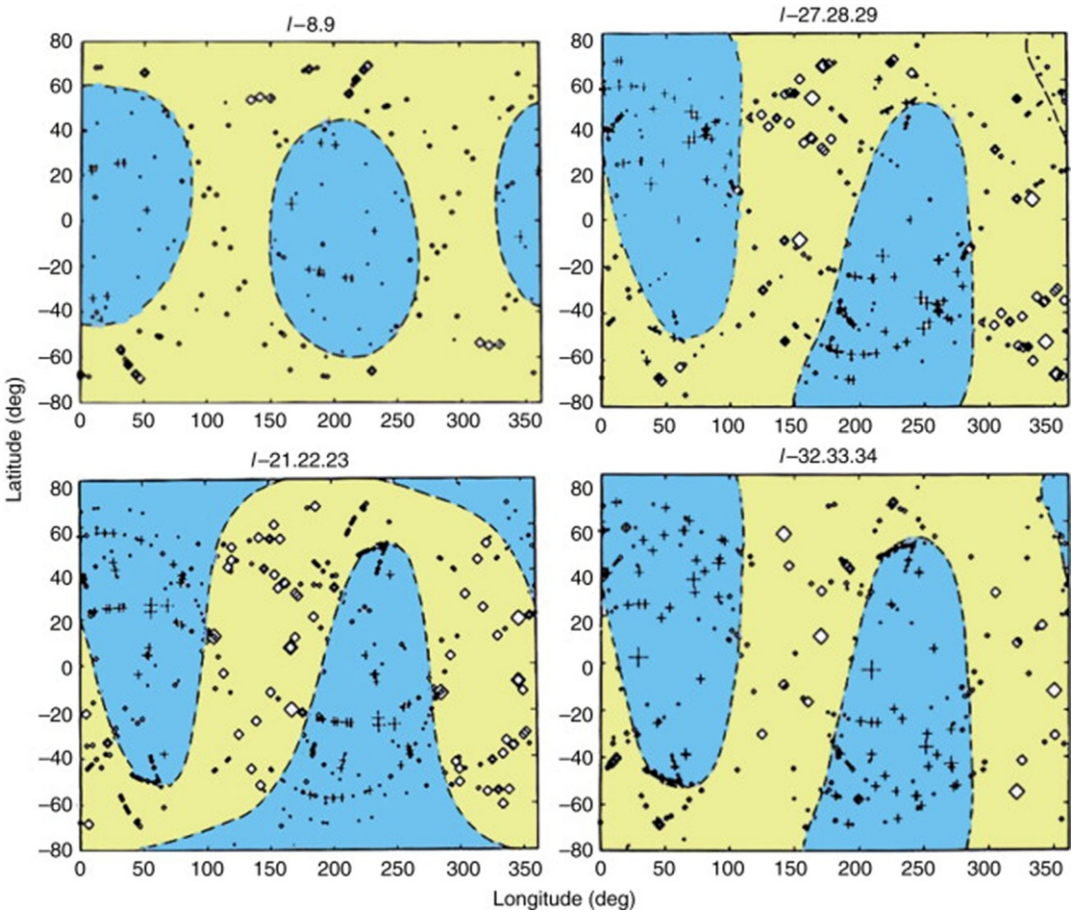

Figure 9 Maps of the observed frequency shifts of the fundamental spheroidal modes for four ranges of the order numbers as reported by Masters et al. (1982). The frequency shifts are plotted at the poles of the individual great-circle paths. It indicates the presence of very large wavelength–velocity anomalies in the Earth's interior; the preferred location of the source of the anomaly shown in the figure is the transition zone. However, the frequency shifts for the largest wavelength panel (top left; modes ${}_0S_8$ and ${}_0S_9$) show a different pattern than in the other three panels (modes from ${}_0S_{27}$ to ${}_0S_{34}$); the low-ℓ data have the greatest sensitivity in the lower mantle. Modified from Masters G, Jordan TH, Silver PG, and Gilbert F (1982) Aspherical Earth structure from fundamental spheroidal mode data. *Nature* 298: 609–613.

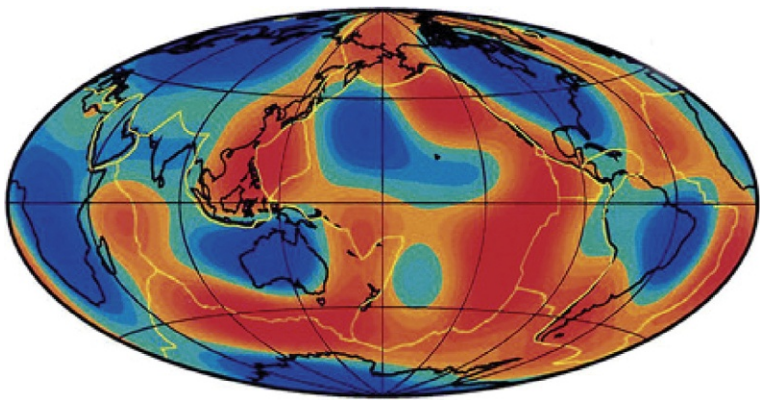

Figure 10 Shear velocity anomalies at a depth of 100 km in the model M84C of Woodhouse and Dziewonski (1984). The scale range is $\pm$5% and the resolving half-wavelength is 2500 km. Plate boundaries are shown as thin yellow lines. Except for the correction for crustal thickness, there was no other a priori information included in the inversion. Thus, the result demonstrates that the waveform inversion approach is able to distinguish the slow velocities under the mid-ocean ridges and ancient cratons, for example.

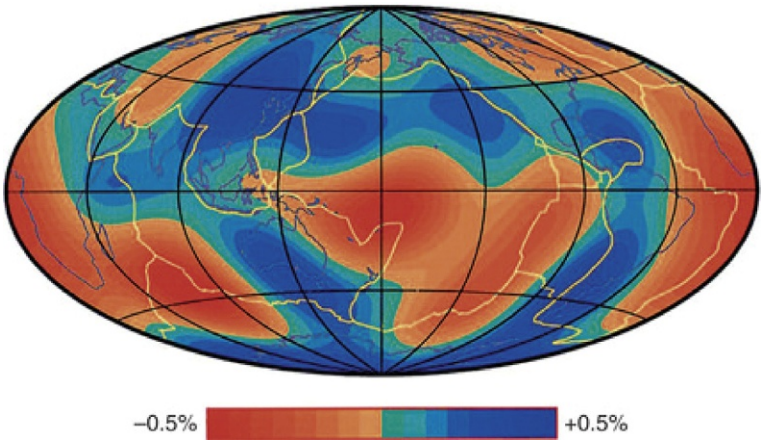

Figure 11 Map of P-velocity anomalies at a depth of 2500 km in model of Dziewonski (1984) derived from inversion of travel-time anomalies from ISC Bulletins. The resolving half-wavelength of the model is about 3500 km (at the surface). The model, dominated by the harmonics 2 and 3, clearly shows two large superplumes (African and Pacific) and the ring of fast velocities circumscribing the Pacific Rim. The scale is ±0.5%.

Another result also affected future developments, even though this study was not based on waveform analysis, but on the ISC bulletin data. With greater computational resources, it was possible to cast the inverse problem for lateral heterogeneities in the lower mantle on a larger scale using a substantially greater body of data than in Dziewonski et al. (1977). Unlike in this earlier study, in which blocks were used, Dziewonski (1984) used global basis functions: spherical harmonics representing horizontal variations and Legendre polynomials for radial variations. The degree of expansion was modest: only degree 6 in harmonics and degree 4 in radius, with the inversion limited to lower-mantle structure. In many ways, this new study confirmed the earlier one – including the correlation of lower-mantle structure with the gravity field (Dziewonski et al., 1977) – but it showed resolution of a truly remarkable concentration of the power of heterogeneity in low-order harmonics. **Figure 11** shows a map of P-velocity anomalies at a depth of 2500 km. The structure, dominated by degree 2 (and, to a lesser extent, degree 3), shows two large slow regions, which came to be known as the African and Pacific 'superplumes', and a ring of fast velocities around the Pacific.

Why does global tomography work? Some suspected that truncation of the expansion at relatively low harmonic order may lead to aliasing and structures dominated by degrees 2 and 3, such as the one shown in **Figure 11**, are an artifact. The short answer is that global mantle heterogeneity has a 'red' spectrum. That is, the power spectrum of the spherical harmonic expansion begins to drop rapidly above a certain wave number ('corner wave number'). Su and Dziewonski (1991, 1992) showed that it is clearly visible even in data, such as maps of travel-time anomalies of SS-S or ScS-S. The concept is illustrated in **Figure 12**, using the continent–ocean variations of crustal thickness.

Figure 12 illustrates the point that for functions with a 'red' spectrum that is flat for small wave numbers but rapidly decreasing for larger wave numbers, it is possible to extract most of the signal using the 'red' part of the spectrum. Panel (a) shows the power spectrum of the continent–ocean function. It is flat for degrees from 1 to 5, and then, the power is offset at degree 6 and begins to decrease rapidly, roughly as ℓ^{-2}; the 'corner wave number' is in this case $\ell = 5$. Part (b) is the synthesis of this function using degrees from 1 to 8 (81 coefficients). The shapes of the continents are clearly recognizable, but details of the coastlines or islands are missing. Panel (c) shows the result of a synthesis using harmonics from 1 to 32 (1089 coefficients or 15 times more). There is an obvious improvement: Madagascar, New Zealand, Japanese Islands, Gulf of Mexico, can be identified, but the principal information on the outline of continental masses is already contained in panel (b).

Another point is that power at degree 32 is two orders of magnitude less than at degree 3. Actually, it is lower by three orders for the individual $Y_{\ell m}$ coefficients, since we define the power as the sum of all squared coefficients of degree ℓ. It is impractical to think that such a large range of values could be resolved in an inverse problem, particularly because the strength of the kernels commonly decreases with increasing wave number (see Figure 3 a–d in Dziewonski, 1984). However, if the continents were broken up into many smaller 'islands,' then a synthesis of the spherical harmonic coefficients up to degree 8 might be misleading and provide an aliased picture.

The 'corner wave number' seems to be a feature of many geophysically important functions: Su and Dziewonski (1992) showed that it occurs in spectra of several global functions, such as free air gravity, SS-S travel-time residuals, phase velocity, and 3-D models, which have a power spectrum that is relatively flat up to degrees from 6 to 8, after which it begins to decrease as ℓ^{-2}. This seems typical of the spectra of two-dimensional functions that are characterized by a set of large 'patches,' such as the large land masses in the continent–ocean function. If the spherical harmonic expansion is truncated at an order number beyond the corner wave number, the synthesis of such truncated series retains the main character of the original function (e.g., **Figure 12**). Similarly, an inversion for a truncated series of spherical harmonic coefficients does not introduce aliasing if truncation occurs in the steeply decreasing part of the power spectrum. Of course, there are some geophysically important functions

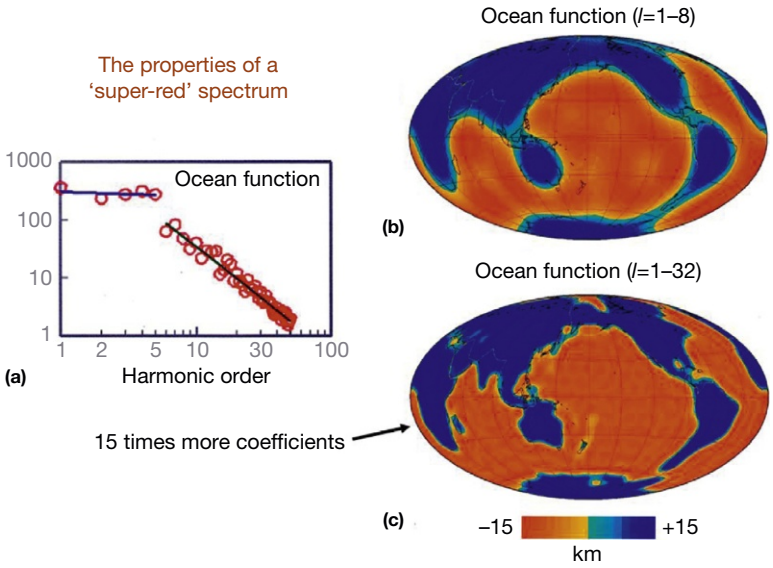

Figure 12 An example of a global function with a 'super red' spectrum. Crustal thickness under the oceans and continents, with a constant crust thickness for a given type, is expanded in spherical harmonics and then synthesized using a different cutoff wave number. Panel (a) shows the power spectrum of the continent–ocean function. Note the nearly flat spectrum for orders from 1 to 5 and then nearly linear decrease (in the log–log scale) for orders 6 and higher. The slope of that line is about ℓ^{-2}; the corner wave number is $\ell = 5$ in this case. Panel (b) shows the synthesized continent–ocean function for $\ell_{max} = 8$. All contours of continents are delineated and much of the variance is explained by this low-order model; this expansion has been used by Woodhouse and Dziewonski (1984) to introduce corrections for crustal structure. Panel (c) shows the result of a synthesis using $\ell_{max} = 32$. The details such as coastline and recovery of larger islands are clear, but they are achieved by using about 15 times more coefficients than those used to obtain panel (b). Also, the coefficients at higher wave numbers are very small, and it would be unlikely to be correctly derived through an inversion of observations with errors.

whose spectra have distinctly different characters, for example, linear features (slabs) have power spectra that are flat with harmonic order; point-like features (plumes?) have power spectra whose values increase with ℓ. In these cases, truncation would result in significantly lower amplitudes in the low-pass-filtered image.

This could also happen if the truncation of the spectrum occurred before the corner wave number. An example of the consequences of such an action is given by Mégnin et al. (1997). In a synthetic test, they limited to degree-6 inversion of waveform data calculated for a degree-12 model and showed that the results are aliased by the missing part of the structure (degrees 7 through 12). But in their test, the power spectrum had a maximum at degrees 6 and 7, and truncation at the maximum power is bound to cause aliasing. Boschi and Dziewonski (1999) demonstrated that there is no aliasing when travel times computed for a degree 40 model are inverted for a synthetic model limited to degree 12 (their plate 6), but the truncation was applied at the corner wave number.

Thus, in the 1980s, seismologists demonstrated that they can resolve 3-D structure within the Earth interior, giving the promise of an unprecedented ability to look at a present-day snapshot of mantle dynamics. Yet, the observing networks were in decline, with the support for the GDSN likely to be discontinued altogether and the original IDA network (limited to recording of vertical-component mantle waves and free oscillations) not meeting the needs of the broader community. In 1983, a plan was put forward to create a GSN of some 100 broadband, three-component seismographic stations sending the data in nearly real time to a central collection facility. The expectation was that this network would be supported by the National Science Foundation (NSF), in analogy to NSF supporting astronomy facilities. At the same time, seismologists using portable instrumentation came to the realization that they needed a centralized and standardized instrument pool. This led to the formation of a project called Portable Array for Seismic Studies of the Continental Lithosphere – PASSCAL. The GSN and PASSCAL groups merged and formed a consortium known as Incorporated Research Institutions for Seismology (IRIS), which incorporated in 1984.

At the same time, Steim (1986) was developing at Harvard his very broadband (VBB) instrument, based on the STS-1 broadband seismograph (Wielandt and Steim, 1986), and a very high-resolution (24-bit) digitizer. The response of a VBB instrument is designed to have a flat response to ground velocity between 5 Hz and 3 mHz, that is, over more than three orders of magnitude. Such an instrument had to have a very large dynamic range, of about 140 dB to span the range of ground velocities from the minimum Earth noise to a magnitude 9.4 earthquake at 30° epicentral distance. All these requirements were met, and Steim's VBB system became the design goal for the GSN and other networks. **Figure 13** shows the operating range of the system, and **Figure 14** illustrates the dynamic range of the GSN station in Albuquerque. The high-pass-filtered (75 s) record of the Sumatra–Andaman $M_w = 9.3$ earthquake shows surface waves with an amplitude of several millimeters and a record of a local microearthquake ($M < 1$) extracted from the same record; the ratio of the amplitudes is about 10 000 000! **Chapter 1.02** describes in detail the concept and history of the modern broadband

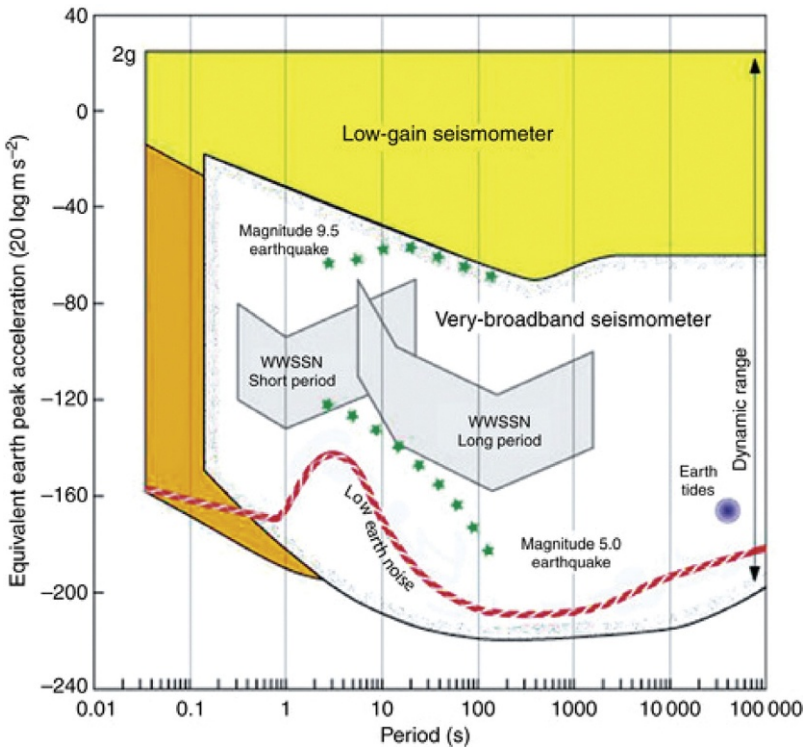

Figure 13 The dynamic range of the VBB channels of a Global Seismographic Network station. The range of the WWSSN short- and long-period channels are shown for comparison. At some GSN stations, the VBB channels are augmented by very short-period channels and accelerometers. The response was designed to resolve the ground noise from 5 Hz to tidal frequencies and to record on scale a magnitude 9 earthquake at a distance of 30°. Courtesy of IRIS.

digital seismograph that has now been implemented in stations of the global international network as well as many regional seismic networks.

Meanwhile, as the US seismologists were organizing themselves, a French effort named GEOSCOPE had already began taking shape. The objective of GEOSCOPE was the establishment of a global network of some 20–25 broadband digital seismographic stations utilizing the STS-1 seismometer, and destined in priority for locations around the world that filled gaps in the distribution of seismic stations. The project had officially begun in 1982, and in 1984, there were already five operational stations (Romanowicz et al., 1984), and 13 in 1986, (e.g., Romanowicz et al., 1991; Roult et al., 2010a,b).

While telemetry of the data was established later (in 1987), the state of health of the remote stations was monitored from early on using the satellite system Argos, which greatly facilitated their maintenance. As it was clear that it was inefficient to have two competing global networks, the need for a framework for international cooperation arose. Also, many countries were interested in deploying broadband instrumentation for their national or regional purposes and were agreeable to share these data. The international Federation of Digital Seismographic Networks (FDSN) was formed in 1986 (Romanowicz and Dziewonski, 1986), with the purpose of coordinating site selection, data exchange, and standardizing instrument responses. The FDSN has been very successful in achieving these goals, despite the fact that it is a purely voluntary, zero-budget organization. **Figure 15** shows a map of the FDSN network as of January 2014 (after some 25 years of development); there are over 200 participating VBB stations, most of which now send data in nearly real time.

Similarly impressive progress was made in the area of field seismology, where progress in electronics led to overall improvement of the portability of the equipment and, in particular, reduction of power requirements, which makes operations much easier. In parallel with the development of the PASSCAL program of IRIS in the United States (see **Chapter 1.16**), other portable arrays were developed in other countries in the last 20 years, such as the LITHOPROBE cross continental project in Canada (Hammer et al., 2010), Lithoscope program in France (Poupinet et al., 1989), or the SKIPPY array in Australia (van der Hilst et al., 1994). Most recently, an ambitious program, USArray, was launched in the United States in 2007 as part of the EarthScope project. USArray is aimed at a systematic investigation of the structure under the contiguous United States with uniform resolution. It consists of three parts: a Permanent Array of 100 stations (the 'backbone' or 'reference array'), a Transportable Array (TA), and a Flexible Array (FA). The FA provides some 300 broadband seismographs and over 1000 active-source instruments, for experiments proposed by individual research groups, aimed at elaborating detailed local structure. The TA is the largest component of the program, and it consists of 400 broadband seismograph systems that, starting from the West Coast of the United States, have been moving gradually across the continental United States to cover the entire area with, roughly,

2000 deployments for up to 2 years in a given location; the average instrument spacing is 70 km. In 2013, it has reached the East Coast and preparations are under way to redeploy about half of the instruments in Alaska. The 'reference array' provides the means to relate the waveforms recorded at different stages of TA deployment. Many other portable networks for regional studies of the crust and lithosphere using passive and active sources have been developed and deployed in the last 20 years (see Chapters 1.11, 1.16, and 1.17).

1.01.4 Current Issues in Global Tomography

In parallel with instrument development, scientific progress in seismic tomography has been rapid during the last 20 years, and most of the accomplishments are summarized in two reviews by Romanowicz (1991) and Romanowicz (2003), as well as in Chapters 1.10 and 1.19. However, there are still issues that remain unresolved or controversial. Certainly, there are confusing observations related, for example, to anisotropic properties or differential rotation of the inner core, the core–mantle topography, anticorrelation of density and shear velocity near the bottom of the mantle, the strength and depth distribution of anisotropy in the Earth's mantle, the presence of the postperovskite phase at the base of the mantle, and its role in mantle dynamics.

But the foremost issue in our view relates to the derivation and interpretation of 3-D Earth models. We will mention three issues in particular: parameterization, datasets used for model construction, and theoretical assumptions.

Ever since it was discovered that inversion of ill-conditioned matrices can be dealt with by requiring minimization of the norm or roughness of the model, we have been obtaining models whose reliability is difficult to assess.

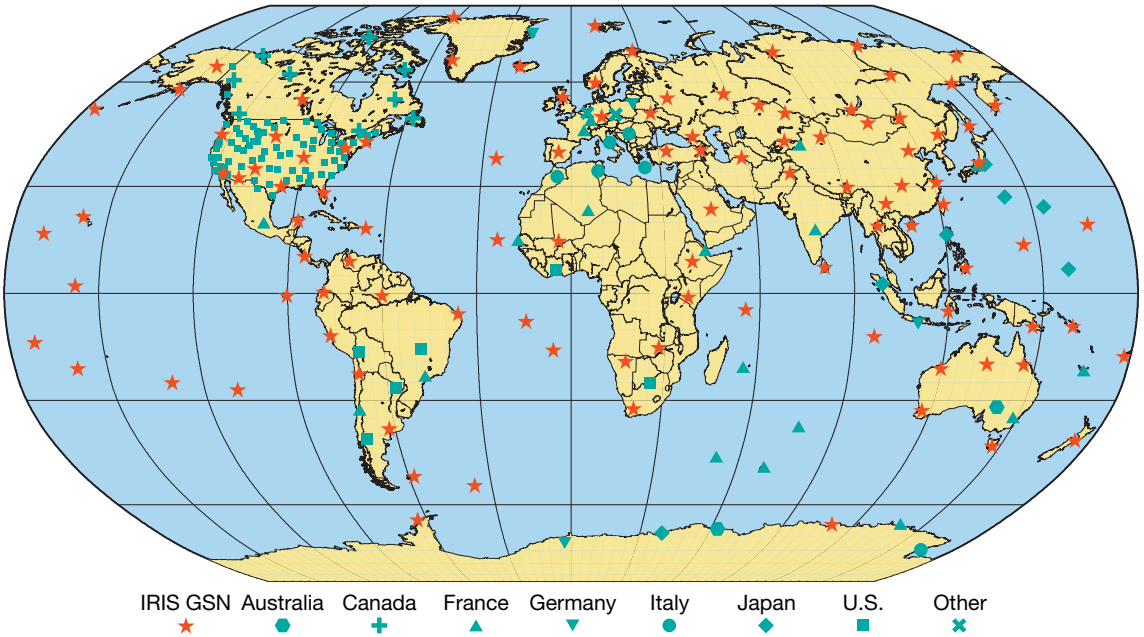

Figure 15 Current (January 2014) map of the stations of the Federation of Digital Seismographic Networks. Stations of different member networks are identified by symbols shown at the bottom. Courtesy of Andy Frassetto (IRIS Instrumentation Services).

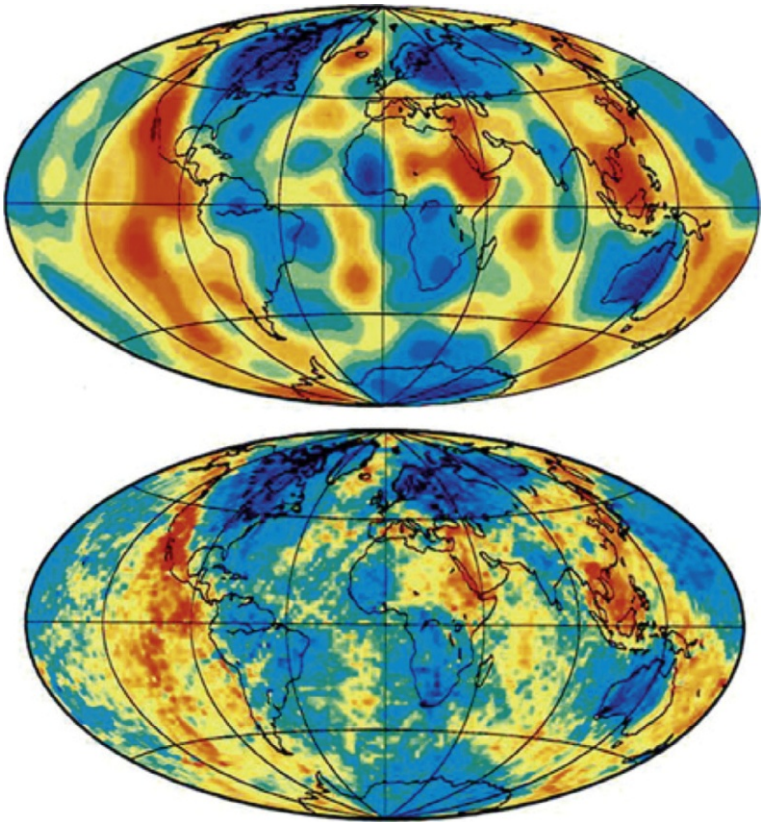

Figure 16 Demonstration of the results of inversion of the same data set (40 000 phase-delay data for 75 s Rayleigh waves measured by Ekström et al., 1997) for different numbers of parameters. The top map shows inversion for spherical harmonic coefficients up to degree 16 (289 parameters). The bottom map shows the results of inversion for about 10 000 equal-area blocks; in this case, matrix conditioning is necessary. The amplitude of the anomalies is lower, artifacts of an uneven path distribution are visible (e.g., across the central Atlantic), and it is difficult to find features that have not been resolved by the top map. The conclusion is that there is a price for unduly increasing the number of unknowns. Courtesy of L. Boschi.

Figure 16 illustrates an example of how the results can be altered with the change of parameterization. A set of about 40 000 phase-delay data for Rayleigh waves with 75 s period (Ekström et al., 1997) are inverted for 'local' phase velocities. The top panel of Figure 16 shows the result in which the data were inverted for a set of basis functions represented by spherical harmonics up to degree 16; this requires solving for 289 unknown coefficients. Because the data set is so large and the global coverage is good, the solution was obtained by an exact matrix inversion. The results look reasonable, without any indication of instability. The lower panel of Figure 16 shows the result obtained using a $2^\circ \times 2^\circ$ block expansion, which requires solving for approximately 10 000 unknown values. Matrix conditioning was required in this case, and it was accomplished by applying combined norm and roughness damping. What is clear from the 'high-resolution' solution is that the amplitudes are generally lower and there are 'streaks' indicating artifacts caused by uneven sampling of the area. What is difficult to find, however, are any features that appear to be significant that are not present in the solution with 30 times fewer parameters. Thus, sometimes, less is better. There is no absolute rule; as discussed in the previous section, the answer depends on the character of power spectra of a particular function.

The issue of parameterization is an important one, particularly if the global behavior of the solution is to be preserved. Figure 17 illustrates cross sections of four global P-velocity models – derived from the same data source (ISC Bulletins) – that span three orders of magnitude in the number of parameters. Clearly, there is not a simple relationship between the number of parameters and information contained in the model. It is so, partly, because the lower-mantle spectrum is dominated by the very low degrees that are well recovered by the degree-6 model.

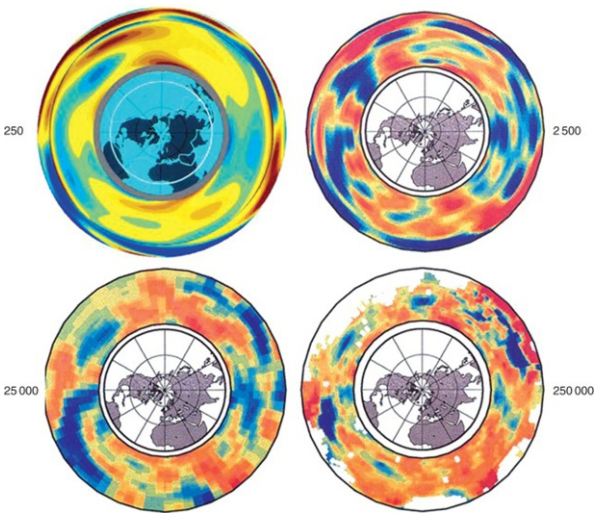

Figure 17 Comparison of the equatorial cross sections of four P-velocity models obtained by inversion of travel-time residuals from ISC Bulletins using a number of unknown parameters that span three orders of magnitude. The image of the African and Pacific superplumes is clearly seen in the model derived by using 250 parameters, while it could not be readily inferred from the model that used 250 000 parameters. The models obtained using 2500 and 25 000 parameters support the conclusion drawn from discussion of Figure 16. Modified from Boschi L and Dziewonski AM (1999) 'High' and 'low' resolution images of the Earth's mantle – Implications of different approaches to tomographic modeling. *Journal of Geophysical Research* 104: 25567–25594.

1.01.4.1 Resolving Power of Datasets Used for Constructing Models

Another important issue in assessing global, as well as regional, tomographic models is the data set (or subsets) and the resolving properties that were used to derive them. The mantle models derived using only teleseismic travel times, for example, have very little radial resolution in the upper mantle, because the ray paths do not bottom there. The teleseismic travel times are sensitive to velocity perturbations in the upper mantle, but the variations with radius cannot be satisfactorily resolved above the lower mantle. For example, all maps of upper-mantle velocity anomalies in Figure 18 show that a model derived using only teleseismic travel times has slow velocities under mid-ocean ridges at all upper-mantle depths, simply from the smearing with depth of the large slow anomalies occurring near the surface. This is a result of norm damping in a situation where sampling is inadequate: a compromise between fitting the data and having a low norm (low sum, or integral, of squared model perturbations). The spreading centers and cratons have largest signal in the uppermost 250 km of the upper mantle; the variance in the next

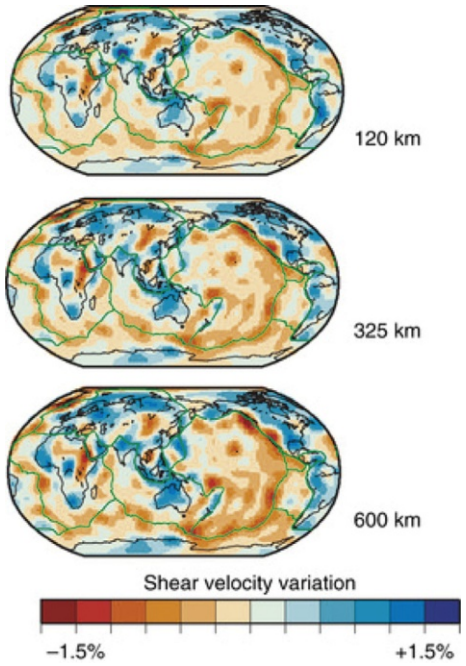

Figure 18 A fragment of a figure from Ritsema et al. (2004) illustrating a typical result of an upper-mantle structure obtained using teleseismic travel times, whose rays do not bottom in the upper mantle. The three maps show smeared-out structure from near the top of the mantle (mid-ocean ridge anomalies). The conclusion drawn from the full figure (see Chapter 1.10) is that, to obtain a whole-mantle model, one should use diverse types of data. Modified from Ritsema J, van Heijst HJ, and Woodhouse JH (2004) Global transition zone tomography. *Journal of Geophysical Research* 109: B02302, http://dx.doi.org/10.1029/2003JB002610.

400 km is an order of magnitude less. Thus, the minimum norm compromise leads to the smearing of the shallow structure over the entire upper mantle (for positive integers, $l+m+n=3$ has the minimum norm solution (1, 1, 1) with the norm of 3, the 'true' solution (3, 0, 0) has a norm of 9, and an intermediate solution (2, 1, 0) has a norm of 5). Another way to accommodate the minimum norm compromise is to make the upper-mantle model small; there are published models derived using only teleseismic travel times that have heterogeneous structure in the upper mantle with very small amplitude.

Models built using teleseismic travel times and fundamental-mode dispersion data do not have sufficient resolution in the transition zone to distinguish its unique properties. So far, only three research groups involved in whole-mantle modeling (Michigan/Oxford, Berkeley, and Harvard) use data allowing sufficient resolution in this region; it is interesting that they obtain these models using different kinds of data and theories, therefore adding to the credibility to the results. The use of waveforms in deriving 3-D models was pioneered by Woodhouse and Dziewonski (1984), but in the original paper, only data with periods longer than 135 s were used. Long-period body waves were used in inversions by Woodhouse and Dziewonski (1986) and Woodhouse and Dziewonski (1989). Dziewonski and Woodward (1991) combined waveforms and teleseismic travel times measured by Woodward and Masters (1991). The immediate result was that the two models they derived showed a sudden change in the pattern of heterogeneities across the 670 km boundary, and this was pointed out and discussed by Woodward et al. (1994). Later inversions by the Harvard group included also surface-wave dispersion data reported by Ekström et al. (1997). This increased resolution near the surface but did not alter the behavior across the upper–lower mantle boundary (Gu et al., 2001, 2003; Kustowski et al., 2008). All these models were obtained using the path average approximation (PAVA), which assumes constant average structure along the great-circle path connecting the source and the receiver. The Berkeley group pioneered use of a more advanced theory called nonlinear asymptotic coupling theory (NACT) first described by Li and Romanowicz (1995) and based on the across-branch coupling asymptotic development of Li and Tanimoto (1993). This theory allowed them to construct body-wave kernels that give good representation of the sensitivity along and around the ray path as shown in **Figure 19** and therefore opened the way to tomographic inversions for whole-mantle structure based entirely on waveform data and thus exploit more information in the seismograms than can be achieved with only those phases that are well separated from others in teleseismic records. In applying NACT to the development of several generations of global mantle models (Li and Romanowicz, 1996; Mégnin and Romanowicz, 2000), most recently including attenuation (Gung and Romanowicz, 2004) and radial anisotropy (Panning and Romanowicz, 2006), the Berkeley group divided the seismograms into wave packets containing one or several body waves or surface-wave overtones, which allowed them to weigh different phases differently in order to obtain uniform sensitivity with depth. The Berkeley group does not use travel times explicitly, but information on structure is included in the phase of a waveform of, for example, an SS-arrival. Thus, a large collection of waveforms containing

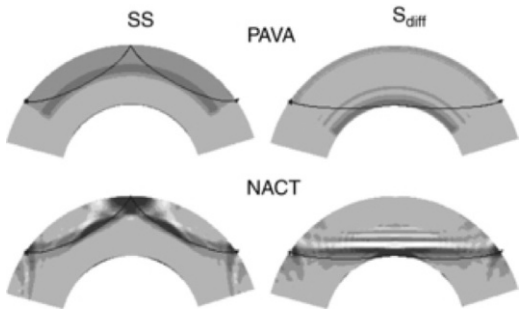

Figure 19 Comparison of sensitivity kernels in the vertical plane containing the source and the receiver for SS waves (left) and S_{diff} waves (right), using the path average approximation (PAVA, top) and the nonlinear asymptotic coupling theory (NACT, bottom). PAVA produces 1-D kernels, which do not represent well the ray character of body waves. NACT, which includes across-branch mode coupling, produces 2-D finite-frequency kernels that more accurately represent the sensitivity along and around the ray path as well as its variations with position along the ray. Because this is a time domain formalism, the NACT kernels are time-dependent and are here represented at a particular point in the waveform, with positive maxima in black and negative ones in white. Shadows beyond the source and receiver are due to the truncation in the coupling series. Adapted from Li XD and Romanowicz B (1995) Comparison of global waveform inversions with and without considering cross branch coupling. *Geophysical Journal International* 121: 695–709.

images of phases such as S, SKS, S_{diff}, Love, and Rayleigh fundamental and overtone waves will represent similar information as the combination of teleseismic travel times and surface-wave phase velocities in the Caltech/Oxford or Harvard models. In addition, unlike travel-time analysis, wave packets containing several phases with close arrival times but different sampling of mantle structure can be included, improving resolution. An important element of the data set used by Ritsema et al. (1999) is a set of maps of Rayleigh wave overtone dispersion from the first to the fifth overtones. These were obtained by 'stripping' the seismograms of subsequent overtones, thus providing the data on the average phase velocity of a particular overtone between the source and the receiver (van Heijst and Woodhouse, 1997). Since body waves represent superposition of overtones, use of complete waveforms is, to a large extent, equivalent; however, the separation of data for individual overtones allows assignment of different weights to different overtones, while direct waveform methods use them with the weight that is determined by their excitation; generally, the amplitude of overtones decreases with the overtone number. On the other hand, waveforms contain information about all the overtones. The importance of the overtones (body-wave waveforms) was shown implicitly by Gu et al. (2001) and explicitly by Ritsema et al. (2004). The importance of using adequate kernels for overtone and body waveforms was illustrated by Mégnin and Romanowicz (1999) in a comparison of the PAVA and NACT inversion approaches.

1.01.4.2 Theoretical Assumptions

Ray theory vs. finite-frequency theory has been the subject of a lively debate within the seismological community during the last decade. Much of it has revolved around the

'banana–doughnut' kernels (Dahlen et al., 2000) and its application to mantle modeling (Montelli et al., 2004a,b). The implication conveyed by those authors was that the results obtained using finite-frequency theory were distinctly superior to those obtained using ray theory. The serious implication of this was that all tomographic studies to date were deficient. Yet, a direct comparison of the finite-frequency and ray theory models published by Montelli et al. (2004b, Figure 9) demonstrates that the two models are nearly identical, save for a scaling factor of 1.14 (van der Hilst and deHoop, 2005). This is because these authors introduced finite volume parameterization by tetrahedra with unknown velocity perturbations at the vertices (with linear interpolation within each tetrahedron) without acknowledging that this is equivalent to a low-pass filtration.

There have been quite a few papers published on this subject (e.g., Peter et al., 2007). While it is obviously desirable to use a more accurate theory, it is worthwhile to investigate why the ray theory and finite-frequency theory yield nearly identical results. A particularly clear explanation of this effect is presented by Dalton (2007) who used the orthogonal basis functions (spherical harmonics) for both the kernels and velocity perturbation, with the phase velocity model truncated at degree $\boldsymbol{L}$. A perturbation in phase travel time between source located at s and receiver at **r** can be calculated by integration over the surface of the sphere Ω:

$$\delta t_{\mathrm{s,r}} = \int_{\Omega} \frac{\delta v}{v_0}(\theta, \varphi) K^{\mathrm{s,r}}(\theta, \varphi) \mathrm{d}\Omega \qquad [1]$$

where v_0 is the reference velocity and $K^{\mathrm{s,r}}(\theta,\phi)$ is the kernel calculated for a particular location of the source and the receiver. Expanding δv and $K^{\mathrm{s,r}}(\theta,\phi)$ in spherical harmonics and truncating expansion of δv at $l = L$, we have

$$\delta t_{\mathrm{s,r}} = \int_{\Omega} \left(\sum_{l=0}^{l=L} \sum_{m=-l}^{m=+l} \delta v_{l,m}/v_0 Y_{l,m}(\theta, \varphi) \mathrm{x} \right) \cdot \left(\sum_{l'=0}^{l'=\infty} \sum_{m=-l'}^{m'=+l'} K^{s,r}_{l',m'} Y_{l',m'}{}^{*}(\theta, \varphi) \right) \mathrm{d}\Omega \qquad [2]$$

However, because of the orthogonality of spherical harmonics, this reduces to

$$\delta t_{\mathrm{s,r}} = \sum_{l=0}^{l=L} \sum_{m=-l}^{m=+l} \delta v_{l,m}/v_0 K^{\mathrm{s,r}}_{l,m} \qquad [3]$$

with the terms in expansion of the kernel function for $l' > L$ having no effect.

Figure 20 (*top*) shows the frequency-dependent kernels for Love waves at 35 and 200 s period. In the *middle*, there is the frequency-dependent kernel expanded to degree 18. At the bottom is the spherical harmonic expansion of a line ('ray theory') along the equator $K = \delta(\theta - \pi/2)$ for $\phi > 0$ and $\phi < \Phi$ and zero elsewhere. At the period of 35 s, it is difficult to tell the difference between the *middle* and the *bottom* 'effective' kernel functions. The difference is still quite small at 200 s period. Thus, finite parameterization can imitate the finite-frequency effect, and for relatively low L, the advantage of using the finite-frequency kernels vanishes. Dalton showed that differences are more pronounced at larger L, but the earlier discussion indicates that there is very little power in the higher degrees of $\delta v_{l,m}$ and the effect on the observed, or computed, $\delta t_{\mathrm{s,r}}$ will be insignificant because of 'natural truncation.' Thus, under the circumstances presented here, the effect of using finite-frequency kernels is very small. In general, the ratio of the width of the finite-frequency kernel to the path length

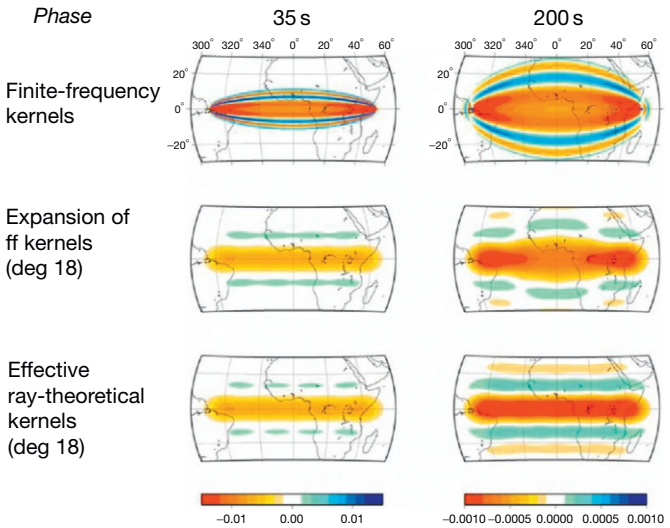

Figure 20 Demonstration of the perhaps counterintuitive fact that 'finite-frequency' kernels and 'ray theory' kernels may lead to very similar models if the model to be obtained using 'ray theory' is parameterized. Parameterization using spherical harmonic expansion up to a maximum order L is used here, because the result is exact. *Top*: Born (finite-frequency) kernels for the phase travel-time delay for Love waves at 35 s (left) and 200 s (right). *Middle*: Synthesis of the Born kernels above obtained by synthesis of spherical harmonic coefficients up to degree $L = 18$. The spherical harmonic coefficients for $l > 18$ are irrelevant because of the orthogonality of the basis functions. *Bottom*: Expansion of a 90° long ray up to the same $L = 18$. The effective kernels for 35 s waves are difficult to distinguish from the expanded finite-frequency kernels; the differences are more noticeable at 200 s period but they are still minor.

determines how good the ray theory approximation is; finite-frequency kernels can be important in regional-scale studies.

Indeed, as discussed earlier, the possibility of inverting complete seismograms (i.e., seismic waveforms) without selecting individual phases for travel-time measurements opens the way for exploiting more of the information contained in the recorded wavefield, thereby achieving better sampling of the mantle. In particular, we note that models based entirely on the inversion of time domain waveforms are able to achieve comparable results, with an order of magnitude fewer records (e.g., a total of 20 000 records in Panning and Romanowicz, 2006) as models based on the standard combination of surface-wave dispersion and body-wave travel times, which typically use tens to hundreds of thousands of measurements. This is because the smaller number of source-station paths considered is compensated by the inclusion of waves that sample mantle structure in a richer variety of ways.

Since our ability to improve the global distribution of sources and receivers is limited, once it is recognized that waveform inversion represents potential for better sampling of the Earth's mantle, the attention then shifts to improving the methods of computation of synthetic seismograms in a 3-D Earth.

NACT (Li and Romanowicz, 1995) provided a successful theoretical approach for this purpose and has led to several generations of whole-mantle shear velocity models in the last 20 years. However, asymptotic normal-mode perturbation theory is only valid for Earth models for which the wavelength of the structure is large compared to that of the seismic waves considered (i.e., smooth models) and heterogeneity is weak (nominally, lateral variations of up to ~10%). Yet, in the Earth's boundary layers, that is, in the upper mantle and in the D″ region, there is ample evidence for the presence of stronger heterogeneity, whereas throughout the mantle, heterogeneity at many different scales may be present. First-order mode perturbation theory is not appropriate in this case. While higher-order perturbation theory has been worked out (e.g., Lognonné and Romanowicz, 1990; Lognonné, 1991), it is cumbersome for use in practice, in particular because it always requires a 1-D reference model.

In the last decade, advances in numerical methods for the computation of the seismic wavefield in arbitrary 3-D structures, and increased computational power, have made it possible to replace normal mode-based synthetics by more accurate ones, based on the spectral element method (SEM), first introduced in global seismology by Komatitsch and Vilotte (1998) and later perfected by Komatitsch and Tromp (2002). The use of SEM has now been implemented in tomographic inversions for crustal structure at the local scale (e.g., Tape et al., 2010) and upper-mantle structure at regional scales (e.g., Fichtner et al., 2009; Rickers et al., 2013; Zhu et al., 2012). The forward numerical computation is generally combined with an 'adjoint' numerical computation of the kernels for inversion (e.g., Tromp et al., 2005; see **Chapter 1.07**) or, alternatively, with a 'scattering integral formalism' (e.g., Chen et al., 2007). Still, computational time increases as the third power of frequency, so the computational challenge limits the frequency range of computations to relatively long periods (typically longer than 40 or 50 s), especially when using the adjoint framework, which requires many iterations (sometimes 20–30) due to the slow convergence of the conjugate-gradient method.

Because the teleseismic wavefield needs to be computed for a long time interval, in order to include all seismic phases of interest (up to and including second orbit fundamental-mode Love and Rayleigh waves), the use of the SEM for global tomography is particularly challenging computationally. The first global shear velocity models developed using SEM (French et al., 2013; Lekic and Romanowicz, 2011) are limited to the upper mantle due to the use of relatively long periods (longer than 60 s) for computational efficiency. To reduce further computation time, they take advantage of efficiencies gained, in the forward step of the computation, by restricting the numerical computation to the mantle through coupling with 1-D mode computations in the core (CSEM, Capdeville et al., 2003) and replacing the finely layered crust by an equivalent smooth crust constrained by surface-wave dispersion data. In the inverse step, the kernels, which do not need to be as accurate as the forward predictions (e.g., Lekic and Romanowicz, 2011; Tarantola, 2005), are calculated using a mode-based approximation. The use of a Gauss–Newton formulation of the inverse problem leads to much more rapid convergence than the adjoint approach. The use of accurate wavefield computations, such as afforded by SEM, is particularly important to improve resolution of low-velocity regions, which tend to be hidden from observation, when ray theory is used, due to wave front healing effects (e.g., Nolet and Dahlen, 2000). For example, the new-generation tomographic models based on the use of SEM resolve the minimum amplitude of the upper-mantle low-velocity zone better than previously, even in areas far away from sources and stations, as illustrated in **Figure 21**, and are starting to resolve finer details of the 'plumbing' system in the oceanic upper mantle (e.g., Colli et al., 2013; French et al., 2013; Rickers et al., 2013).

1.01.4.3 Robust Features of Current Global Mantle Models and Their Implications

The full impact of the completed FDSN network, progress in automatic processing of data – measurements of travel times from waveforms or selection of time windows for waveform inversion, for example – improved the database by an order of magnitude in comparison with earlier models. This has been accompanied by better recognition of what is required to obtain a stable 3-D model of shear velocity anomalies in the mantle. Among these are as follows:

(i) Assembly of data that are sensitive to structure from the Moho to CMB; usually, this calls for a combination of surface-wave dispersion, overtones, and teleseismic travel times.
(ii) Proper weighting of the subsets of data to assure comparable radial resolution.
(iii) Careful selection of matrix stabilization parameters.
(iv) Even though gaps in coverage due to the uneven distribution of sources and receivers are unavoidable, it is desirable to minimize the impact of this inequality. For example, Dziewonski (1984) used a form of a 'summary ray' approach, counting the number of rays connecting a particular 'receiver cell' and 'source cell' (each $5° \times 5°$ at the equator) and then counterweighed individual

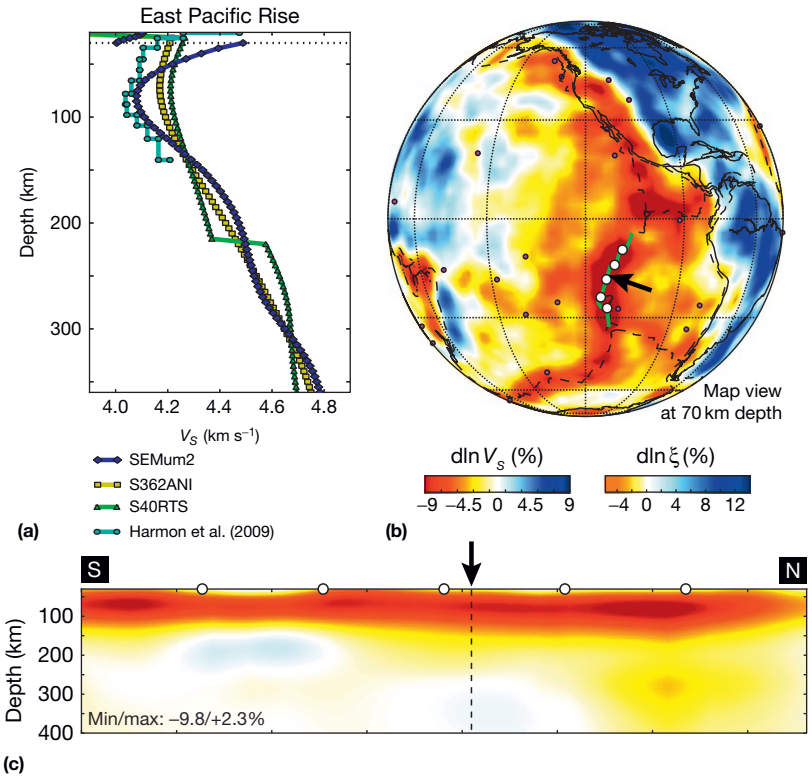

Figure 21 Isotropic V_S structure beneath the East Pacific Rise (EPR). (a) A comparison between the mean 1-D V_S profile obtained from the high-resolution OBS-based tomographic study of EPR structure by Harmon et al. (2009) and that sampled from global models SEMum2 (French et al., 2013), S362ANI (Kustowski et al., 2008), and S40RTS (Ritsema et al., 2011), in the same location. The 1-D profile of the Harmon et al. study was obtained from a harmonic mean of the central portion of their model over length scales consistent with the a priori correlation lengths employed in the SEMum2 inversion (~400 km). SEMum2 more closely recovers the strength and depth of the low-velocity zone (LVZ) beneath the EPR inferred from the local study than either of the other global models. (b) Relative variations in isotropic V_S structure at 70 km depth in SEMum2, focused on the EPR, showing both the location of the comparison in (a) (black arrow) and the extent of the ~3750 km line of section in (c) (portion of EPR highlighted in green). (c) A cross section along the EPR, following the green line and white dots shown in (b), illustrating the strength and extent of the strong low-velocity anomaly imaged beneath the EPR in SEMum2 (c), nearly −10%. Black arrow and dashed line indicate approximate location of profiles in (a). Reproduced from Figure S6 of French S, Lekic V, and Romanowicz B (2013) Waveform tomography reveals channeled flow at the base of the oceanic asthenosphere. *Science* 342: 227–230.

observations such that impact of a given pair of cells was equal regardless of the number of connections. Since there were about 25% of pairs with only one connection and only 25% had more than ten connections, the variance reduction was very modest.

Figure 22 compares model S40RTS (Ritsema et al., 2011) at seven different depths with four other relatively recent models: S362ANI (Kustowski et al., 2008), SAW642AN (Panning and Romanowicz, 2006), TX2008 (Simmons et al., 2009), and HMSL-S (Houser et al., 2008). The data sets used to derive each of these models were different; even the theories used were different. Therefore, their overall similarity (with one exception) indicates congruence of the global 3-D models of the whole mantle. There are differences, of course, and some of them should be resolved, but the 'big picture' is robust and its implications should be considered in modeling the global mantle flow. Such modeling is necessary to understand mantle dynamics and evolution, since tomography can retrieve only the present-day picture. What makes the work of Ritsema et al. (2011) particularly important is that the data set used in this inversion is an order of magnitude greater than in their earlier model S20RTS (Ritsema et al., 1999) and, yet, the differences between the two models are small, especially at larger wavelengths. This means that the features within the 'red' part of the spectrum are well resolved and further increase in the data set will not change the image appreciably at long wavelengths.

There is a fundamental similarity among the models; all show an order of magnitude decrease in power between 100 and 400 km depth (the scale for the top row of maps is ±7%, or 3.5 times larger than at other depths). While the dramatic difference between the maps at 600 and 800 km is distinct for the first three models, it is less so for the last two; the explanation is that models TX2008 and, especially, HMSL-S did not use enough data with resolution in this depth range to map properly this critically important feature. The rms amplitude is the lowest between 650 and 1800 km depth but then increases again to reach the maximum at the CMB.

The power spectrum as a function of depth and wave number is a robust feature (see Figure 9 in Kustowski et al., 2008). On this basis, it is possible to distinguish several depth regions with different spectral characteristics; Dziewonski et al. (2010)

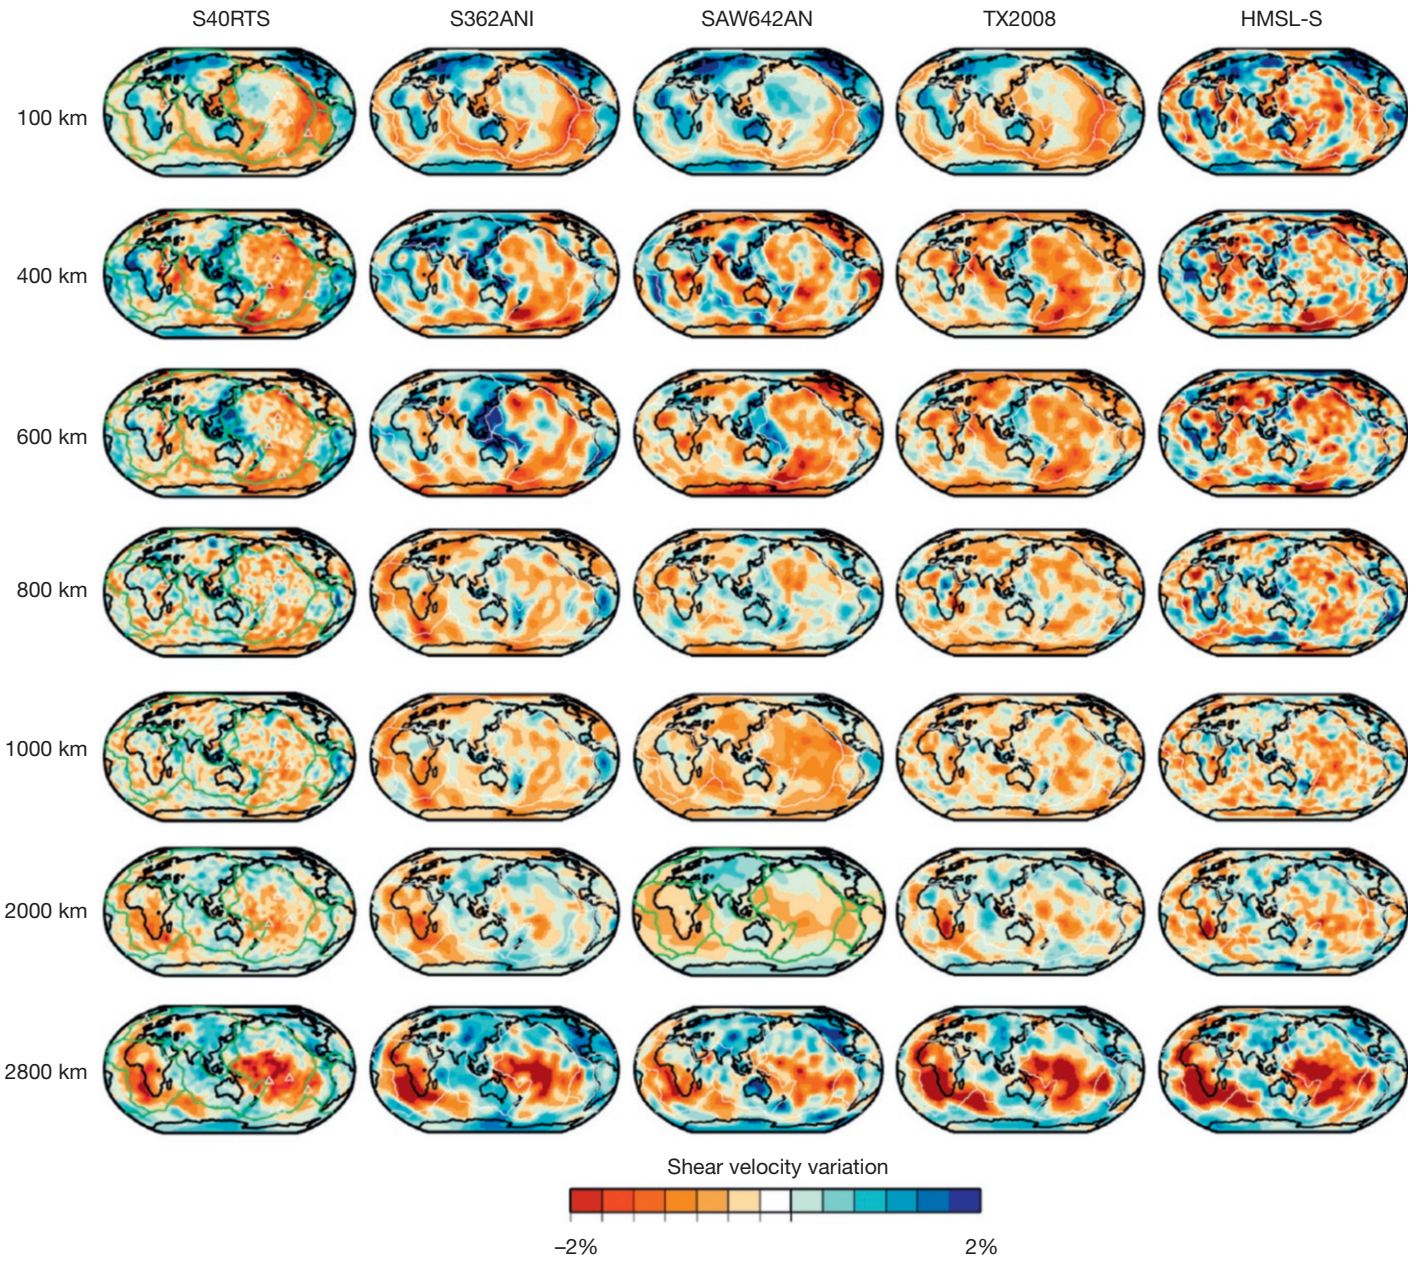

Figure 22 Comparison of shear velocity maps at depths of (from top to bottom) 100, 400, 600, 800, 1000, 2000, and 2800 km for models (from left to right) S40RTS (Ritsema et al., 2011), S362ANI (Kustowski et al., 2008), SAW642AN (Panning and Romanowicz, 2006), TX2008 (Simmons et al., 2009), and HMSL-S (Houser et al., 2008). The velocity varies from −2% to +2% from the average value. Shear velocity perturbations are between −7% and +7% from the average value for the map at 100 km depth. Reproduced from Ritsema J, Deuss A, van Hejst HJ, and Woodhouse JH (2011) S40RTS: A degree-40 shear-velocity model for the mantle from new Raleigh wave dispersion, teleseismic traveltime and normal-mode splitting function measurements. *Geophysical Journal International* 184: 1223–1236, http://dx.doi.org/10.1111/j.1365-246X.2010.04884.x.

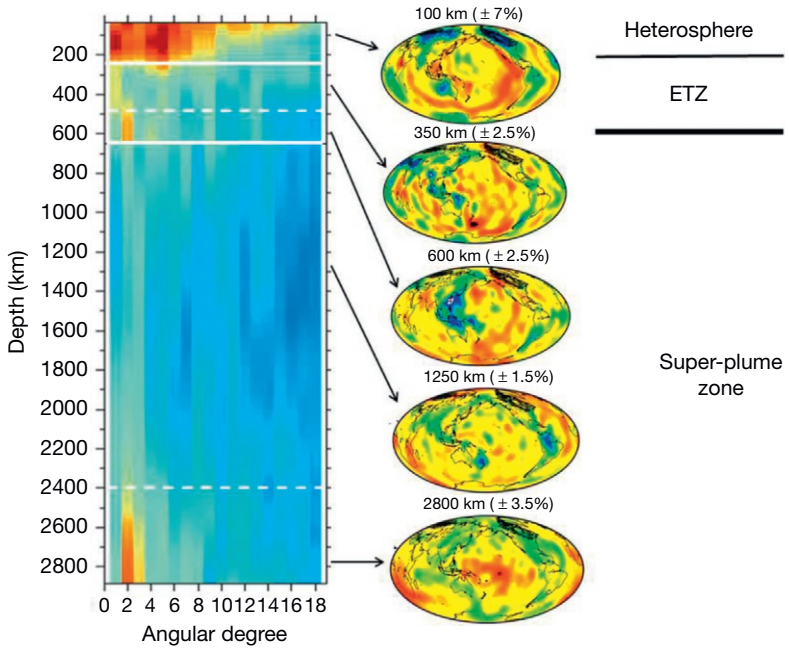

Figure 23 *Left:* Power spectrum of model S362ANI of Kustowski et al. (2008) as a function of harmonic degree and depth. Continuous white lines indicate inferred major divisions in spectral characteristics; broken white lines show additional subdivisions. *Center*: Maps of shear velocity anomalies at depths 100 km (±7%), 350 km (±2.5%), 600 km (±2.5%), 1250 km (±1.5%), and 2800 km (±3.5%). *Right*: Schematic division of the mantle into three zones with profound changes at their boundaries: 'heterosphere' with a very high level of heterogeneity; 'extended transition zone,' with a weak, white spectrum at the top and power shifting to degree 2 above the 650 km discontinuity; and 'superplume zone' dominated by degrees 2 and 3, which is strongest at the CMB but continuing with decreasing amplitude throughout the entire lower mantle.

proposed five such regions; more recent analysis (Dziewonski et al., 2013) finds that these can be combined into three principal zones.

Figure 23 shows the power spectrum of model S362ANI with maps of shear velocity anomalies at five different depths. The principal divisions are between the 'heterosphere' (HS, Moho – 250 km depth), the 'extended transition zone' (ETZ; 250–650 km), and the lower mantle or 'superplume zone' (SPZ). The spectrum changes gradually within the ETZ from white to being dominated by degree 2, but this change is not sudden and is not associated with the 410 km discontinuity. In the SPZ, there is a change in the gradient of heterogeneity at about 2400 km depth (e.g., Lekic et al., 2012), but the pattern does not change. These two more subtle spectral changes are shown with broken lines; the fundamental ones - with continuous lines.

Comparison of the five maps shows that the heterogeneity is distinctly different in each zone or subzone. 'Heterosphere' is dominated by surface tectonic features: slow ridges, cooling plates, and fast cratons. Between 150 and 250 km depth, the power of heterogeneity decreases by an order of magnitude, hence the name.

Below 250 km, the upper part of the ETZ is characterized by a nearly white spectrum. Oceans, particularly Pacific, are slow but do not show the age signature; continental structure tends to be faster than average, but the location of the anomalies is not as closely associated with the cratons as at 100 km depth. Between 450 and 650 km depth, the degree-2 anomalies become dominant. Regional-scale studies such as Fukao et al. (1992, 2001, 2009), Fukao and Obayashi (2013), and **Chapter 1.20** as well as global scale of Gu et al. (2001, 2003) explain this by stagnation above the 650 km discontinuity of the recently subducted slab, which appears to lay flat at the bottom of the transition zone for sometimes as far as 2000 km. This is consistent with the already discussed pattern of abrupt change of shear velocity anomalies at depths of 600 and 800 km for the first three models in Figure 22.

At the top of the 'superplume planet' in the mid-mantle, the signal is weak and has a somewhat flat spectrum, even though the degrees 2 and 3 have the largest power. The amplitude of anomalies begins to increase below 1800 km depth. In the 'abyssal layer' (2400 km – CMB), degrees 2 and 3 are clearly dominant and show the pattern of two superplumes (African and Pacific) separated by a wide circumpolar ring of higher than average velocities. This pattern of zero line is very robust, as shown by Lekic et al. (2012).

Figure 24 shows the result of cluster analysis of the deepest 1000 km of the mantle of the five models shown in Figure 22. On a constant area $2^\circ \times 2^\circ$ grid, the average velocity anomaly for a particular model is classified as either 'slow' or 'fast'; if it is slow, integer 1 is added to the voting map and 0 if it is fast. If all models are 'slow' at a given grid point, the corresponding color is deep red; if all models are fast, then deep blue. The robustness of this classification is demonstrated by the fact that over 95% of the area is either deep red or dark blue. The other important inference is that even though the individual models show variations in amplitude, these do not lead to the change in sign of the anomaly: the dark red and dark blue regions are contiguous. One exception is a distinctly separated 'slow' anomaly, which Lekic et al. (2012) named the 'Perm anomaly' because of the proximity of its surface projection to the city of Perm (Russia). Another possible exception is a larger area beneath the East Pacific Rise, but the models are not

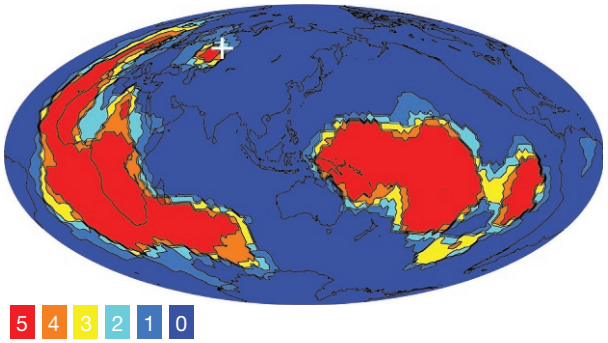

Figure 24 Cluster analysis of shear velocity (V_s) profiles (1000–2800 km depth range) from five recent global tomographic models (Houser et al., 2008; Kustowski et al., 2008; Mégnin and Romanowicz, 2000; Simmons et al., 2010; Ritsema et al., 2011) in the lower mantle defines two regions whose geographic extents are consistent across models, tracing out the African and Pacific superplumes, as well as a single, globally contiguous faster-than-average region. Pixels that make up this map are color-coded according to how many models assign the V_s profile beneath that point to the slow cluster. The models are spatially filtered to exclude power at spherical harmonic degrees $\ell > 18$. Reconstructed location (Torsvik et al., 2008) of the center of Siberian Trap eruptions is indicated by the white cross. Reproduced from Lekic V, Cottaar S, Dziewonski A, and Romanowicz B (2012) Cluster analysis of global lower mantle tomography: A new class of structure and implications for chemical heterogeneity. *Earth and Planetary Science Letters* 357–358: 68–77.

unanimous here. The white cross indicates the location of the Siberian Traps 250 Ma ago by Torsvik et al. (2008).

In order to put the Perm Anomaly on the map, it is necessary to synthesize the first 12 harmonics of the expansion of the map shown in **Figure 24** (see Figure 7 in Lekic et al., 2012). The significance of the unanimity of all five models is that we can resolve the structure near the CMB to about 1000 km half-wavelength. This confirms the conclusion that degree-2 and degree-3 anomalies are real features rather than a result of insufficient data to resolve smaller-scale structures. Another conclusion is that there is a dichotomy between the planetary-scale structures (superplumes) and smaller-scale anomalies, such as ULVZs or hypothetical narrow plumes. It is not clear, therefore, that the latter structures play a predominant role in whole-mantle dynamics. On the other hand, the superplume pattern continues upward to the middle mantle. Figure 3 in Lekic et al. (2012) shows that the voting pattern of **Figure 24** continues into the middle mantle; even though the signal-to-noise ratio is considerably lower in the 800–1800 km depth range. The superplume pattern is distinct and contains all the surface locations of hot spots; also, the band of faster-than-average velocities continues to maintain its width, indicating that the fundamental pattern of velocity anomalies continues throughout the lower mantle, although with decreasing amplitude.

A by-product of the voting procedure is the derivation of average fast and slow velocity anomalies for each of the all five models (see Figure 5 of Lekic et al., 2012). There are two important conclusions that can be drawn from this comparison. First, the slow anomalies are about three times stronger than the fast ones; this is consistent with the fact that in **Figure 24**, the area of 'blue' is much larger than that of 'red.' Second, there is a sharp change in the gradient of the velocity anomalies at about 500 km from the CMB, above which it becomes much shallower. It is possible to speculate that the steep gradient in the lowermost mantle is due to a chemical heterogeneity whose strength decreases with radius to reach that of the ambient mantle 500 km above the CMB. Further, it would be possible to modify the 'average' Earth model by adding a small 1-D linear increase of velocities between 1600 km depth and the CMB, where it would amount to 0.5%. If this were then subtracted from the 3-D model, the map of anomalies in the abyssal zone region would be mostly limited to slow anomalies, such that with this modification, the principal anomalies would be limited to superplumes. Thus, the chemical heterogeneity and the abyssal layer could be limited to the base of the superplumes.

1.01.4.4 Stability of the Planetary-Scale Heterogeneities

Richards and Engebretson (1992) mapped four geophysical functions (their Figure 1): geoid, hot-spot locations, velocity anomalies near the CMB, and a sum of the mass of all slabs subducted during the last 120 Ma. Correlation is significant only for degrees 2 and 3. Of the four functions, the first three are surface observables; only the seismic velocity anomalies correspond to a particular depth – the lowermost mantle. Even though Ricard et al. (1993) and Lithgow-Bertelloni and Richards (1998) proposed a model with the sinking slabs distributed at different depths according to their age, correlation between the velocity and the density anomalies (sinking slabs) is poor in the lowermost mantle. This may be called the 'slab sinking paradox': how the velocity anomalies near the CMB may "know" about slabs that are still suspended higher in the mantle? Dziewonski et al. (2010) proposed that this paradox could be explained if the long-term (~100 Ma) slab subduction cyclically repeats itself and the anomalies in the lowermost mantle reflect a long-term average of these cycles. The important degrees are 2 and 3; for each of these degrees, the correlation is very high, but the relative power of degree 2 of seismic anomalies is three times greater than that of degree 3; in integrated slab expansion, degree 3 has higher power than degree 2. This may mean that degree 2 may be more stable in time than degree 3. Because of its apparent longevity, Dziewonski et al. (2010) named the degrees 2 and 3 the 'mantle anchor structure' (MAS).

The degree-2 anomaly, which dominates the abyssal layer, has geometric properties that have led Dziewonski et al. (2010) to a speculation – which some thought 'outrageous' – that degree-2 anomalies may be stable over very long times. What is special about degree-2 is that when translated into density anomalies, it may affect the Earth's nonhydrostatic moment of inertia tensor. **Figure 25** shows a comparison of the degree-2 anomaly at 2800 km depth in 3-D models S362ANI (Kustowski et al., 2008), SAW24B16 (Mégnin and Romanowicz, 2000) and S20RTS (Ritsema et al., 1999). It shows nearly identical images that are very close to the harmonic Y_{20} rotated so that its symmetry axis lies in the equatorial plane. The random test shows that to obtain such a result by chance is less than 1 in 1000. If the negative velocity anomalies are associated with higher effective density, then the minimum moment of inertia axis would be crossing the equator at the center of the red anomalies (about 10° east or 170° west) as required by the rotation dynamics. The solution is degenerate for the other two principal components: any axis

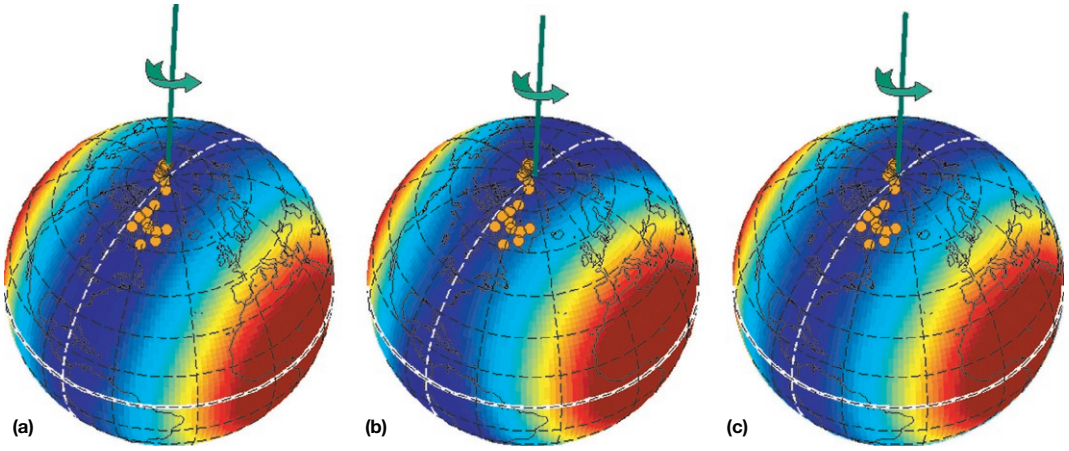

Figure 25 The nearly indistinguishable degree-2 structures at 2800 km depth of three global tomographic S-velocity models: (a) S362ANI (Kustowski et al., 2008), (b) SAW24B16 (Mégnin and Romanowicz, 2000), (c) S20RTS (Ritsema et al., 1999). Pink circles indicate paleopole locations from the true polar wander reconstructions of Besse and Courtillot (2002). Reproduced from Dziewonski A, Lekic, and Romanowicz A (2010) Mantle anchor structure; an argument for bottom up tectonics. *Earth and Planetary Science Letters* 299: 69–79.

passing through the polar great circle crossing the equator at 100° east or 80° west will have the maximum moment of inertia. Thus, this great circle would be the preferred direction of 'true polar wonder' (TPW) due to mass redistribution. The orange dots in Figure 25 are the TPW positions during the last 200 Ma as determined by Besse and Courtillot (2002); the agreement is good even though no TWP observations were included in building the seismic models. Modeling of TPW using geodynamic data was initiated by Steinberger and O-'Connell (1997) and continues till the present (c.f. Conrad et al., 2013; Rouby et al., 2010; Steinberger and Torsvik, 2010). The TPW is increasingly difficult to determine for times before the magnetic stripes on the oceanic floor have been destroyed. Some paleomagnetic evidence exists that the MAS hypothesis is consistent with the data as old as 1.3 Ga (Jean Besse, 2013, personal communication). If this is correct, then there is no reason not to test an assumption that it was formed not long after the Earth's accretion.

1.01.4.5 The Need for Consideration of More Complete Modeling of Mantle Flow

A quadrupole convection essentially identical to the pattern in Figure 25 has been proposed by Busse (1983) and its stability implications pointed out by Le Pichon and Huchon (1984) on the basis of correlation of the degree-2 geoid with velocity anomalies in the lowermost mantle (Dziewonski et al., 1977). With the incomparably higher quality of current global models of heterogeneity, we do not have a mantle flow model that reproduces large-scale features revealed by mantle tomography.

The concepts of 'top-down' or 'bottom-up' tectonics are not contradictory, but rather complementary. The heterosphere of Figure 23 is highly energetic – it contains above 80% of the volume integrated power of mantle heterogeneity – and acts on a relatively short timescale: the pattern of subductions has changed considerably during the last 200 Ma (Lithgow-Bertelloni and Richards, 1998, Figure 6). The lower-mantle heterogeneity structure (superplume zone) shows great stability, as indicated by the 'slab paradox' and TPW results, and may impose the long time influence on the heterosphere's behavior. The 'ETZ' is the critical region in which the communication between the heterosphere and the superplume zone is taking place. It is clear that some slabs become stagnant above the 650 km discontinuity, but the degree-2 velocity anomaly is well correlated with the integrated slabs during the last 15–20 Ma and does not show evidence of earlier accumulation. Thus, it is not clear what happens with the material subducted earlier. It is also not clear how the superplumes interact with the transition zone. The Pacific is slow both below and above the 650 km discontinuity, but this is not as obvious for the African superplume. Romanowicz and Gung (2002) argued that attenuation in the transition zone better reflects its thermal state than the velocity anomalies and that the Q anomalies in the transition zone are well correlated with the velocity anomalies at the CMB.

The paradigm of three-layer mantle dynamics, each of which acts on a different spatial and temporal scale and has been derived mostly from seismic data providing a present-day snapshot of 3-D velocity anomalies, must be tested by geodynamic modeling. From the published results of numerical modeling of mantle flow, it is clear that such a structure with three boundary layers has yet to be realized and match the observations.

With the recent advances in numerical modeling, a clearer picture of the connection between lower-mantle and transition zone structure on the one hand and structure in the asthenosphere on the other hand is starting to emerge. Figure 26 shows a 3-D rendering of the central Pacific portion of upper-mantle model SEMum2 (French et al., 2013), viewed from the east to the west, which shows a number of vertically elongated low-velocity columns (plumes?), many of them rooted in the lower mantle and extending up to about 350 km depth. At shallower depths, this structure is replaced by a series of horizontally elongated low-velocity channels or 'fingers,' aligned parallel to the absolute plate motion and extending into the low-velocity zone right below the lithosphere. These low-velocity channels, which are present in all major ocean basins, are spaced regularly with a wavelength of about 1800–2000 km and manifest the dynamic interaction in the 'heterosphere' between the upwellings from the 'superplume zone' and ETZ (e.g., Figure 23) and the tectonic plates.

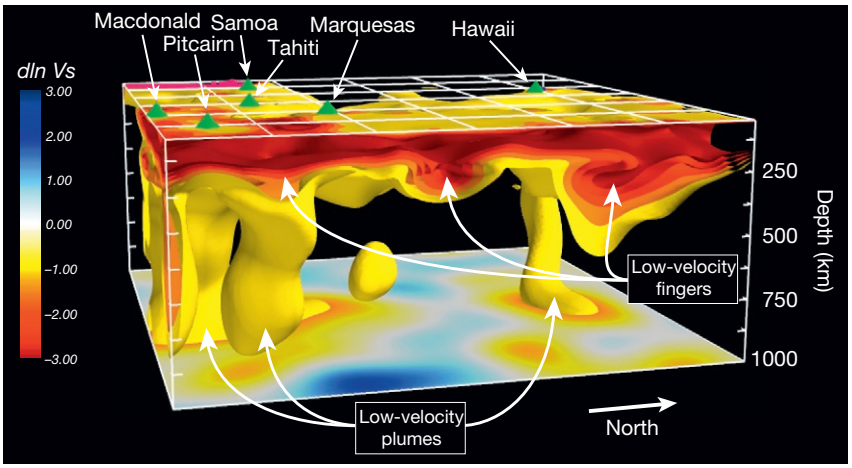

Figure 26 3-D rendering of the low-velocity parts of a portion of model SEMum2 (French et al., 2013) in the central Pacific, shown down to 1000 km depth. The range of velocity anomalies shown is −1% to −3%. The view is from the east, standing in the vicinity of the East Pacific Rise and looking towards the west. Green cones indicate major hot spots. Note the regularly spaced low-velocity fingers right below the very slow low-velocity zone. These fingers extend for several thousand kilometers into the Pacific basin, in the direction of the Pacific Plate absolute plate motion. Similar structures are seen in the south and North Atlantic Ocean and in the Indian Ocean.

We expect that, in the next 5–10 years, these images, as well as those of the lower mantle, will become even sharper, as the frequency range accessible to global tomography based on numerical methods increases, providing definitive clues on such fundamental questions as the relation of hot spots to plumes, and plumes to superplumes, and the role of superplumes in the global mantle circulation and the fate of subducted slabs.

1.02.1 Introduction

Dewey and Byerly (1969) explained that by 1900, the first global network of observatories equipped with seismographs designed by the British seismologist John Milne regularly sent records to Milne's laboratory (Hoover, 1912) and contributed to the development of the first global travel-time tables. Milne's broadband seismograph photographically recorded ground displacement with low mechanical magnification. By 1903, Galiztin's seismographs incorporated the important features of instrumentation used for global and regional observation for much of the twentieth century (Reid, 1912). Galiztin's design used an inertial pendulum having an electrodynamic transducer and damping, with photographic recording of ground velocity over a broad range of frequencies using a beam of light deflected by a sensitive galvanometer. Such

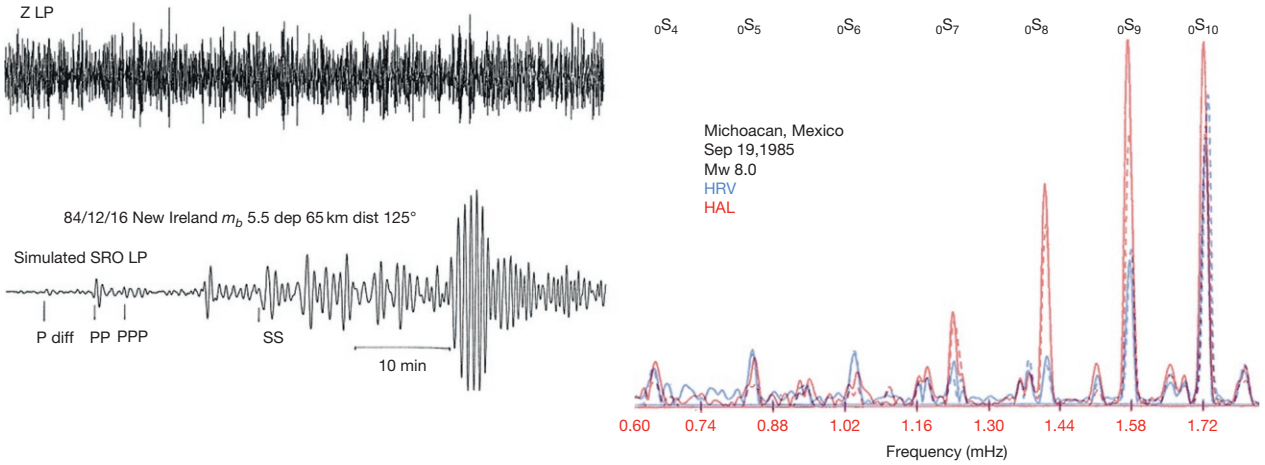

Figure 1 Two examples showing low-frequency information obtained from very broadband (VBB) recordings. Resolution of signals such as these previously required instrumentation specialized for low-frequency measurement. The left panel shows extraction of a long-period seismogram from VBB data that appears to contain only noise. The upper trace is dominated by 3–4 s microseisms. The trace below has been digitally filtered to reveal a small, distant event. The right panel shows observed (solid) and synthetic (dashed) free-oscillation amplitude spectra from the Michoacan, Mexico, Mw 8.0 event on 19 September 1985 recorded on the prototype VBB system at HRV (blue) and very long-period IDA station HAL (red) in Halifax, Nova Scotia. Signal-to-noise and synthetic agreements are comparable at the two sites located at similar distances and azimuths from the event. Horizontal axis is frequency from 0.60 to 1.8 mHz. Adapted from Steim, J., 1986. The very broadband seismograph, PhD Thesis, Harvard University.

instrumentation evolved during the early twentieth century (Benioff, 1932; Press et al., 1958) and remained a standard for sensitive observation of long-period and short-period signals well into the 1980s in the World-Wide Standard Seismograph Network (WWSSN) (Oliver and Murphy, 1971).

Early studies using hand-digitized photographic records (e.g., Bloch and Hales, 1968; Dziewonski et al., 1969; Iyer, 1964; Satô, 1958) showed the information that could be harvested through digital processing of seismograms. At the same time, the need to detect and quantify the yield of nuclear explosions began to shape much of the development of instrumentation for global observation. The resulting focus for several decades during the second half of the twentieth century was on the detection of the smallest signals. Because of the limitations of recording technology then available, instrument designers were driven to shape the frequency response of seismographs to amplify, selectively, segments of the seismic spectrum where ambient Earth noise is least, above and below the frequencies of marine microseisms (Longuet-Higgins, 1950), roughly 0.02–0.04 Hz, and in a narrowband around 1 Hz.

The potential advantages of a seismograph having a broad, flat frequency response with direct digital recording in a computer were recognized as early as 1961 in Caltech's broadband digital seismograph project (Miller, 1963):

> The broad-band system can be used to simulate any desired standard seismograph and provides greater dynamic range and more flexibility than most existing seismographs. (Smith, 1965)

Some efforts during the 1970s concentrated on idealized wideband accelerometers (e.g., Usher et al., 1977, 1978, 1979), including the venerable Teledyne–Geotech KS-36000-01 – an anachronistic combination of new electronic force-feedback (EFFB) and narrowband filtration – used in the Seismic Research Observatory (SRO) stations (Peterson et al., 1976). Evolution of the broadband seismographs of the early twentieth century was delayed by the detection mission. The Graefenberg (GRF) array project (Harjes and Seidl, 1978) during the 1970s, however, illustrated the unrealized potential of digital broadband data.

Although the available digitally recorded low-frequency data (Agnew et al., 1976; Peterson et al., 1976) were limited in the early 1980s, the use of whole waveforms (Dziewonski and Steim, 1982) began to elucidate features of global earth structure, culminating in derivation of the first Earth models (Woodhouse and Dziewonski, 1984) using information contained in the entire waveform. This type of analysis was not possible before the availability of substantial amounts of high-quality digital data made possible by the pioneering digital networks. Both the great potential and considerable limitations of the digital instrumentation deployed during the 1970s became apparent (Dziewonski et al., 1981; Peterson, 1982).

Desire for better, higher dynamic range broadband instrumentation as well as simultaneous rapid development in electronics finally enabled the realization of an instrumentation technique that could embody in a practical way most of the requirements of global seismological research. Building upon the works of Plešinger and Horalek (1976) and Wielandt and Streckeisen (1982) and the first broadband array at GRF (Harjes and Seidl, 1978), the very broadband, or VBB, system was developed at ETH, Zürich, and Harvard University in the early 1980s (Steim, 1986; Steim and Wielandt, 1985; Wielandt and Steim, 1985, 1986). The objective was a single high-quality digital broadband data stream that included low frequencies previously measured only with specialized instrumentation that tended to saturate on large earthquakes (Agnew et al., 1976). Results from experimental VBB systems (**Figure 1**) showed that the objective was achievable.

Except for implementation, the technology now in global and regional networks is largely unchanged from the system

design developed at Harvard in the early 1980s (Peterson and Hutt, 1989; Steim, 1986; Steim and Wielandt, 1985), using a single sensor (Wielandt and Steim, 1986) to acquire the seismic spectrum from tidal frequencies to about 10 Hz, a high-linearity analog-to-digital (A/D) converter, contemporaneous digital data reduction with compact data streams at several sampling rates, and remote data access (Steim, 1987). The initial goals of instrumentation for new global and regional networks (Lay et al., 2002, after IRIS, 1985) had been achieved in the Harvard system, enabling rapid establishment and growth of broadband networks during the past 25 years:

(1) On-scale broadband recordings of earthquakes as large as Mw = 9.5 (equivalent to the 1960 Chile earthquake) at 30°. On-scale low-gain recordings of all earthquakes at 1 sps (samples per second)
(2) Noise below ambient Earth noise
(3) Bandwidth spanning all solid Earth free oscillations and regional body waves (up to 15 Hz or higher as regional wave propagation considerations dictate)
(4) Linearity sufficient to record signals near ambient noise in the presence of signals near clipping at well-separated frequencies
(5) Response known to 1% across the bandwidth
(6) Sensor cross axis coupling less than about 1%
(7) Timing adequate to measure teleseismic body wave arrivals to 0.01 s

In 1987, the addition to the data system of strong motion for the first time in a station of the global network, Caltech's PAS (Pasadena, CA) station (Kanamori, 1990; Kanamori et al., 1990), achieved the goal of measurement at a single station of more than 220 dB dynamic range in ground acceleration. This chapter will focus on the technology of global and regional teleseismic observation as currently practiced in the widely used facilities comprising the continuously recording research networks typical of contributors to the International Federation of Digital Seismic Networks (Dziewonski, 1994).

This instrumentation comprises sensitive inertial broadband seismometers and associated recording equipment and provides the majority of data for studies of earthquakes and deep earth structure. Complementary instrumentations, including, 'strong motion,' arrays, strainmeters (Barbour and Agnew, 2012), or rotational (Forbriger, 2009) sensors, are not treated here. The 'broadband revolution' was approached in the 1980s mainly from the perspective of standards appropriate for global science-driven seismology. Over the past 30 years, VBB design elements have diffused throughout most aspects of modern earthquake instrumentation for regional and global-scale observation and will continue to influence new instrumentation developed over the next decade.

1.02.2 Seismic Signals and Noise

Seismologists are primarily interested in seismic signals. Seismic signals may appear as transient wavelets lasting seconds to minutes or oscillatory wave trains lasting as long as days or months and, in terms of acceleration, span eleven orders of magnitude. Signals occur in the presence of background activity that also spans a wide range in frequencies and amplitudes and exhibits a variety of characteristics, appearing as impulses, steps, transient wavelets, quasioscillatory wave trains, or apparently random waveforms, and may originate as ground motion or artifacts of instrumentation. Some continuous background activity, for example, marine microseisms, may be considered noise in many contexts, however, may contain significant information (Shapiro and Campillo, 2004). Noise for an instrument designer is the background level of actual or instrument-generated equivalent ground motion observed at the output of a seismograph. Instrument designers, sometimes to the consternation of seismologists, devote considerable effort to the study and minimization of noise. Noise defines the smallest detectable signal in an instrumentation system and, therefore, its usefulness for many requirements. Studies, for example, of small, low-frequency signals, such as normal modes from moderate earthquakes or 'hum' (Kurrle and Widmer-Schnidrig, 2008; Tanimoto et al., 1998), require instrumental resolution at the level of minimum Earth noise. Understanding instrument behavior requires some representations appropriate to describe simultaneously the amplitude and frequency of signals and noise to be measured.

1.02.2.1 Representations: Time Series and Spectra

1.02.2.1.1 Spectral analysis

Spectral analysis (e.g., Bracewell, 1978; Oppenheim and Schafer, 2009; Scherbaum, 2001) is a primary tool for characterization of ambient seismic noise and instrument behavior and is possible because the Earth and seismographic instrumentation systems can be considered within some range of input to be linear time-invariant, or LTI (Oppenheim and Schafer, 2009). Although spectral analysis is an essential tool for instrumentation, seismic signals occur and are measured in the time domain. Some phenomena – for example, 'clipping' – can be described adequately only in the time domain, since these violate the LTI assumption. This chapter therefore develops a representation to characterize the range of amplitudes and frequencies measured by instrumentation from the perspective of behavior in the time domain.

Let a real sequence $\{x_m\}$ represent M samples at discrete times $m\Delta t$ of a continuous function of time $x(t)$ containing seismic noise or signals. Define a sequence $\{X_\kappa\}$ of length M:

$$\mathcal{D}\{x_m\} = X_\kappa = \frac{1}{\sqrt{M}} \sum_{m=0}^{M-1} x_m e^{-i2\pi\kappa m/M} \qquad [1]$$

as the discrete Fourier transform (DFT) of the sequence $\{x_m\}$. The corresponding inverse DFT represents a sequence in time as the sum of its DFT spectral coefficients X_κ:

$$\mathcal{D}^{-1}\{X_k\} = x_m = \frac{1}{\sqrt{M}} \sum_{k=0}^{M-1} X_k e^{i2\pi km/M} \qquad [2]$$

In practice, the DFT is computed by one of many fast Fourier transform (FFT) (Cooley and Tukey, 1965) algorithms for efficiency. We assume familiarity with operations with the DFT but will review some topics relevant to the description of seismic signal and noise spectra.

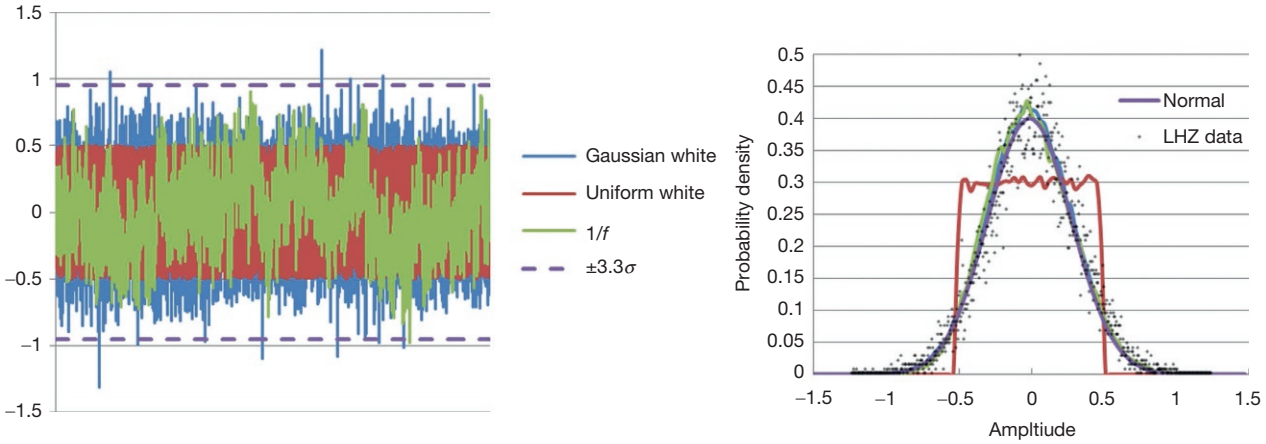

Figure 2 Left: Three types of noise, all with identical variance = $\text{rms}^2 = \sigma^2 = 1/12$: white noise having a normal distribution (blue), white noise with uniform distribution (red), and 1/*f* noise (green). The crest factor for 1/*f* and normally distributed white noise is ~3–4, while the crest factor for uniform white noise is $\sqrt{3}$. The crest factor 3.3 includes most peaks for normally distributed noise. The noise of quantization in digital instrumentation (Bennett, 1948) is uniformly distributed and can be minimized by design. Right: Amplitude probability density distributions for the three noise sources at left. The scattered dots show actual (scaled) amplitudes of a broadband velocity seismic noise sample with a bandwidth of ~0.4 Hz, having a normal distribution. Stationary seismic noise not of cultural origin typically is normally distributed; the time-domain amplitude can be estimated with a crest factor 3.3.

1.02.2.1.2 Power spectral density: power and amplitude

Power spectral density (PSD) is defined as power per unit of bandwidth. This can be written for the discrete series X_κ as

$$\text{PSD}_\kappa = \frac{|X_\kappa|^2/M}{\text{width of frequency bin}\,\kappa} = \frac{|X_\kappa|^2/M}{1/M\Delta t} = \Delta t|X_\kappa|^2 = \frac{|X_\kappa|^2}{\rho} \quad [3]$$

where $\rho = 1/\Delta t =$ the sample rate in samples per second. PSD has units *amplitude*^{2}/Hz or *power*/Hz. PSD contains no phase information – only the distribution of power over frequency – and therefore cannot be inverted to infer time-domain amplitudes for arbitrary waveforms. For a real sequence $\{x_m\}$, X_κ is conjugate-symmetric about $M/2$. PSD may therefore be reported as twice the value for $0 < \kappa \leq M/2$; the value for $\kappa = 0$ is the mean of $\{x_m\}$. Spectra are often represented as $dB(P) = 10\log(P)$, where P represents power density PSD_κ, or power $\text{PSD}_k\Delta f$. $\Delta f = 1/M\Delta t = \rho/M$ is the frequency bin width.

The types of stationary noise typically encountered in seismic systems comprise both *white* and *1/f* noise with amplitudes having uniform or normal (Gaussian) probability density functions (PDFs). White noise is defined as noise in which $|X_\kappa| \cong$ constant in eqns [1] and [2]. 1/*f* noise typically includes a large class of physical behaviors in which $|X_\kappa|^2$ grows with inverse frequency raised to some power, often as f^{-1}.

The *crest factor* for a waveform is defined as the ratio of peak amplitude to rms (root mean squared). For a sine wave, this is $\sqrt{2}$. For a sequence of normally distributed noise of reasonable length for analysis, the crest factor is typically ~3–4. The crest factor 4 corresponds to a statistical confidence level of ~99.99% that the maximum amplitude in a sequence is contained within four standard deviations from the mean of the sequence. PSD is a correct measure of stationary noise power as a function of frequency, but not transient signals, and can be used to approximate the amplitude in the time domain of stationary noise with a known crest factor. Minimum ambient seismic noise has been shown to behave as normally distributed random noise (Peterson, 1993). The time-domain amplitude of seismic noise can be estimated by the product of the crest factor for normally distributed noise times the rms amplitude within a defined bandwidth. Figure 2 shows the time-domain amplitudes of several noise sources and their amplitude probability density distributions compared with the (scaled) distribution for a sample of broadband velocity data representing marine microseisms. The choice of crest factor is arbitrary. A peak will typically be distinguishable above noise using a crest factor of 3.3.

1.02.2.1.3 Bandwidth

Signal and noise amplitudes are measured in the time domain over a finite bandwidth. Bandwidth is important when considering seismic signals that span more than five decades in frequency. The integrated power of a constant PSD over the decade from 10 to 100 Hz contains 10 000 times the power in a decade from 1 to 10 mHz. Development of a representation to describe, simultaneously, large transient signals and small stationary noise therefore requires an appropriate consideration of bandwidth.

A seismograph responds to both signals and noise in a band of frequencies in which the signals are contained. An objective in instrument design is to maximize the signal-to-noise (SNR) ratio in the band of frequencies of interest. Seismic signals – body and surface waves at frequencies higher than a few mHz – comprise wave groups of widely varying amplitude (more than 11 orders of magnitude) recognized in frequency bands of constant relative width (width proportional to frequency) spanning perhaps a small fraction to several octaves. Below several mHz, seismic noise represented as any typical function of ground motion (e.g., acceleration, velocity, or displacement) increases. Over the large bandwidth of more than four decades in frequency from ~0.3 mHz to 10 Hz or above, SNR can be maximized by a sensor with an output having roughly equal noise (and large signal) power in bands of constant relative width across the entire frequency range of

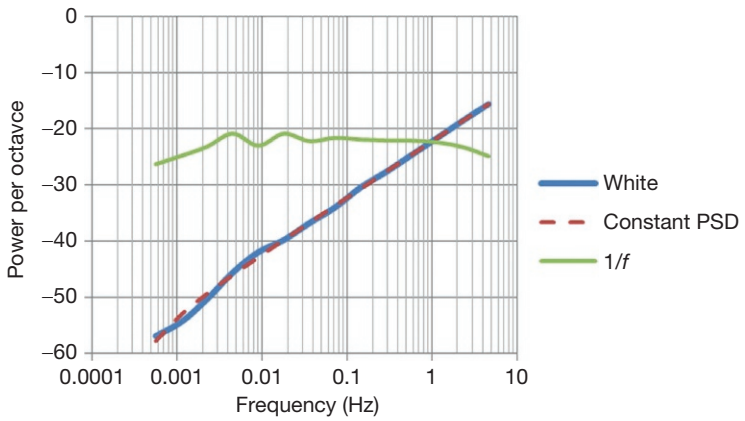

Figure 3 Power spectra of synthetic random noise representing white noise (blue) and 1/*f* noise (green) sampled at 20 sps (samples per second) having identical variance 1/12, summed over bands of constant relative width of one octave. For reference, an isoline of PSD = variance/sample rate is also shown (dashed red). Constant PSD produces increasing power with increasing frequency in bands of constant relative width, as appropriate for signal measurement. 1/*f* noise produces constant power when summed over bands of constant relative width. 1/*f* noise in bands of constant relative width cannot be reduced by filtering to reduce bandwidth. 1/*f* noise is typical of physical systems below some corner frequency.

interest. Under this condition, at the sensor output, the band, for example, from 0.005 to 0.01 Hz, would contain the same noise and signal power as the band from 5 to 10 Hz. While this cannot be exactly achieved, it is approximated with VBB seismograph systems.

Discrete PSD spectra represent power density in bands of constant, finite, width, for example, the bin width equal to ρ/M in previous examples. The power in a band of constant relative width centered at frequency f is computed by integrating (summing) PSD over bands from frequency f_1 to f_2 that are proportional to f. For example, the band limits for a one-octave band where $f_2 = 2f_1$ may be defined as $f_1 = f/\sqrt{2}$ and $f_2 = f\sqrt{2}$. The bandwidth, therefore, is $f_2 - f_1 = f(\sqrt{2} - 1/\sqrt{2}) = f/\sqrt{2}$. Constant PSD in bands of constant relative width produces power increasing proportional to f. Processes, including many instrumentation and physical noise sources, characterized by 1/*f* noise produce constant power in bands of constant relative width (**Figure 3**).

To appreciate the contrast in consideration of power in bands of constant width or constant relative width, the particular relative band size, for example, 1/3 octave or one octave, is not important. The important aspect is the dependence on f of the power over a large range of frequencies. The choice of bandwidth for signals to determine the frequency dependence of their time-domain amplitudes is more significant.

1.02.2.1.4 Minimum earth noise

A number of parametric models of ambient seismic noise have been constructed over the past 50 years (Agnew and Berger, 1978; Berger et al., 2004; Brune and Oliver, 1959; Fix, 1972; Melton, 1976; Murphy and Savino, 1975; Peterson, 1980, 1993; Peterson and Tilgner, 1985; Wielandt and Streckeisen, 1982). All models are based on a collection of observations and hence limited by instrumentation of the era and represent minimum noise levels in observed spectra. The minimum level observed at any particular frequency is not necessarily observed simultaneously at another frequency. Although obvious instrumental disturbances and earthquakes were omitted, the intrinsic noise and the sensitivity of the instruments to environmental inputs are included in these models. These models, therefore, tend to be biased toward high estimates of actual Earth noise. The models could be interpreted as a behavioral model of the performance expected from a well-installed, properly running instrument of similar technology. Generally, the progression of models has been toward lower minimum noise over a wider frequency range, although recent estimates of noise >1 Hz based on actual global and regional stations are somewhat higher than some earlier, perhaps optimistic, models. The general rise in observed levels >1 Hz may reflect the encroachment of man-made noise sources on many of the observation sites that comprise existing networks. **Figure 4** compares several important vertical models. The GSNtypZ trace is the visually estimated low percentile of the most often observed quiet levels in the Global Seismographic Network (GSN) low-noise model (Berger et al., 2004). At low frequencies, GSNtypZ is roughly equivalent to the Peterson (1993) new low-noise model (NLNM). From the perspective of instrument design, low vertical noise levels present a greater challenge than higher horizontal noise levels. Horizontal noise levels between 100 and 250 s period in the GSN and GEOSCOPE (Roult et al., 2010) networks typically are between −160 and −165 dB acceleration PSD, more than 20 dB above vertical levels.

Heightened cold-war detection work during the 1980s drove efforts to find unusually quiet sites at frequencies >1 Hz, remote from man-made noise sources (Bache et al., 1986; Berger et al., 1988; Bungum et al., 1985; Herrin, 1982; Li et al., 1984; Rodgers et al., 1987; Gurrola et al., 1990). More recent efforts have found quiet sites in Antarctica (Anderson et al., 2006) and Central Asia (Hutt, personal communication). High-frequency levels at exceptionally quiet sites can be as low as 30–40 dB below typical levels at many global and regional stations, although these low levels are observed infrequently during no-wind periods and at culturally quiet time times (nights and weekends). Resolution of the lowest high-frequency levels constitutes a weak goal for general broadband

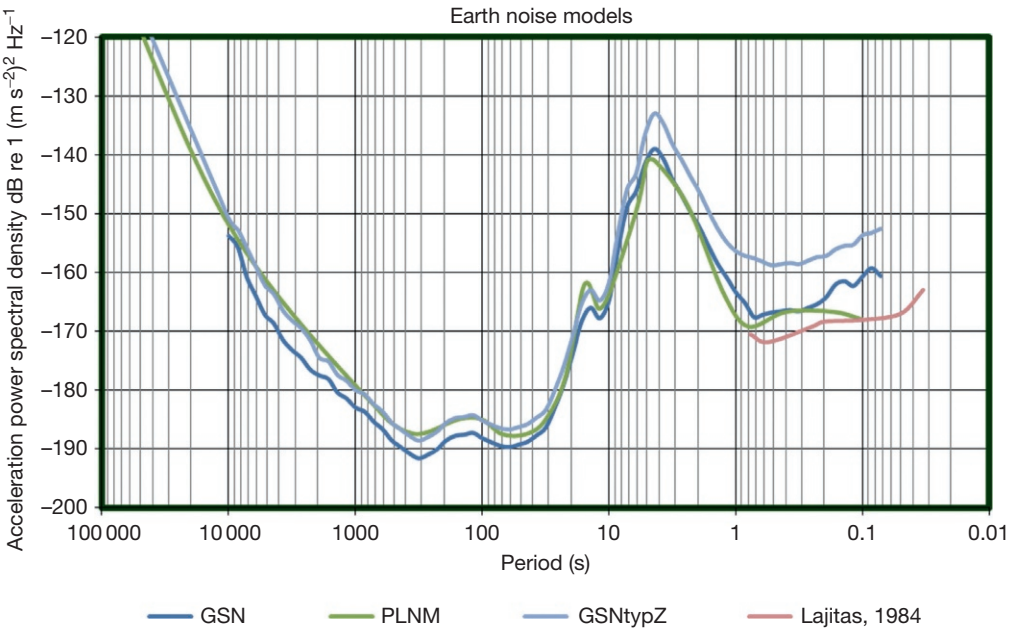

Figure 4 The two most commonly used vertical minimum Earth noise models: the Peterson model (Peterson, 1993; green) and the global seismographic network (GSN) noise model (Berger et al., 2004; blue) as acceleration PSD. The trace-labeled GSNtypZ (light blue) is the visually estimated lower limit of the most dense areas (not the lowest percentile) of the probability distribution in the GSN model, representing typical observations at quiet sites. The Lajitas, 1984 trace (Li et al., 1984; pink) shows the low-percentile, no-wind measurements in boreholes at a then-quiet remote site in Lajitas, TX, United States. Current levels at that site are above the levels seen three decades ago. The Peterson (trace-labeled PLNM) model represents a reasonable estimate of achievable minimum noise at the quietest sites at frequencies near 10 Hz (Hutt, personal communications) and is not typically observed at current operating sites of global and regional networks. Above ~1 Hz, seismic noise is mainly man-made and wind-generated (Carder, 1963). The range from ~0.05 Hz to 1 Hz is dominated by marine microseisms. Minimum levels below 0.01 Hz are observable only on lowest-noise instruments in thermally stable installations.

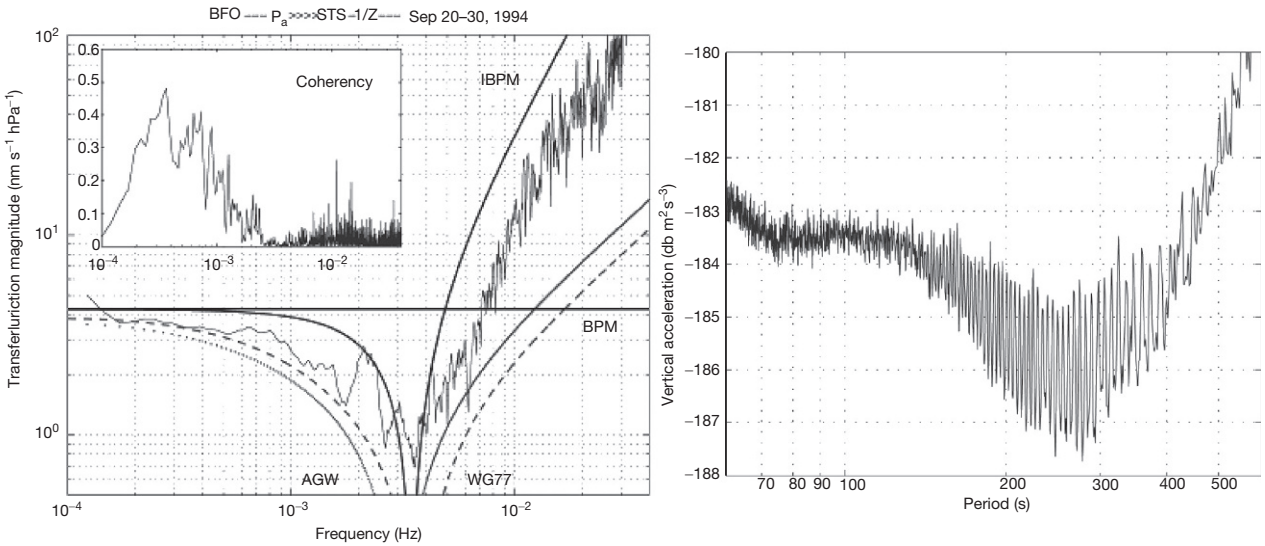

Figure 5 Left: Admittance of several models between local atmospheric pressure and vertical acceleration versus frequency for 10 days data from September 1994. The models show minima near 3 mHz where effects of Newtonian attraction and surface loading approximately cancel. Reprinted by permission from W. Zürn and E. Wielandt. On the minimum of vertical seismic noise near 3 mHz *Geophysical Journal International* (2007) 168 (2): 647–658, Figure 8. Right: Stack of quiet-time noise spectra from 32 of the lowest-noise GSN stations, showing 'hum' (Nawa et al., 1998) in the frequency range of the Earth noise minimum near 3 mHz. With permission from Berger et al. (2004).

instrumentation for earthquake studies where low gain is required to acquire large signals on-scale. Instrumentation for detection purposes may require very low intrinsic sensor noise and may also exchange dynamic range for increased gain to overcome A/D noise.

The vertical noise minimum at frequencies less than several mHz may not be fully described by existing models. Figure 5 shows that the low levels frequently observed near 3 mHz comprise clear signals ('hum') above the background minimum (Zürn and Wielandt, 2007) in atmospherically generated noise.

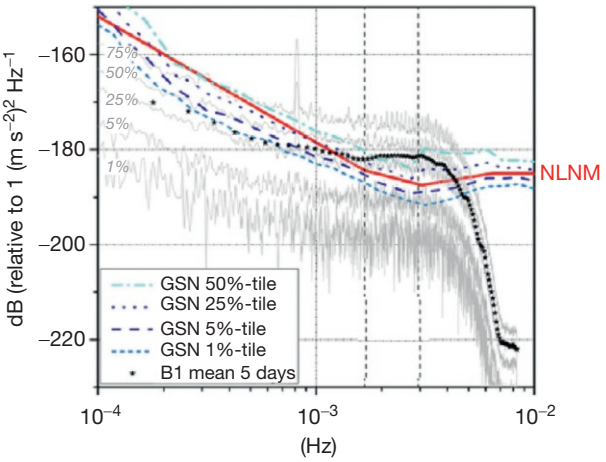

Figure 6 Observed gravity residuals (1st, 5th, 25th, 50th, and 75th percentiles, gray lines) from the OSG-056 (B1) superconducting gravimeter (SG) at BFO (Schiltach, Germany), compared with the 1st, 5th, 25th, and 50th percentiles for the vertical GSN noise model (Berger et al., 2004 – dashed blue lines) and USGS NLNM (red). The 75th percentile of the mean PSD of the five most quiet SG days (small black stars) is also plotted. The GSN noise model is derived from STS-1/VBB sensors and is not corrected for barometric pressure. Adapted from Rosat S and Hinderer J (2011). Noise levels of superconducting gravimeters: updated comparison and time stability. *Bulletin of the Seismological Society of America* 101(3), 1233–1241.

Hum (Nawa et al., 1998) is at the current limit of instrumental resolution (Widmer-Schnidrig, 2003) and can be observed only in spectra stacked to reduce uncorrelated noise. Observation on horizontal sensors is unusual (Kurrle and Widmer-Schnidrig, 2008). Minimum ambient seismic noise may be below current models at frequencies <1 mHz. Spectra (**Figure 6**) from superconducting gravimeters (SG) show levels (Rosat and Hinderer, 2011; Widmer-Schnidrig, 2003) below the current noise models at frequencies <1 mHz when the SG data are corrected for barometric pressure (see later this chapter), suggesting future model revisions. Recent increased availability to seismologists of SG data (Van Camp et al., 2008; Xu et al., 2008; GWR-Instruments, 2011) may encourage re-examination of the low-noise models for frequencies <1 mHz. With the deployment of digital networks over the last 25 years, long observation times and millions of observations are now possible.

1.02.2.1.5 Measuring signal amplitudes

Signals generated by earthquakes span a range of 11 orders of magnitude in amplitude from the level of minimum Earth noise, roughly 10^{-10} m s^{-2}, to greater than 10 m s^{-2} near a significant earthquake. The goal for instrumentation is to sense and record the largest possible range of amplitudes across the broadest frequency range. The peak time-domain amplitude of signals defines the ability to measure the largest signals linearly. Every instrumentation system has a maximum amplitude limit, its *saturation* or *clip* level, above which the LTI assumption is invalid, and all frequencies are affected. Clip level expressed as ground motion is dependent on the frequency of signals comprising a transient wave group. Peak time-domain signal amplitude, with an estimated frequency content, therefore appropriately describes the largest signals encountered by instrumentation.

Like noise, signals span a broad range of frequencies, and their time-domain amplitudes depend on their bandwidth and frequency content. Definition of a bandwidth over which to consider, simultaneously, signals and noise enables description of the dependence on frequency of the largest and smallest signals observed and measurable by a system. The particular choice of bandwidth is arbitrary; however, the bandwidth should be sufficiently wide to make a reasonable estimate of the peak time-domain amplitude of coherent signals within the band while not so wide as to obscure the dependence on frequency. Wave groups tend to be dominated by a small range of frequencies comprising, for example, often on the order of an octave or two (Steim, 1986). Clinton and Heaton (2002) chose one-octave bands to estimate the frequency dependence of time-domain amplitudes using ~1000 recordings. One octave may be appropriate for most dispersed waveforms, that is, typically for events beyond 100 km. One octave is not adequate for nondispersed waveforms, for example, from nearby events, potentially containing high frequencies in phase, and hence tightly grouped in time, creating brief peaks considerably higher than would be observed in an arbitrarily limited band. **Figure 7** (Clinton and Heaton, 2002), for example, shows that the one-octave filtered acceleration of a large close-by event has ~20% of the actual peak amplitude of the signal energy over a wide bandwidth.

The peak time-domain amplitude of signals is used here without arbitrary bandwidth restriction. To estimate the band of frequencies comprising a signal peak, a band-pass filter is used that is sufficiently wide to retain, say, at least 80% of the peak amplitude. This may require two or more octaves, depending on frequency content. Such an approach is roughly equivalent to estimation of frequency based on measuring the reciprocal time of zero crossings of a peak oscillatory signal cycle. This approach to represent the frequency dependence of peak signal amplitudes differs from some previous analyses (Bormann and Wielandt, 2013; Clinton and Heaton, 2002; Evans et al., 2010; Steim, 1986) in which signal amplitudes may be somewhat underestimated by arbitrary band limiting. A seismometer never 'sees' a peak signal limited to an arbitrary band such as 1/3 octave. The seismometer sees all frequencies comprising a wave group. We seek an approximation of the frequency content of signal peaks in order to localize, on a plot of amplitude versus frequency, a data point that may be compared with the saturation level of instrumentation.

1.02.2.1.6 Observed signal amplitudes and noise

Figure 8 shows noise models and selected signals, represented as measured peak amplitudes (for signals) and equivalent peak amplitudes for the GSN LNM (Berger et al., 2004) and new high-noise model (Peterson, 1993). Some peak signal measurements are shown as one-octave-wide bars, although the actual measurement bandwidth may be wider. Spectra extending from <0.1 Hz to >10 Hz are based on one-octave filtered seismograms of large events from Clinton and Heaton (2002). In addition, the amplitude of solid Earth tides and the amplitude of free mode $_0S_0$ during the first days following the Mw 8.8 Chile earthquake of 2010 are shown. The range in measured peak accelerations exceeds 230 dB, which no wideband accelerometer has ever come close to resolving.

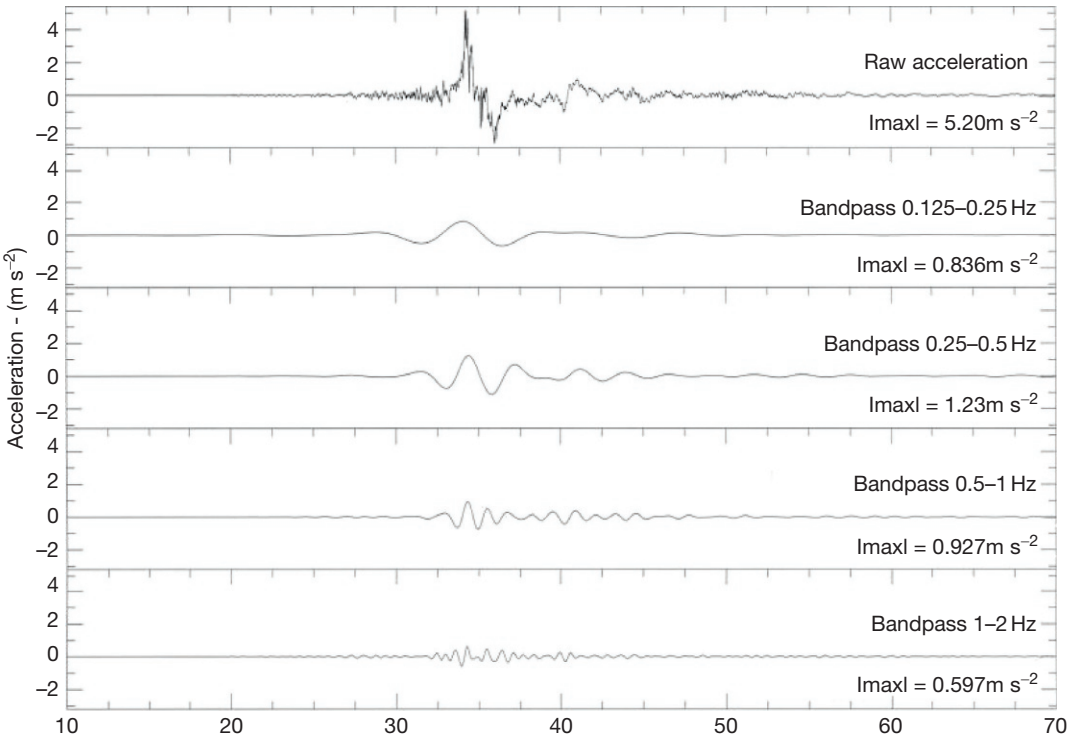

Figure 7 Sample of vertical acceleration data band-passed for M7.5 earthquake at 10 km distance (from Clinton and Heaton, 2002). The actual peak acceleration is approximately five times higher than viewed in one-octave bands.

1.02.2.1.7 Saturation (clip) level

Within some defined band of frequencies, the saturation level of a sensor in terms of ground motion in principle is the maximum output (voltage or digital representation) divided by the transfer function relating the output to ground motion. For an EFFB sensor, the power supply voltage and maximum feedback force define the actual saturation level across some range of frequencies. There may be additional design-dependent physical mechanical or electrical limits that reduce the actual input-equivalent saturation level. For example, the saturation level of a Streckeisen STS-2 seismometer is specified as ± 13 mm s^{-1} velocity at 20 Hz, decreasing linearly to ± 5.3 mm s^{-1} at 50 Hz. This is because the maximum input acceleration that can be balanced by the feedback system is ± 1.67 m s^{-2}. Outside the nominal signal passband, there may be additional limitations.

1.02.2.1.8 Operating range

Hutt et al. (2009b) defined operating range as

> The portion of the ground motion spectrum between the clip level and the self noise of a seismometer, [where the latter is represented as the root mean square (rms) of a sliding half-octave window.] Operating range depends on the bandwidth in which the noise is measured.

The present analysis considers peak amplitudes; however, this results in small differences compared with appropriate use of rms values. The overall dependence on frequency of operating range as the interval between noise and clip level describes the important aspect of a sensor's ability to measure signals. The most striking feature is the extent in amplitude and frequency of the operating range required of a broadband system meeting the goals for global network operation. *Dynamic range*, like operating range, is frequency-dependent and can be considered to be the frequency- and bandwidth-dependent ratio of maximum/minimum operating range limits. One may also consider definition of a companion *useful dynamic range* for a seismometer, as the interval between a seismometer's clip level and the level of ambient seismic noise at the seismometer output. The difference in definition can be quite large. The KS36000-01 seismometer used in the SRO system (Herrin, 1982), for example, was described as having 120 dB dynamic range, whereas the useful dynamic range was typically only about 50 dB at 6 s period, because high gain caused much of the operating range to be occupied with microseismic noise. Using peak or rms descriptions of amplitudes, the required useful dynamic range for broadband systems reaches a maximum of order 10^7, or 140 dB.

The frequency dependence of a system's operating range is readily visualized as a bounded area in a two-dimensional amplitude–frequency plot. Steim (1986) introduced such a representation as a readily interpretable method to visualize the dependence of seismograph operating range on frequency and to describe the optimum approach to realize design goals established for new networks. Such a representation is approximate because of the arbitrary choices necessary to represent simultaneously the amplitude of stationary noise and transient signals as a function of frequency. The approach, however, has become frequently used in the past three decades (Hutt et al., 2009a). Evans et al. (2010) recently proposed this approach to represent the operating range of instrumentation in a standardized way.

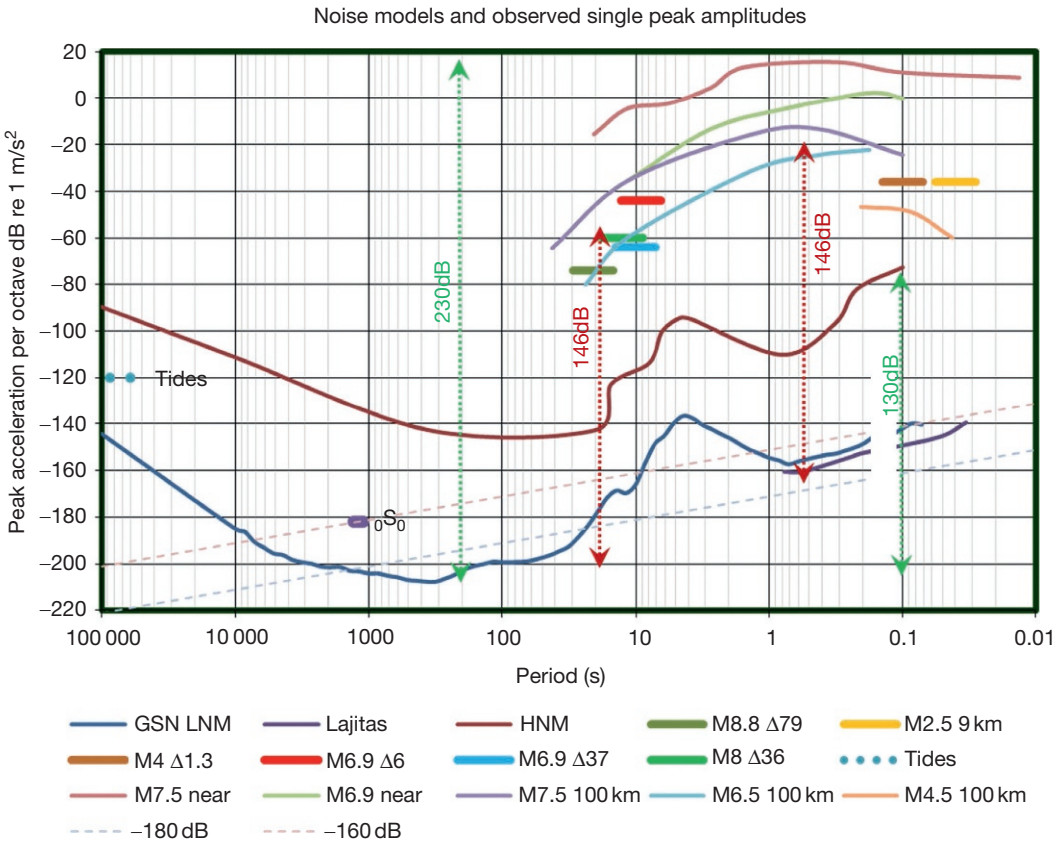

Figure 8 Noise models and signals as equivalent peak acceleration in a one-octave bandwidth. The peak amplitude of transient signals and stationary noise cannot be represented exactly in a common representation. The equivalent peak amplitude of stationary noise is approximated as 3.3 times the rms value in a one-octave band in order to compare with peak earthquake signal amplitudes. Peak levels (GSN stations HRV and PFO, 1985–2010) of six events, for example, M6.9Δ37 (an earthquake of undifferentiated magnitude 6.9 at epicentral distance 37°; thick blue), are represented as a one-octave wide bar at the estimated frequency of the wave group having the maximum peak amplitude. The peak amplitude of these signals is not band-limited. Four spectra spanning the frequency range ~0.1–10 Hz, for example, M6.5 100 km (light blue), are peak amplitudes measured in one-octave wide bands (from Clinton and Heaton, 2002). The GSN (dark blue) and Lajitas (violet) noise models from **Figure 4** are included along with the Peterson (1993) new high-noise model (HNM; brown). Additionally, the amplitude of solid Earth tides and mode ${}_0S_0$ (0.8 nm s^{-2} peak) following the 2010 Chile Mw 8.8 earthquake are shown. The ratio of maximum acceleration to minimum noise level exceeds 230 dB, while the amplitude range from just below the LNM to the amplitudes of moderate events at global and regional distances exceeds 140 dB. Relatively small nearby events produce accelerations exceeding that of the greatest earthquakes seen at distances >30°. Isolines of constant acceleration PSD appear with increasing power per octave. Power of the HNM near 10 Hz exceeds minimum Earth noise at 3 mHz by ~130 dB. The octave-filtered (M4.5 100 km; tan) spectra are much lower than the peak amplitude (M4 Δ1.3; thick brown) over a larger bandwidth.

While the bandwidth used to estimate the frequency content of signal peaks may be variable, the choice of an arbitrary bandwidth for the estimation of the time-domain amplitude of stationary noise affects only the interval between signals and noise. Various noise contributions are compared exactly to each other, when the conversion to time-domain amplitude for all noise sources is consistent. Signal peaks also compare with instrument clip level.

Clinton and Heaton (2002) partially compensated for bandwidth limitation in peak signal estimation by reducing the representation of instrumental clip level by a bandwidth-dependent factor. The approach here is simply to plot actual peak signal amplitudes at an estimated frequency, along with instrument peak clip level and an empirically justified representation of noise as an equivalent peak amplitude in the time domain.

1.02.2.2 Representations: Instrumentation Systems

The problem of optimization over a large operating range of SNR of a seismograph system requires a consideration of seismograph system frequency response. The *transfer function* of a continuous-time LTI system, such as a seismometer, is typically described using Laplace transforms (e.g., Bracewell, 1978). The Laplace transform $F(s)$ of the function $f(t)$ is given by

$$F(s) = L\{f(t)\} = \int_0^\infty e^{-st} f(t)dt \qquad [4]$$

where $F(s)$ is defined as the Laplace transform of $f(t)$, a function of time $t \geq 0$, and s is complex. In the case of $s = i\omega = i2\pi f$, the Fourier transform results. $f(t)$ and $F(s)$ define a Laplace transform pair. When $f(t)$ is convolved with the *impulse* response $h(t)$ of a system assumed to be LTI, such as a

seismometer, the resultant output $y(t)$ may be represented in the time domain as the convolution $f(t)*h(t)$ or in the frequency domain as $Y(s)$, the product of $F(s)\bullet H(s)$, where $H(s)$ is the transfer function describing the LTI system with impulse response $h(t)$. The transfer function $H(s)$ of an LTI system is defined as the ratio of the Laplace transforms of the system output $Y(s)$ divided by the system input $F(s)$.

An analogous *Z-transform* is defined for discrete-time causal systems (which all digital seismographs can be considered):

$$X(z) = Z\{x_m\} = \sum_{m=0}^{\infty} x_m z^{-m} \qquad [5]$$

where $\{x_m\}$ is a real sequence and z is complex. A particularly useful feature of the Z-transform is that a unit delay in the time domain is represented by multiplication by z^{-1} in the z-domain, that is,

$$Z\{x_{m-n}\} = z^{-n}X(z) \qquad [6]$$

A *digital filter* may be described by

$$y_m = \sum_{n=0}^{N} d_n x_{m-n} \qquad [7]$$

where a sequence $\{d_n\}$ of N real constant coefficients is convolved with the input sequence $\{x_m\}$ to produce an output sequence $\{y_m\}$. The operation may be expressed as multiplication of rational polynomials in the z-domain using the transfer function $D(z)$ of the filter:

$$D(z) = \sum_{n=0}^{N} d_n z^{-n} \qquad [8]$$

and

$$Y(z) = Z\{y_m\} = D(z) \cdot X(z) \qquad [9]$$

Equation [7] represents a class of digital filter called a finite impulse response (FIR) filter used universally in the digitizing and processing systems of broadband seismographs. FIR filters have the desirable property of unconditional stability, since their evaluation depends solely on current and prior samples of an input sequence, and not on the output of the filter. Low-pass FIR filters are typically used as digital anti-alias filters because of the ability to construct very sharp filters of high rejection of unwanted frequencies while preserving a maximum passband.

The general topic of discrete-time signal processing is beyond the scope of this section. The reader is referred to the general literature on discrete signal processing (e.g., Welch, 1967; Bracewell, 1978; Cooley et al., 1970; Oppenheim and Schafer, 2009; Rabiner et al., 1972; Rader and Gold, 1967) and specific seismological applications (e.g., Haney et al., 2012; Harjes and Seidl, 1978; IRIS, 2012; Scherbaum, 2001; Seidl, 1980). This chapter will use Laplace and z-transforms, however, to describe important aspects of seismometer and system behavior.

1.02.2.2.1 Seismograph systems

The seismograph systems providing global and regional data comprise one or more sensors with a voltage output that is digitized in an A/D converter. Additional digital processing follows to record and transmit digitized data. Other approaches to convert ground motion to numbers are in principle possible, but until now, and likely during at least the next decade, sensors having a voltage output followed by an A/D will continue to be dominant.

The major elements of a system are represented in Figure 9: a sensor with transfer function $H(s) = E(s)/V(s)$ relating the transforms of, say, input ground velocity $v(t)$ to output voltage $e(t)$; a digitizer converting samples of voltage $e(m\Delta\tau)$ at

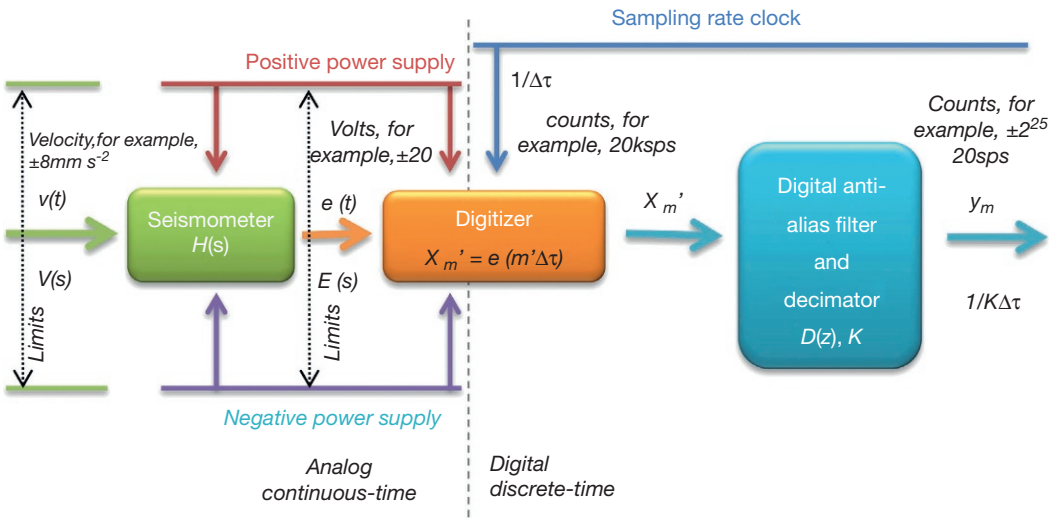

Figure 9 A simplified digital seismograph. The elements include a sensor with Laplace transfer function $H(s)$ to produce a voltage, a digitizer to sample the voltage, and low-pass digital filters to produce a digital sequence $\{y_m\}$ representing the physical ground motion input, for example, ground velocity $v(t)$. The transfer function $H(s)$ maps the strong frequency dependence of ground motion amplitude, in terms of ground acceleration, onto a weaker frequency dependence of voltage measured by the digitizer. The transfer function $H(s)$ is designed to maximize SNR (signal-to-noise) across the frequency range of operation, not to enhance specific signals. The system saturation (clip) level is limited partially by power supply voltages, although additional limits may exist.

discrete times $m'\Delta\tau$ to an output digital sequence $x_{m'}$ at a rate $1/\Delta\tau$ much higher than the highest signal frequency of interest; and a digital anti-alias filter with transfer function $D(z)$ and decimator of factor K. The final stage decimates the filtered sequence

$$y'_{m'} = \sum_{n=0}^{N} d_n x_{m'-n} \quad [10]$$

at a high rate $1/\Delta\tau$ to the reduced-bandwidth output sequence $\{y_m\}$ delivered for analysis at a lower sample rate $1/\Delta t = 1/K\Delta\tau$:

$$y_m = y'_{Km} \quad [11]$$

This description is greatly simplified to focus on the effect of sensor frequency response on system operating range and omits important features: noise in the sensor and digitizer, analog anti-alias filtration in the digitizer, time labeling, and additional stages of digital filtration and decimation. Although anti-alias filtration in the digitizer is an essential element, its impact on the overall system behavior seen at seismic frequencies is generally only a small time delay that can be compensated in a time label, since *oversampling* A/D converters operate with a high rate $1/\Delta\tau$.

1.02.2.2.2 Noise, signals, and sensor response

The central issue for broadband system design is the choice of response $H(s)$ that both optimizes SNR in the output voltage of the sensor $E(s)$ and allows the greatest operating range to be 'mapped' onto the available capability of the digitizer, defined by its intrinsic noise and maximum signal limits. The limits may be mechanical and electrical in the seismometer and are electrical in the A/D. Power supply voltages partially define these limits.

1.02.2.2.2.1 Significance of frequency response

The question of an 'optimum' frequency response for a broadband seismic sensor was not frequently considered before the 1980s (e.g., Berckhemer, 1970; Lake, 1964). Because of the limitations of photographic recording and then-current A/D and digital data storage technology, considerable efforts in networks such as the WWSSN, high-gain long-period (HGLP), and SRO programs were devoted to shaping the frequency response of instruments to enhance signals suitable for detection of small nuclear explosions and reject frequencies considered to be dominated by noise (Murphy and Savino, 1975; Oliver and Murphy, 1971; Peterson et al., 1976; Sutton and Oliver, 1959).

The objectives for sensor frequency response in a broadband system instead are to include many frequencies, to maximize SNR, and to minimize gain. It is not surprising that such a system was not the focus of attention and in fact was considered cumbersome (Smith, 1964) until digital computing and storage became widely available during the 1980s.

Digital VBB instrumentation shapes sensor frequency response $H(s)$ to include most signals seen at teleseismic distances at the sensor output in a manner approximately optimally matched with the A/D. Matching means that the noise voltage at the sensor's output is only slightly larger than the noise voltage of the A/D as a function of frequency and that the maximum voltage produced by a large signal roughly corresponds to the maximum voltage measurable by the A/D. The frequency response of the sensor maps the sensor's operating range as a function of frequency onto the operating range of the A/D and ideally preserves maximum SNR. While a variety of sensor frequency responses are possible, particularly in an EFFB seismometer, only a small class of frequency responses and gains similar to VBB are useful in optimally delivering a voltage representing seismic signals from <1 mHz to >10 Hz so matched to a digitizer.

Frequency response and gain are not strictly related to a seismometer's SNR. For example, although a strong-motion accelerometer has a frequency response extending to zero frequency, its SNR is many orders of magnitude less than a modern broadband seismometer at frequencies of, say, 1 mHz, despite the fact that such a seismometer has a high-pass response to acceleration. It is also possible to design an electronic seismometer with very high sensitivity resulting from high gain and a flat frequency response extending from 10 s to 100 Hz, but this could result in having an SNR and dynamic range worse than a simple geophone.

1.02.2.2.2.2 Synthesis of a VBB system response

Figure 10 shows spectra of the seismic noise models on land shown in Figure 8 represented as ground velocity. The amplitude in bands of constant relative width from ~3 mHz to >10 Hz is roughly constant and increases approximately 40 dB/decade at frequencies <3 mHz. Let $V(s)$ represent ground velocity, $E(s)$ the voltage output of a seismometer, and G a *generator constant*, having units volts/velocity, for example, V m^{-1} s. A second-order high-pass transfer function $H(s)$ relating $E(s)$ to $V(s)$ of the form

$$\frac{E(s)}{V(s)} = H(s) = G\frac{s^2}{s^2 + 2\xi\omega_0 s + \omega_0{}^2} \quad [12]$$

where ξ is the fraction of critical damping, is proportional to velocity above a corner at angular frequency ω_0. The choice of $\omega_0 \cong 2\pi/360$ tends to equalize noise and, coincidentally, signal power in bands of constant relative width from 0.01 mHz to 10 Hz. $H(s)$ can be considered the frequency response of a VBB seismometer. An aside: on the sea floor surface, the seismic noise distribution is different, resulting in a better match over 0.02–10 Hz to the higher overall noise level there with a response proportional to acceleration (Webb, 2002; Webb et al., 2001). Sea floor low-frequency noise levels are high relative to sea floor high-frequency levels, although all sea floor levels are above quiet levels on land (Webb and Crawford, 2010).

Figure 11 shows the match between seismic noise levels at the output of a VBB seismometer described by eqn [12] and actual representative noise of a high-resolution A/D converter (Quanterra Q330HR) used in global and regional networks. The constant $G \cong 2200$ V m^{-1} s has been chosen to adequately resolve minimum noise without loss of large signals. In such a system, both seismic noise and A/D noise are described by roughly flat noise amplitude in frequency bands of constant relative width from <0.1 mHz to >10 Hz. The noise of 24-bit quantization (Bennett, 1948) at 100 sps with a range of ± 20 V is also shown for comparison. The typical vertical noise levels observed at quiet GSN sites are well above actual A/D noise. Only high-frequency noise during the quietest

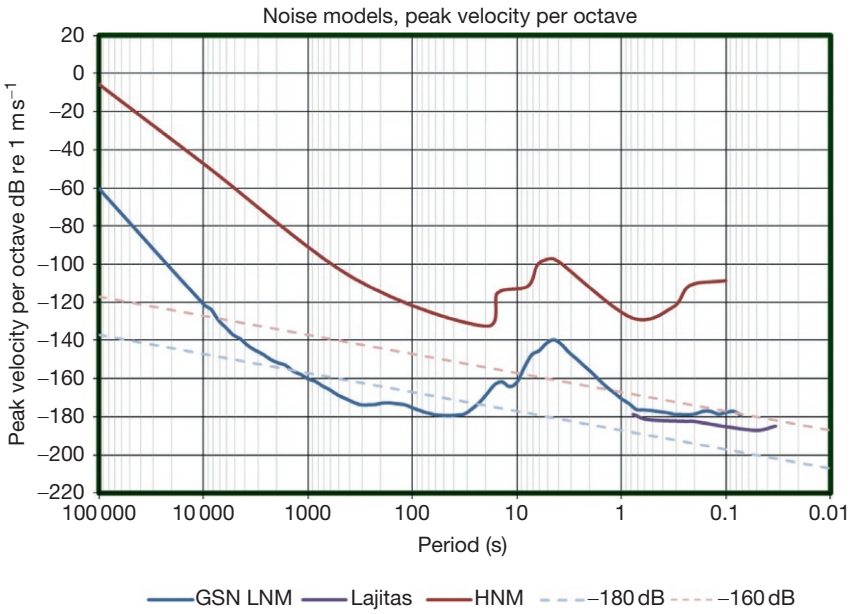

Figure 10 This figure shows the noise models of **Figure 8** represented as peak ground velocity (crest factor 3.3) in one-octave bands. The noise models are approximately 'rotated' clockwise compared to acceleration per octave, reducing the ratio of maximum to minimum amplitude over the frequency range from ~3 mHz to >10 Hz. Noise levels at frequencies below ~3 mHz increase ~40 dB per decade. The amplitude in bands of constant relative width from 0.01 mHz to 10 Hz or higher can be roughly equalized with a second-order high pass at ~3 mHz. −180 dB (dashed light blue) and −160 dB (dashed violet) are acceleration PSD isolines.

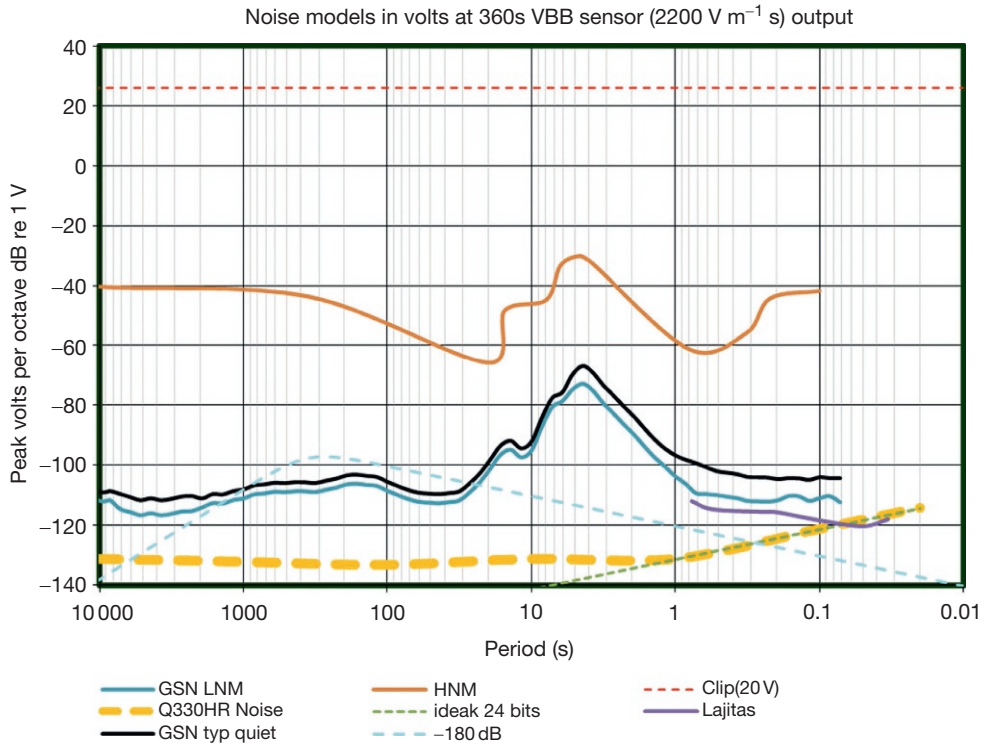

Figure 11 The noise models of **Figure 10** represented as peak voltage (crest factor 3.3) at the output of a very broadband (VBB) seismometer having a response flat to ground velocity with a two-pole high-pass corner at 360 s period and gain 2200 V m^{-1} s. The noise models are compared with the actual noise of A/D systems (thick yellow dashed line) used in global network stations. Except for the peak containing marine microseisms, the amplitude of the noise models as a function of frequency is nearly equalized with this frequency response. The amplitude variation of minimum Earth noise with frequency is ~50 dB over the entire frequency range. The margin between low Earth noise and A/D noise is positive and roughly uniform. The interval from noise to 20 V clip level (red dotted line) is similarly nearly constant. 24-bit, 100 sps quantization noise is also shown (dashed green). The isoline −180 dB acceleration PSD is 'bent' and 'tilted' by this approach showing VBB's frequency-dependent map of constant acceleration PSD to voltage at the A/D converter (dashed blue). The frequency response described is VBB, originally implemented in the STS-1/VBB seismometer for frequencies <10 Hz.

periods at exceptional sites, such as Lajitas, TX, during the 1980s (current levels; there are higher), is not well resolved by such a system.

A system as represented in Figure 11 with flat response to velocity extending from 360 s to arbitrarily high frequency does not quite exist. Existing Streckeisen STS-1/VBB and Geotech KS54000I sensors used in global networks, however, provide an approximation, with an upper second-order corner frequency at 5–10 Hz. A number of existing broadband sensors with a lower corner period of 120 s or more have nearly flat frequency responses extending well above 10–40 Hz or higher but do not typically resolve minimum Earth noise at frequencies <4–5 mHz. The development of sensors better approximating the wide response depicted in Figure 11 with lowest noise is an area of current research.

1.02.2.3 Actual GSN Operating Range

Figure 12 shows the signals and noise of Figure 8 and includes the actual saturation and estimated noise level of the STS-1/VBB seismometer to represent the frequency dependence of the operating range of global network systems. A similar figure would result with other types of velocity broadband sensors, such as the Geotech KS54000I, the Streckeisen STS-2, and the Nanometrics T240, with differences in the clip level and low-frequency noise level (discussed later). With the STS-1/VBB, such a system is capable of high-SNR recording of free oscillations and on-scale recordings of most events to at least M8 at 30° distance. Moderately large events at regional distances, illustrated by the M6.9, 6°, are at the maximum signal-handling limit. Small, nearby, felt events, illustrated by M4, 1.3°, are well within the capability. Large events nearby and at regional distances are well above the maximum signal-handling capability and require a lower-gain sensor to measure on scale. Although the interval between the sensor's intrinsic noise and saturation level is ~146 dB, this range is never fully exercised, since Earth noise defines the minimum output level. Figure 11 or 12, based on peak levels as described earlier, shows that a maximum observed dynamic range of ~135–140 dB defined as $20\log\left[\frac{\text{clip level}}{\text{noise level}}\right]$ using peak amplitudes (the more often defined rms ratio is $20\log(3.3/\sqrt{2}) = \sim 7$ dB higher) is achieved in an octave band of frequencies near 30 s period, where surface wave signals may be large and seismic noise low.

Such an operating range representation helps illustrate the difference between a sensitive instrument and a low-gain or strong-motion instrument. Strong-motion instruments designed for large signals as seen in the near field of an earthquake are defined from the 'top down' by their maximum peak signal levels, usually 2 g; their noise level is subordinate, defined by their electronics and mechanical system at a level somewhere below their defined maximum signal level. Strong-motion sensors in current use achieve a typical useful dynamic range approaching 150 dB, diminishing at frequencies <1 Hz. Instruments intended for the most sensitive low-frequency measurements, however, are designed from the 'bottom up' for a target noise level and achieve some maximum signal level dependent on electronics.

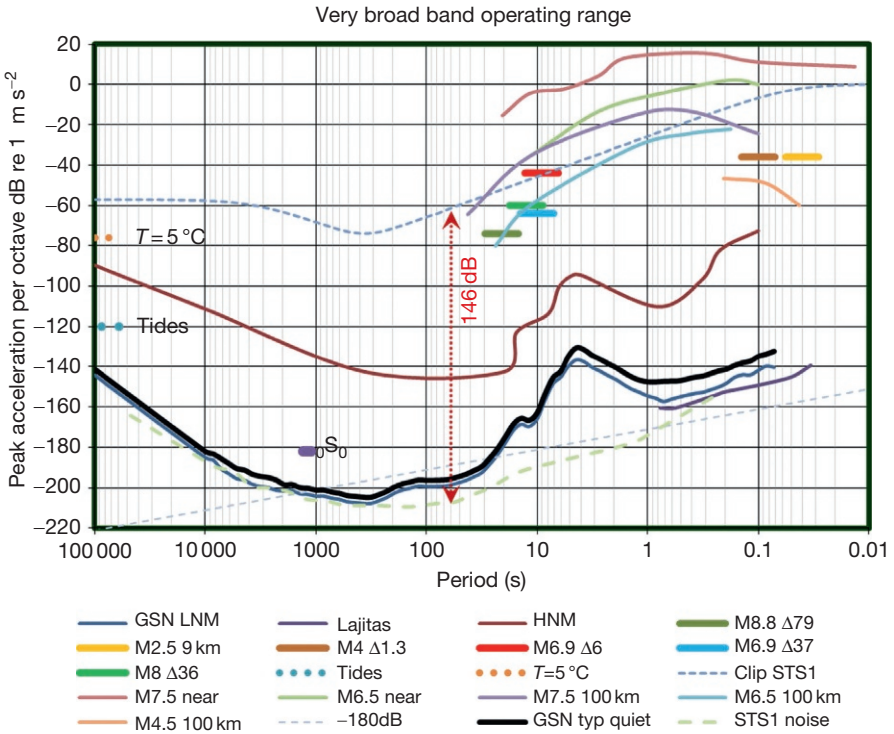

Figure 12 The frequency-dependent operating range of a VBB system. The seismic noise models and signals of Figure 8 are combined with the instrumentation noise (dashed green) and clip level (dashed blue) of a VBB system using the frequency response illustrated in Figure 11. Many large signals at regional and teleseismic distances are within the operating range. The largest signals at regional and near distances are above the maximum capability. The actual maximum useful dynamic range of a VBB system exceeds 140 dB at some frequencies. Also shown is the approximate acceleration equivalent of a 5 °C temperature change on the effective mass position. Thermal stability in the installation is required.

1.02.2.4 Dynamic Range and Bandwidth

Dynamic range is a number often used to describe the ratio of the largest to smallest time-domain signal handled by an instrumentation system. Dynamic range, however, is meaningless without specification of the frequency band over which the measurement is made. In the case of a broadband seismic system spanning nearly seven decades in frequency, the particular choice of band limits greatly affects the resulting ratio. A few examples illustrate this point.

The useful dynamic range observed over the full bandwidth of the GSN VBB sensors is not particularly impressive when deployed at a noisy site. The interval between short-period ambient noise and clipping may be only 80 dB or less: this is the ratio of clip level to the voltage produced by the sensor that one would measure with a voltmeter at such a site. The maximum dynamic range defined as an rms ratio, say in one octave near 30 s, on the other hand, exceeds 140 dB. Dynamic range is usually specified in instrumentation as the rms ratio of a maximum amplitude sine wave to the noise within a specified band of frequencies. For the system shown in Figure 11 where actual A/D noise is ~75 nV rms/octave and the A/D maximum rms level for a sine wave is 14.14 V, actual A/D rms dynamic range is roughly a constant 164 dB in one-octave bands below the $1/f$ corner and ~147 dB in a one-octave band at 50 Hz.

1.02.3 Seismometers and Systems

Measurement conventions, models of Earth noise and signals, and a system matching frequency response to noise and signals to achieve design goals of global and regional networks have been introduced. This section will discuss the design and operation of sensors and systems to achieve the result depicted in Figure 12. The discussion partially follows Steim (1986).

1.02.3.1 Mechanical Pendulum

An inertial seismometer sensitive to vertical motion consists of a mass suspended elastically against gravity from a frame that rests on the Earth's surface. The inertial mass and viscoelastic suspension create a mechanical oscillator that for small motions can be described by a second-order linear differential equation:

$$\ddot{x}(t) + \frac{b}{m}\dot{x}(t) + \frac{k}{m}x(t) = a(t) \qquad [13]$$

where m is the inertial mass, $x(t)$ is the displacement of the mass as a function of time in a fixed coordinate system, b describes frictional damping of the mass motion and has units force/velocity, k is the spring constant of the elastic suspension and has units force/displacement, and $a(t)$ is the acceleration of the seismometer frame as a function of time. If the seismometer frame is coupled firmly to the ground, $a(t)$ also represents ground acceleration. Laplace transformation of eqn [13] gives

$$s^2X(s) + s\frac{b}{m}X(s) + \frac{k}{m}X(s) = A(s) \qquad [14]$$

where s is the complex frequency variable and $X(s)$ and $A(s)$ represent Laplace-transformed mass displacement and ground acceleration. The transfer function of the mechanical system $M(s)$ is defined as

$$M(s) = \frac{X(s)}{A(s)} = \frac{1}{s^2 + s\frac{b}{m} + \frac{k}{m}} \qquad [15]$$

Equation [15] can be written as

$$M(s) = \frac{X(s)}{A(s)} = \frac{1}{s^2 + 2\xi\omega_0 s + {\omega_0}^2} \qquad [16]$$

where ξ represents the fraction of critical damping of the oscillator and $\omega_0 = 2\pi/T_0 = \sqrt{k/m}$ is the (angular) resonant frequency of the undamped mechanical oscillator having period T_0. Above resonance ω_0, the displacement $X(s)$ of the mass relative to the frame represents ground displacement $D(s)$:

$$X(s) \approx \frac{A(s)}{s^2} = D(s) \qquad [17]$$

Below resonance, $X(s)$ is proportional to ground acceleration:

$$X(s) \approx \frac{A(s)}{{\omega_0}^2} \qquad [18]$$

The addition of an electrodynamic transducer, that is, a coil of wire moving through a magnetic field, with generator constant G to measure $X(s)$ creates the familiar seismometer producing a voltage $E(s)$ proportional to mass velocity:

$$E(s) = G \cdot sX(s) = G\frac{sA(s)}{s^2 + 2\xi\omega_0 s + {\omega_0}^2} = G\frac{s^2V(s)}{s^2 + 2\xi\omega_0 s + {\omega_0}^2} \qquad [19]$$

Well above resonance ω_0, $E(s)$ is proportional to ground velocity $V(s)$. This is the form of response of a conventional electrodynamic geophone:

$$E(s) \approx G \cdot V(s) \qquad [20]$$

The frequency response of eqn [19] is simulated by a force-feedback broadband velocity sensor. Compare eqn [12]. Traditional seismographs such as the WWSSN with photographic recording are described by eqn [19] with an additional second-order low-pass function describing the galvanometer (Hagiwara, 1958; Wielandt and Mitronovas, 1976).

1.02.3.2 Electronic Force Feedback

EFFB has been used in seismometry since at least the mid-1950s (Benioff, 1955). EFFB was originally used primarily to generate a restoring force to maintain the inertial pendulum within its mechanical operating limits, typically under variation of position caused by temperature change, tilt change, and mechanical creep (Sutton and Latham, 1964). At least one early effort (DeBremaecker et al., 1962) included direct digitization having a claimed dynamic range of 100 dB, and a system with EFFB featuring laser displacement sensing of the inertial pendulum and a dynamic range up to 140 dB (Hemelrick, 1964) was proposed, but apparently not constructed.

EFFB sensors first reached wide deployment in the International Deployment of Accelerometers (IDA) network (Agnew et al., 1976) with the Block and Moore (1966) conversion of gravimeters (LaCoste, 1934) by the addition of capacitive displacement sensing. The weak electrostatic feedback limited the

saturation level. The low-frequency noise, however, was quite low and these systems provided valuable data.

The present era of high-dynamic-range EFFB sensors began with the deployment of relatively small sensors having strong feedback to shape response using electromagnetic transducers. The SRO (Melton, 1976; Peterson et al., 1976) program using the Geotech KS36000 and the GRF array (Harjes and Seidl, 1978) using the newly developed Streckeisen STS-1 (Wielandt and Streckeisen, 1982) provided the first significant volumes of high-quality digital data from broadband EFFB sensors. The KS36000 operated as an accelerometer, which unnecessarily restricted its potential operating range (Peterson, 1982; Steim, 1986). The STS-1's application of EFFB for the first time enabled a dynamic range of 140 dB in a broadband sensor. The STS-1/VBB version with a 360 s corner period enabled by 1986 (Wielandt and Steim, 1986) the first realization of digital VBB seismometry in global and regional networks. At the same time, miniaturized versions of EFFB sensors (Usher et al., 1977, 1978, 1979) were developed throughout the 1980s and 1990s. The use of EFFB allows a relatively compact sensor that is comparatively easy to isolate against environmental inputs to achieve the response of a much larger equivalent open-loop sensor. The stable 360 s corner period of the STS-1/VBB, in fact, is not practically achievable in an open-loop sensor. For a review of EFFB seismometers during this period of rapid development, see Steim (1986).

Figure 13 shows the mechanical seismometer of eqn [16], with response $M(s)$ converting ground acceleration $A(s)$ into inertial mass displacement $X(s)$. EFFB requires an electrical transducer that converts the inertial mass displacement $X(s)$ into an electrical voltage $E(s)$. The electrical transducer may, in general, have any frequency response $R(s)$, although the primary types of transducer would be an electromagnetic velocity transducer, as in a geophone, or a displacement transducer, in which $R(s)$ would equal a constant, say, r having units volts/displacement. The choice of a displacement transducer is most appropriate for resolution of the inertial mass motion at very low frequencies. The combined frequency response of the mechanical seismometer and electrical transducer is given by $O(s) = M(s)R(s)$, the *open-loop* response, that is, without feedback.

In the model of **Figure 13**, a feedback force is generated by an electrical frequency response – shaping network that drives a force transducer acting on the inertial mass. The network is described as an admittance, or inverse impedance, network that converts a voltage to a current $I(s)$ for driving a transducer that generates a feedback force proportional to applied current. The force operates on the sensor's suspension to produce an input to the mechanical sensor that is equivalent to an acceleration acting on the mass of the sensor.

The admittance network contains the electrical components or subcircuits that determine the overall response of the seismometer in the *closed loop*, that is, with feedback applied. An admittance network to convert a voltage to a current for the force transducer may consist simply of resistors and capacitors, or it may include active circuits. An electromagnetic force transducer is typically a coil of wire in a magnetic field, equivalent to an electromagnetic velocity transducer used to sense motion in, for example, a geophone. The coil produces a force proportional to the current flowing through it. The admittance network has response $N(s)$ having units current/voltage $= 1\ \Omega^{-1}$. The force transducer and inertial mass may be considered together to have a response $G(s)$ that can be simply a constant, say, g (not to be confused with the acceleration of gravity), having units acceleration/current. In this formulation, a current applied to the force transducer produces an equivalent acceleration of the mass of the mechanical seismometer. The combined response of the feedback from voltage to ground acceleration is then $F(s) = N(s)G(s)$.

The voltage $E(s)$ may be written as the sum of ground and (negative) feedback accelerations acted upon by the open-loop transfer function $O(s)$:

$$E(s) = (A(s) - E(s)F(s))O(s) = A(s)O(s) - E(s)F(s)O(s) \quad [21]$$

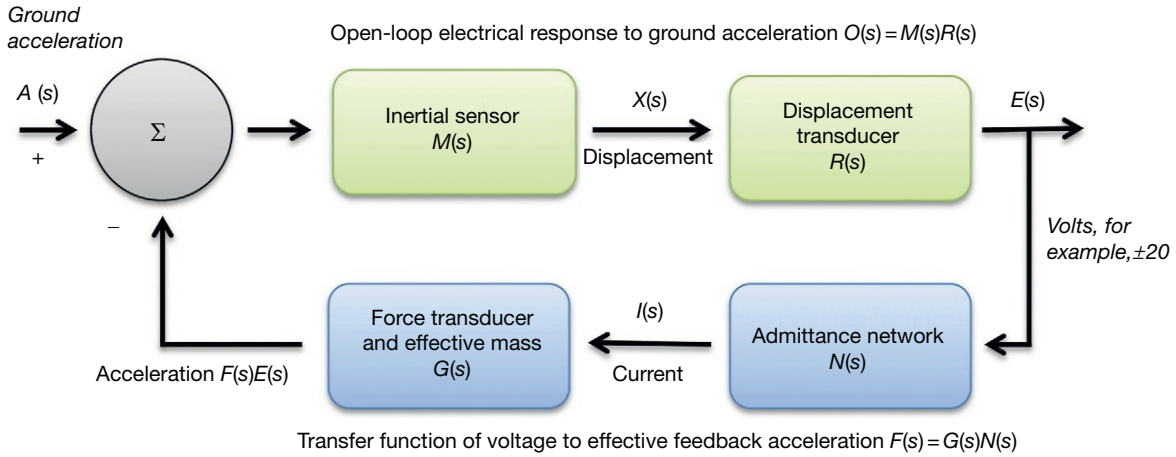

Figure 13 A generalized Laplace-transformed description of an electronic force-feedback (EFFB) seismometer, with acceleration input $A(s)$, and voltage output $E(s)$. Feedback reduces the displacement of the inertial mass $X(s)$ by a frequency-dependent factor $O(s)F(s)$ (the loop gain) compared to the open-loop case. Smaller physical displacement improves linearity in the closed loop. Useful dynamic range can be very high in terms of acceleration over a wide frequency range if the feedback path $F(s)$ is controlled by passive electrical components. Active components in the feedback path introduce noise that appear in the output signal $E(s)$. At frequencies where $O(s)F(s) \gg 1$, the frequency response $E(s)/A(s)$ of the closed loop is $\sim 1/F(s)$, controlled mainly by the feedback network.

which may be rewritten to give the output voltage $E(s)$ as a function of ground acceleration or the closed-loop transfer function:

$$\frac{E(s)}{A(s)} = \frac{O(s)}{1 + O(s)F(s)} \quad [22]$$

At frequencies where $O(s)F(s) \gg 1$ (true for frequencies up to about 5 Hz in the STS-1/VBB), the closed-loop response is approximately

$$\frac{E(s)}{A(s)} \approx \frac{1}{F(s)} \quad [23]$$

In this case, the closed-loop response of the seismometer is controlled entirely by the feedback network and force transducer and is independent of the mechanical response of the seismometer without feedback. The quantity $O(s)F(s)$ is called the *loop gain* and is a measure of the effectiveness of feedback in determining the seismometer response. Loop gain is a fundamental descriptor of any feedback system.

In a high-dynamic-range VBB sensor, such as the STS-1/VBB, the admittance network has the form illustrated in Figure 14. The three feedback paths describe a system with proportional, integral, and derivative (PID) feedback. This architecture is common in many feedback control systems (Ang et al., 2007). At frequencies where the feedback force is strong (loop gain $\gg 1$), the feedback current delivered to the force transducer by the admittance network balances ground acceleration. Each of the three parallel paths has the highest admittance over different frequency ranges. The voltage $E(s)$ is proportional to the integral of ground acceleration, or ground velocity in the broad range where the path across C is dominant, and to the derivative of ground acceleration or the second derivative of ground velocity where the path through the integrator is dominant.

The open-loop $O(s)$ and feedback $F(s)$ transfer functions can be generalized to better model a typical sensor:

$$O(s) = R(s)M(s) = \left[\frac{r}{sT_D + 1}\frac{M'(s)}{M_{eq}(s)}\right]M(s) = \left[\frac{r}{sT_D + 1}\right]M'(s) \quad [24]$$

$$F(s) = G(s)N(s) = \frac{g\left(sC + 1/R_p + 1/s\tau R\right)}{sCR_C + 1} \quad [25]$$

where R_C is the resistance of the feedback transducer coil and the transfer function $R(s)$ of the displacement transducer includes a single-pole time delay T_D and the response of an *inverse filter* (Wielandt and Steim, 1986). The inverse filter has response $M'(s)/M_{eq}(s)$. If $M_{eq}(s) \approx M(s)$, the inverse filter converts the second-order mechanical response $M(s)$ into a response of the same form $M'(s)$ describing an effective mechanical sensor with a much longer free period $T_0' = 2\pi/\omega_0'$ than the actual sensor. The purpose is to boost the loop gain at frequencies where the condition $O(s)F(s) \gg 1$ is not otherwise met. The identical match $M_{eq}(s) = M(s)$ is not required, and the exact choice of parameters of the inverse filter has little effect on the overall closed-loop response. Higher loop gain enforces the approximation in eqn [23] and desensitizes the closed-loop response to variations in the free period and damping of the mechanical suspension.

Substitution of eqns [24] and [25] into eqn [22], and some approximations, gives the closed-loop response to acceleration explicitly including the effects of finite $R_{C'}T_{D'}$ and ω_0':

$$\frac{E(s)}{A(s)} = \frac{1}{gC} \times \frac{s(sCR_C+1)}{s^5\frac{R_C T_D}{rg} + s^4 K + s^3\frac{1}{rgC} + s^2\left[K\omega_0'^2 + \frac{2\xi}{rgC}\omega_0' + 1\right] + s\left[\frac{1}{CR_p} + \frac{\omega_0'^2}{rgC}\right] + \frac{1}{\tau RC}} \quad [26]$$

where $K = (R_C + T_D/C)/rg$

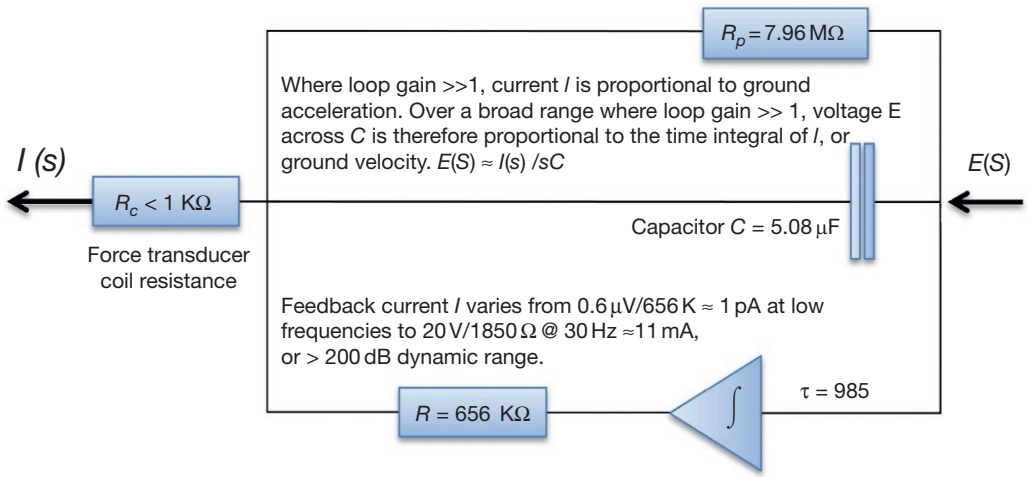

Figure 14 An admittance network in an EFFB seismometer converts an output voltage to a frequency-dependent current applied to a force transducer. The feedback force is equivalent to ground acceleration with a maximum useful dynamic range exceeding 200 dB. The feedback path controlling closed-loop response is frequency-dependent and dominated by the capacitive path over a broad range. Feedback current is limited at high frequency by force transducer internal resistance. The network is a simplified version of the network used in the STS-1/VBB. In the actual sensor, two force transducers are used: one for the R_p and C path, and one with a smaller transducer constant and opposite polarity for the integral path, which is inverted. The values of feedback components are representative of the median of a population of ~200 vertical and horizontal sensors, and hence do not represent a specific instrument.

Consider first the case where $R_C = T_D = 0$, that is, there is no feedback transducer coil resistance or time delay in the displacement transducer. Even for relatively large values of ω_0', the term $\frac{2\xi}{rgC}\omega_0' \ll 1$, allowing eqn [26] to be written:

$$\frac{E(s)}{A(s)} = \frac{1}{gC}\frac{s}{s^3\frac{1}{rgC} + s^2 + s\left[\frac{1}{CR_p} + \frac{\omega_0'^2}{rgC}\right] + \frac{1}{\tau RC}} \quad [27]$$

The coefficient of s^3 affects frequencies >1 Hz. The remaining second-order polynomial defines the low-frequency behavior of the transfer function, with closed-loop free period $T_C = 2\pi\sqrt{\tau RC}$, and the fraction of critical damping:

$$\xi_c = \frac{1}{2}\left[\frac{1}{R_p} + \frac{\omega_0'^2}{rg}\right]\left[\frac{\tau R}{C}\right]^{0.5} \quad [28]$$

Equation [28] shows the importance of the inverse filter in desensitizing the closed-loop damping to changes in the mechanical period of the inertial suspension. With the inverse filter, $\omega_0' \ll \omega_0$, and $\omega_0'^2/rg \ll 1/R_p$, allowing damping to be set by R_p. Having made this approximation, the closed-loop response including the effects of R_C, T_D can be considered:

$$\frac{E(s)}{A(s)} = \frac{1}{gC}\frac{s(sCR_C + 1)}{s^5\frac{R_C T_D}{rg} + s^4\left[\frac{R_C + T_D/C}{rg}\right] + s^3\frac{1}{rgC} + s^2 + s\frac{1}{CR_p} + \frac{1}{\tau RC}} \quad [29]$$

For $R_C = 800$, $T_D = 10^{-2}$, $r = 100\,000$ V m^{-1}, $g = 82$ m s^{-2} A^{-1}, and other values as in Figure 14, eqn [29] gives the nominal response of the STS-1/VBB, flat in ground velocity with closed-loop generator constant:

$$G_c = 1/gC \quad [30]$$

where with the nominal parameters, $G_c = 2400$ V m^{-1}s from 360 s to ~10 Hz. The behavior above 10 Hz is strongly dependent on the loop gain, defined by r, g, and C, and the poles created by $R_C \neq 0$ and $T_D \neq 0$. While a flat response to higher frequency is possible in principle by increasing r alone with electronic gain, increasing r alone creates a sharply peaked response. A flat response to higher frequency without peaking is possible only if T_D is minimized, and the loop gain is increased using a higher value of r and g/R_C. This is the approach taken in later-generation sensors such as the STS-2, STS-2.5, and T240. Table 1 lists a few parameter variations whose effect on amplitude response is shown in Figure 15. Increasing displacement transducer gain r has no effect on the closed-loop gain,

Table 1 Parameters of the STS-1/VBB closed-loop transfer function, varied to produce the five cases shown in Figure 15

Param\case	*Nominal STS-1*	*r↑*	*g↑*	*g↑, r↑, T_D↓, R_C↓*	*No inverse filter*
r (V m^{-1})	100 000	400 000	100 000	400 000	100 000
R_C (Ω)	800	800	800	100	800
T_D (s)	0.01	0.01	0.01	0.0001	0.01
g (m s^{-2}A^{-1})	82	82	328	328	82
T_0 (s)	30	30	30	30	3

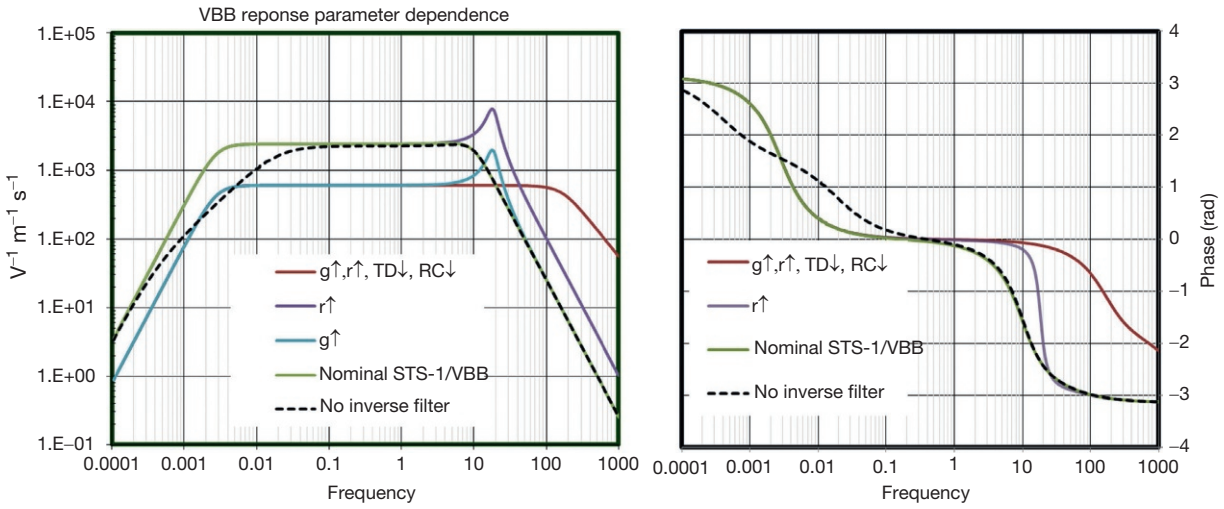

Figure 15 The effect on the closed-loop bandwidth, flatness, gain, and phase of the STS-1/VBB for various parameter changes in Table 1. Other parameter values as in Figure 14. The up and down arrows indicate changes in the parameters relative to the nominal response. Bandwidth may be extended by increasing r or gain reduced by increasing g, but peaking occurs at the upper corner unless T_D and R_C are minimized. The closed-loop gain is controlled by the force transducer constant g and feedback capacitor C. The inverse filter reduces dependence of the low-frequency corner on parameters of the mechanical suspension. The actual sensor uses a smaller T_D, and includes a single-pole low-pass filter external to the feedback network to define the two-pole asymptotic response above 10 Hz. In addition, the effective R_C is higher and is adjusted at the time of manufacture to control uniformity of the response at the 10 Hz corner. These parameter values are representative of the median of a population of ~200 horizontal and vertical sensors. Actual vertical sensors have lower g; horizontal sensors have higher g, resulting in corresponding differences in other feedback components in actual sensors to achieve the nominal response. Actual feedback component values are trimmed to produce a uniform response on all instruments.

which is controlled in the flat portion of the velocity response by the force transducer constant g and value of the feedback capacitor C. Increasing g (or C) reduces gain of the closed-loop transfer function. This flattens frequency response and increases the possible dynamic range of the sensor but places additional demand on the digitizer, since the amplitude of signals (and seismic noise) is reduced. Reduction of closed-loop gain has no effect on the sensor noise level referred to ground motion. At low frequencies, without the inverse filter, the damping at the 360 s corner is strongly dependent on ω_0.

A feedback system that produces a force proportional to applied current using a frequency-dependent admittance allows the generation of a feedback force having a large dynamic range over the operating frequency range. Because seismic noise and signal acceleration amplitude increases with frequency (**Figure 8**), the required feedback force also increases with frequency. A capacitor provides this function over most of the frequency range. The current through the force transducer, producing feedback acceleration, varies over a range of the order of 200 dB. This is roughly two orders of magnitude greater than could be achieved with frequency-independent feedback, such as provided by a resistor. Feedback across a resistor defines an accelerometer in the closed loop.

Noise present at the input of the feedback path $F(s)$ appears in the output signal. Generally, the use of only passive components is preferred in this path, because they tend to operate with minimum noise and, at seismic frequencies, can behave nearly ideally. The integral feedback path, however, although it introduces noise, is required to obtain the desired second-order high-pass to ground velocity discussed earlier.

1.02.3.2.1 Limits on seismometer resolution and operating range

1.02.3.2.1.1 Intrinsic noise

A fundamental limit of resolution of an inertial sensor is defined by the Brownian motion of the inertial mass (Byrne, 1961; Wolf, 1942). The well-known MT_0Q criterion (Melton, 1976; Usher, 1973) can be shown to define the minimum product of inertial mass M (kg), period T_0 (s) of the inertial suspension, and quality factor Q of the suspension. The Brownian noise of the inertial suspension creates a noise-equivalent acceleration power

$$\ddot{x}_{\mathrm{ne}}{}^2 = \frac{8\pi kT\Delta f}{MT_0Q} \qquad [31]$$

in a bandwidth Δf. k is the Boltzmann constant and T is the absolute temperature (minimized in superconducting gravimeters). $Q = 1/2\xi$ in eqn [16]. The resulting acceleration PSD at room temperature is independent of frequency with value

$$\frac{\ddot{x}_{\mathrm{ne}}{}^2}{\Delta f} = \frac{8\pi kT}{MT_0Q} \approx \frac{10^{-19}\left(\mathrm{m\,s^{-2}}\right)^2\mathrm{Hz^{-1}}}{MT_0Q} \qquad [32]$$

Therefore, a sensor with $MT_0Q \geq 1$ will achieve a Brownian noise-equivalent acceleration PSD of -190 dB or less relative to 1 $(\mathrm{m\,s^{-2}})^2\,\mathrm{Hz^{-1}}$. $MT_0Q \geq 1$ is achieved for most broadband sensors in current use having relatively large mass, moderately long period, and moderate subcritical damping. Although not a limitation in these sensors, Brownian motion may limit the potential to miniaturize sensors capable of resolution of minimum Earth noise, which is coincidentally roughly -190 dB acceleration PSD at several mHz. Resolution of seismic noise at the level -190 dB requires on the order of -200 dB intrinsic thermal sensor noise. Few sensors achieve this.

1.02.3.2.1.2 Thermal sensitivity

The sensitivity of a seismometer's mechanical structure to temperature changes presents a challenge to resolving minimum seismic noise levels at frequencies below about 100 mHz. The coefficients of thermal expansion for many of the metals used in typical sensor construction are of order $10^{-5}\,\mathrm{K^{-1}}$. A vertical seismometer must operate in the presence of the Earth's static gravity of $\sim 10\,\mathrm{m\,s^{-2}}$ while simultaneously resolving accelerations corresponding to minimum ambient levels, ~ 11 orders of magnitude less than gravity at, say, 3 mHz (see **Figure 8**). Since a displacement of the inertial mass relative to the frame is proportional to ground acceleration, the change in temperature of the sensor must be maintained within $\sim 10^{-6}$ K over the timescale of minutes to hours in order to resolve the acceleration levels of minimum Earth noise. This level of temperature stability and uniformity throughout the sensor mechanics cannot be achieved through active control and is achieved instead by thermally coupling the sensor to the ground as a heat sink and isolating the sensor through evacuation and insulation against external heat sources. Wielandt and Streckeisen (1982) called this type of passive thermal control the 'cold thermostat.' Burial can provide a thermally stable environment if fluid or air mobility, such as in a borehole casing, does not transport heat over relevant timescales. The 'cold thermostat' is achieved by maximization of the thermal time constant for heat transfer between the sensor mechanics and the ambient environment. A large thermal mass surrounding the sensor and efficient insulation is more effective than insulation alone. The $\sim$2000 installations (http://www.passcal.nmt.edu/taweb) of the EarthScope Transportable Array (http://www.usarray.org/researchers/obs/transportable), for example, achieve the 'cold thermostat' for periods at least to 100 s using a combination of ~ 2 m burial and thermal insulation to stratify air temperature and attenuate large daily surface temperature variations of tens of degrees (**Figure 16**).

Heat sources internal to the sensor can create internal convection, as well as thermal gradients within the sensor structure. The STS-1/VBB sensor (and its replacement M2166-VBB) contains no active heat-producing electronics within the sensor vessel. It is essential for low-frequency observation that the sensor be shielded against the force and heat transport of air motion. Several studies (Berger, 2009; Forbriger, 2011; Holcomb and Hutt, 1992; Trnkoczy et al., 2011; Uhrhammer et al., 1998; Wielandt, 2011a; Widmer-Schnidrig and Kurrle, 2006) have described installation techniques to achieve adequate thermal and physical stability. Despite the best efforts to effectively and uniformly install instruments for low-frequency use, variability of noise performance remains in part because of the variation from sensor to sensor in their intrinsic thermal sensitivity.

1.02.3.2.1.3 Displacement transducer resolution

For an inertial suspension with displacement sensor and a defined minimum observable acceleration on the order of $10^{-10}\,\mathrm{m\,s^{-2}}$, eqn [18] relates the mass displacement at low

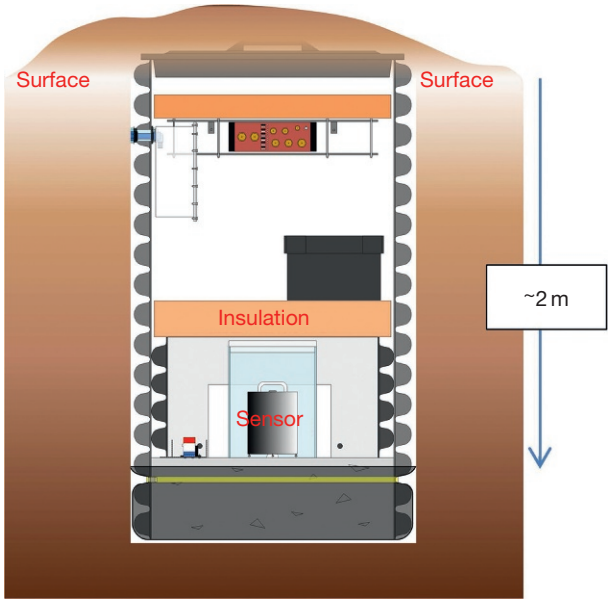

Figure 16 The installation method to achieve thermal isolation in near surface installations of the EarthScope Transportable Array (TA) stations. Approximately 2000 such installations have been made over the past decade, achieving consistent low-frequency vertical noise levels throughout much of the continental United States. Such an installation is not adequate for resolution of minimum Earth noise levels at frequencies <5 mHz; however, near-LNM vertical resolution is possible above these frequencies. Adapted from figure provided by R. Busby.

frequencies to the resonant frequency of the suspension (Melton and Kirkpatrick, 1970; Wielandt and Streckeisen, 1982). The required displacement resolution varies inversely with the square of the suspension natural frequency. The resolution of a suspension with natural frequency >1 Hz must be less than 10^{-12} m. This resolution is achievable with capacitive displacement sensing (Jones and Richards, 1973; Usher et al., 1977). The linear variable differential transformer displacement sensor in the STS-1/VBB with displacement resolution of the order of 10^{-10} m requires a mechanical resonant period of at least 6 s to resolve minimum low-frequency ground acceleration. EFFB broadband sensors used in global and regional networks are not typically limited at low frequencies by resolution of their displacement transducer. Equation [17], however, shows that at high frequencies, the displacement of the inertial mass equals ground displacement. Minimum seismic noise expressed as displacement decreases with increasing frequency. The input-equivalent noise of broadband displacement-sensing EFFB sensors typically exceeds minimum, infrequently observed Earth noise at tens of hertz and above. A displacement transducer with resolution sufficient to resolve minimum ambient Earth noise on the order of 10^{-12} m rms in a 30 Hz bandwidth has proven difficult to realize simultaneously with constraints to achieve high dynamic range and low noise at low frequencies. An electrodynamic transducer can have an SNR advantage (Rodgers, 1992a,b) at frequencies of tens of hertz and above, although in typical installations, commonly used EFFB sensors are not limited by displacement transducer noise. From a low-frequency perspective, a longer mechanical resonant period is preferred, since the requirements on noise and stability of the displacement transducer and dimensional stability of the sensor are relaxed. Wielandt and Streckeisen (1982) note that integrator noise can also be a significant contributor in an EFFB sensor at low frequencies.

1.02.3.2.1.4 Environmental and ambient seismic noise

Local ambient seismic noise defines the minimum observable signal. In addition, the effect of environmental inputs to a sensor may further increase the apparent noise level. Ambient seismic noise divides into three main bands, say, >1 Hz, 0.03–1 Hz, and <0.03 Hz. The range 0.03–1 Hz is dominated by microseisms and presents no challenge to instrumental resolution. Above 1 Hz, two major contributors to ambient noise at most sites are 'cultural,' that is, the result of human activity, including traffic and machinery, and wind-generated. Peterson (1993) showed dependence of noise >1 Hz on local time of day at GSN stations. A recent unpublished study (Coughlin and Harms, 2012) of ~3500 stations including GSN and regional networks during the past 5 years shows noise levels relative to a local reference as a function of time of day and frequency (**Figure 17**). Noise above 1 Hz rises significantly during daytime hours, when both cultural activity and wind velocity typically increase. The same study shows a strong temporal correlation with wind speed and observed noise in stations of the transportable array, uniformly installed at roughly 2 m depth. Few if any typical surface-installed global and regional network broadband sites (see **Figure 12**) are limited by intrinsic sensor noise at frequencies 0.1–5 Hz. In rare, exceptionally quiet locations, and at quiet times, minimum levels observable on broadband sensors may be limited by both sensor intrinsic noise (of the displacement transducer) and input-equivalent digitizer noise, defined by the low gain of broadband systems. A consistent feature in a number of studies of dependence of noise >1 Hz on depth (Carter and Barstow, 1991; Young et al., 1996; Withers et al., 1996) is rapid noise reduction generally within 100 m depth, although a reduction in the variability of noise as a function of surface wind speed is seen down to 2000 m. Douze (1964) examined both signal and noise level as a function of depth for frequencies >1 Hz. Levels of both noise and signals >1 Hz are reduced at depth, with significant SNR improvement only at 1000 m or greater. None of the studies of high-frequency noise in boreholes, nor research on high-frequency noise models discussed earlier, used displacement-sensing seismometers.

A combination of intrinsic sensor noise and site and instrument response to environmental inputs, particularly variation in temperature and barometric pressure, often limits vertical sensor resolution at frequencies <0.03 Hz. Forbriger et al. (2010) suggest that susceptibility to magnetic field variation may also limit many broadband seismometers in current use. The effect of barometric pressure variation is particularly important and plays predominantly different roles in vertical and horizontal low-frequency measurements.

Barometric pressure changes affect a vertical seismometer in four principal ways:

1. Buoyancy variation of the mass producing an equivalent change in ground acceleration (Block and Moore, 1966; Crary and Ewing, 1952; Press et al., 1958; Sorrells, 1971; Wielandt and Streckeisen, 1982)

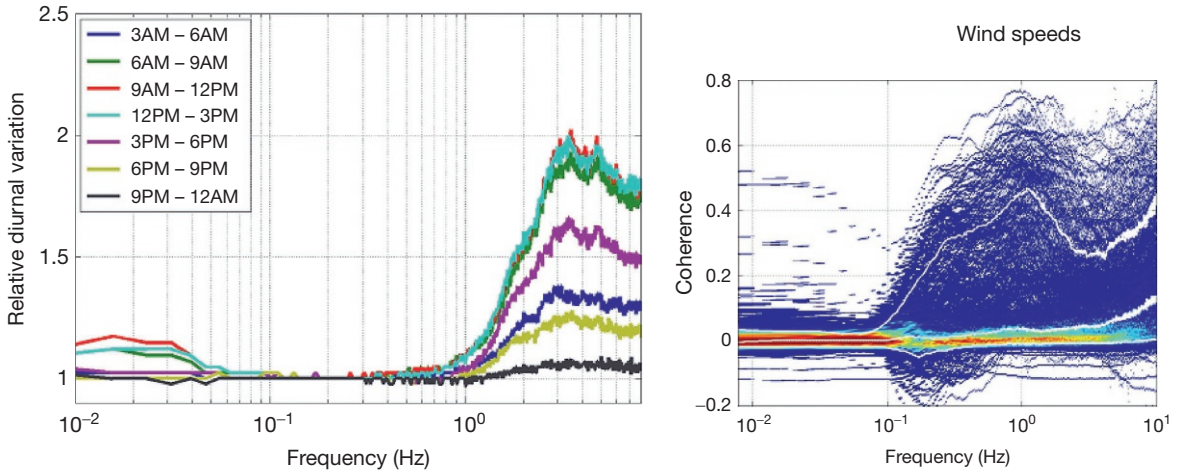

Figure 17 The plot at left shows global noise medians as a function of frequency within seven ranges of local station time divided by the midnight median 12–3 am. Seismic noise is stronger during the day. Only the frequency band of oceanic microseisms does not show significant diurnal variation. At right, noise level as a function of frequency is correlated with local wind speed showing strong dependence above 0.1 Hz. Approximately 3500 stations are used over a period of 5 years. Adapted from Coughlin MW and Harms J (2012) Global characterization of seismic noise with broadband seismometers. arXiv, preprint arXiv:1202. 4826.

2. Variation in Newtonian gravitational attraction of the seismometer mass by the atmosphere (Beauduin et al., 1996; Block and Moore, 1966; Warburton and Goodkind, 1977; Zürn and Widmer, 1995)
3. Deformation, including the instrument housing itself; the local instrument setting, such as the vault; and the Earth's surface (Sorrells and Goforth, 1973; Sorrells et al., 1971; Zürn and Wielandt, 2007)
4. Adiabatic temperature changes accompanying barometric pressure change

Buoyancy is addressed by enclosing the suspension in a sealed vessel such as in the HGLP/ASRO systems (Pomeroy et al., 1969) and STS-1 (Wielandt and Streckeisen, 1982). Evacuation is not necessary, but helps purge the vessel of humidity, which can activate noise-generating chemical processes over years of operation. All broadband sensors developed during the last 40 years are sealed against barometric pressure changes. One source of deformation of the instrument housing has been mitigated using a construction that minimizes the presence of large areas exposed to asymmetrical pressure loading. The so-called *warpless* (Holcomb and Hutt, 1992) construction has replaced the use of large flat mounting bases, such as in the STS-1 and HGLP/ASRO instruments, with mounting systems symmetrically loaded to reduce bending. Careful design and testing is required to reduce the effect of distortion of the housing. This is particularly challenging for horizontal instruments that are very sensitive to tilt. This will be discussed further later. Adiabatic temperature changes are generally suppressed in instruments with multiple isolation methods, such as evacuation, heat sinking, and thermal insulation, as in STS-1 or gravimeter installations.

There are two effects of barometric pressure against which an inertial instrument cannot be shielded: gravitational attraction of the atmosphere on the sensor mass and loading of the Earth's surface under local pressure variation. These effects act with opposite signs (Zürn and Wielandt, 2007) as an equivalent net

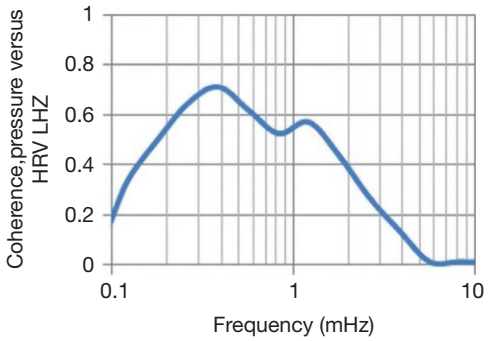

Figure 18 Coherence between barometric pressure and the vertical STS-1/VBB seismometer during a representative 12-day period at GSN station HRV. Significant coherence is common at frequencies from several tenths of 1 mHz to several mHz – the normal mode band. Coherence is rare at frequencies >4 mHz.

ground acceleration proportional to local air pressure. The effect on vertical low-frequency data may be removed (Beauduin et al., 1996; Zürn and Widmer, 1995) from an observed seismogram using an arbitrary scaling constant in the subtraction:

$$z_{\text{corr}}(t) = z(t) - \alpha \cdot h(t) * p(t) \qquad [33]$$

where $z(t)$ represents an observed seismogram, $p(t)$ local observed pressure, $h(t)$ the response of the seismometer to an impulse in ground acceleration, and α an empirically determined constant (often in the range of $\sim 3.5\ \text{nm s}^{-2}\ \text{hPa}^{-1}$) to reduce the resulting variance of $z_{\text{corr}}(t)$. The $*$ denotes convolution. $h(t) * p(t)$ can be calculated quickly on arbitrarily long sequences of sampled data with the application of a suitably derived equivalent recursive digital filter. Zürn and Widmer (1995) stated that this approach is effective up to frequencies of 1–2 mHz. Low-frequency vertical land data and pressure typically exhibit little coherence above 4 mHz (see **Figure 18**).

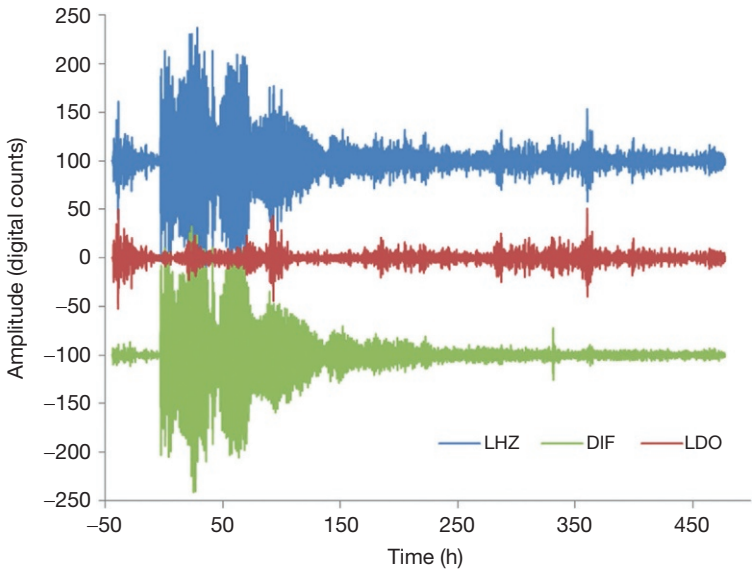

Figure 19 Removal of the effect of barometric pressure on low-frequency vertical data. ~3 weeks of vertical STS-1/VBB data from GSN station HRV for the 2010 Mw 8.8 Chile event, band-pass-filtered 0.25–0.7 mHz. LHZ is the observed data. LDO (red) is barometric pressure with a time-domain filter applied representing the seismometer transfer function to ground acceleration, arbitrarily scaled. Obvious visual correlation exists with the LHZ (blue) envelope. DIF=LHZ – LDO, showing variance reduction (green).

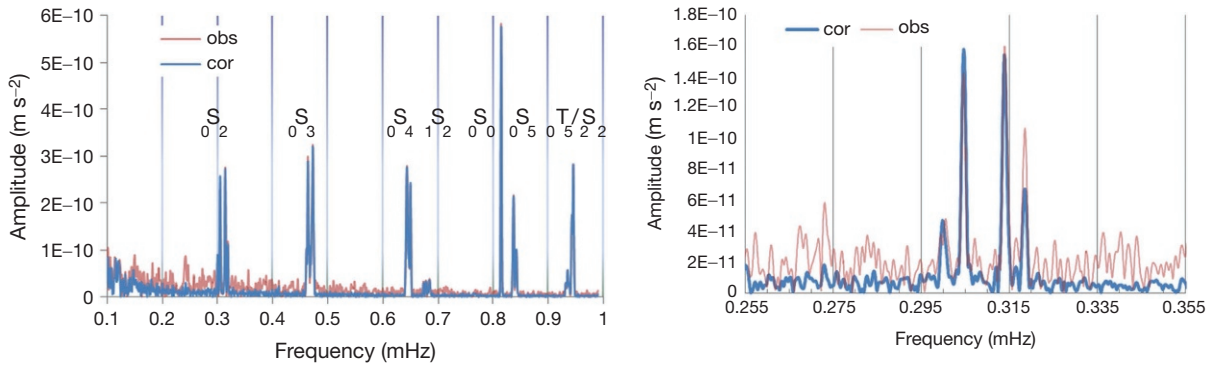

Figure 20 Left: The observed (red) and pressure-corrected (blue) spectra from the data in **Figure 19** spanning 0.1–1 mHz showing improvement in the corrected data. Right: ${}_0S_2$ showing resolution of all singlets present. The apparent frequency of one singlet is slightly shifted in the corrected data.

Figure 19 shows the application of pressure correction to vertical data from the 2010 Mw 8.8 Chile earthquake recorded at GSN station HRV. The reduction in variance in the time domain is clear. Figure 20 shows the observed and corrected spectrum, including a close-up of ${}_0S_2$ with substantial background reduction and a small shift in one singlet. Similarly, Figure 21 shows ${}_0S_3$ with resolution of all seven singlets, one of which is significantly moved. The result is comparable with gravimeter records (Rosat and Hinderer, 2011). Figure 22 shows the result of barometric correction on a measurement of the decay envelope of ${}_0S_0$. The ratio of smoothed envelope amplitude to the decay calculated with various Q values from 5400 to 5700 is shown. With correction, the SNR is improved and the variance of the ratio over 2 weeks is reduced by a factor of three, producing an estimate of $Q=5500–5600$, consistent with recent estimates (Rosat et al., 2007).

The effect of atmospheric pressure changes on the resolution of low-frequency signals observable on horizontal sensors is generally greater and more complex. Pressure changes induce deformation of the Earth's surface resulting in tilts. Horizontal inertial sensors are sensitive to tilt-induced acceleration of the order of the change in tilt angle times the acceleration of gravity (Rodgers, 1968). Hence, a very small tilt change can produce acceleration far above minimum seismically generated signal levels. A tilt angle α of 10^{-10} radians, or 10^{-6} m over a baseline of 10 km, produces an acceleration of $\alpha \bullet g \cong 10^{-9} \mathrm{m\ s^{-2}}$, which is an order of magnitude larger than the amplitude of the gravest free modes from large earthquakes. As Holcomb et al. (1998) point out, this tilt is roughly equivalent to the thickness of a piece of paper inserted under one end of the North American continent. This analogy allows one to appreciate the problem of tilt minimization in instrumentation, where

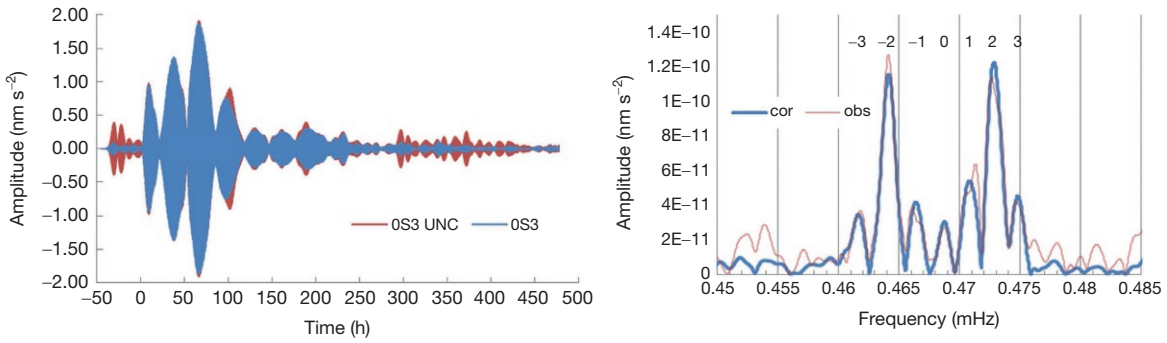

Figure 21 Left: Data of **Figure 19** band-pass-filtered 0.45–0.5 mHz to show the time-domain beating of the multiplet comprising ${}_0S_3$ and variance reduction with barometric correction. Right: All seven singlets in the corrected data with SNR similar to gravimeter records. The frequency of $m=1$ singlet is shifted significantly in the corrected data.

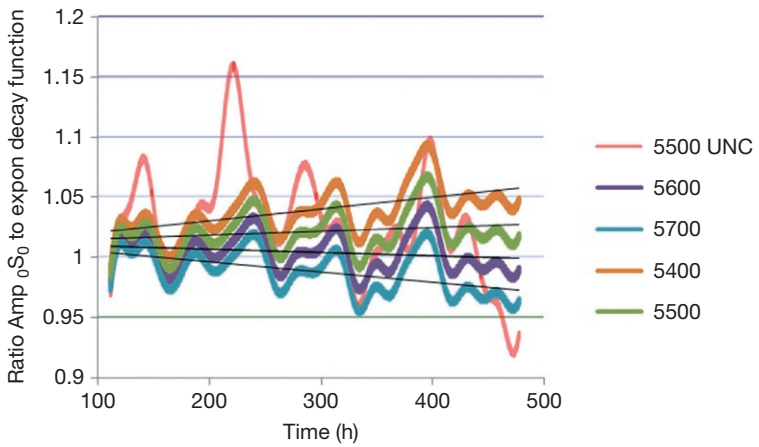

Figure 22 Pressure correction improves estimate of Q of ${}_0S_0$ from the 2010 Mw 8.8 Chile event. The ratio of decay envelopes and trend lines for various Q values compared to the smoothed, band-pass-filtered time-domain record are calculated using observed, uncorrected (trace-labeled 5500 UNC; red), and pressure-corrected data. The variance in the ratio is reduced by a factor of three for the corrected data, leading to an estimated Q 5500–5600, consistent with recent estimates.

the baseline is as little as 0.1 m. Tilts may be induced by barometric pressure variation operating to deform the Earth's surface or the instrument itself. Tilts may also be the result of air convection, ground water mobility, diurnal temperature changes, seasonal freezing and thawing, or mechanical defects in the local installation environment. Typically, several tilt sources combine. Zürn et al. (2007) have demonstrated that the effect of pressure variation on horizontal data can be reduced, although the approach generally requires 'customization' for each time segment analyzed and more complex models than the correction of vertical data.

Figure 23 shows an example of pressure-induced local tilt accompanying the passage of a weather system on the horizontals of EarthScope TA station K62A on 11 September 2013. The E axis is virtually identical to the pressure signal scaled with an apparent coefficient of 2.5×10^{-9} m s^{-2} Pa^{-1} and convolved with the seismometer response to acceleration. If the entire signal is tilt-generated, this is equivalent to a tilt sensitivity to pressure of 2.5×10^{-10} rad Pa^{-1}. The vertical axis is essentially unaffected. The peak acceleration of the pressure-induced signal is $\sim10^{-7}$ m s^{-2} at ~500 s period. The peak pressure signal in this band is ~50 Pa. The entire broadband pressure change accompanying the weather system passage was about 300 Pa. Such effects may be quite localized to the immediate installation environment. It is not uncommon for nearby horizontal sensors to produce significantly different outputs as a result of localized tilt (Hutt et al., 2004). For instrument evaluation purposes, horizontal coherence of adjacent instruments can be increased by placement on a common competent platform, such as a thick granite or metal base.

Crawford and Webb (2000) and Crawford et al. (2006) have shown that on the sea floor, correction of vertical data using locally recorded pressure (Cox et al., 1984) and tilt noise obtained from horizontal sensors can also produce up to 25 dB improvement at low frequency. The relative importance of surface deformation is higher than on land. In addition, because of the large tilts present on the sea floor surface, very slight misalignment of a vertical sensor's sensitive axis with the gravity vector creates tilt-generated noise on the vertical. From an instrumentation perspective, the observed noise levels on the sea floor are high compared with on land and are more easily resolved. Measurement of local pressure and correction

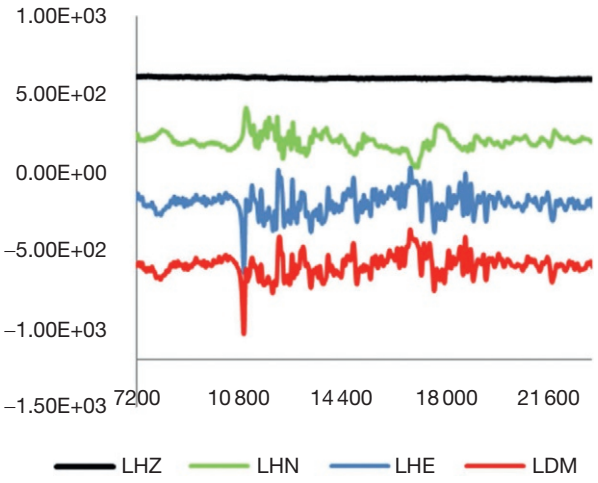

Figure 23 An example of pressure-induced tilt. Station TA-K62A, showing ~3 h, 1 sps, three-axis broadband data, low-pass filtered at 0.01 Hz. Ordinate in digital counts; horizontal axis is time (second). LDM (red) is barometric pressure filtered with the seismometer's response to ground acceleration and scaled with an apparent coefficient of pressure to ground acceleration of 2.5×10^{-9} m s^{-2} Pa^{-1}. The LDM channel records the passage of a weather system. The LHE (blue) and LDM channels are visually nearly identical, while LHZ (black) is undisturbed. The horizontal signal is tilt of the local station environment induced by the air pressure change (see text).

of observed data are necessary, however, to maximize useful SNR (Crawford and Webb, 2000; Taira et al., 2014).

Tilt limits the operating range of a broadband instrument. The low-frequency sensitivity of early mechanical horizontal seismographs was often limited by the maximum allowable tilt or temperature change before hitting mechanical stops. Early efforts at EFFB were mostly directed to maintenance of the sensor mass within its nominal travel range. An EFFB sensor having a PID feedback system (e.g., **Figure 14**) with velocity output can function apparently normally in the presence of static tilts until the electrical limit defined by the maximum static feedback current (the sum of the integral and proportional feedback path) can no longer maintain the equilibrium position of the mass. When this point is reached, the sensor must be 'recentered' to adjust the mechanical portion of restoring force acting on the mass. The 'mass position' signal from broadband EFFB sensors is, in fact, the integrator output voltage. In a frequency band defined by the integrator time constant, a change in mass-position output is proportional to a change in acceleration acting on the sensor's mass. In a broadband sensor designed for the resolution of minimum Earth noise, the strength of the integral feedback path is designed so that the equivalent acceleration noise of the active electronic integrator driving the feedback force transducer is less than minimum Earth noise. Electronic amplifiers, on which integrators are built, typically have of the order of 140–150 dB useful dynamic range at low frequencies, for example, ~0.3–1 μV peak noise and a 10 V peak maximum output. If minimum Earth noise is $\sim 10^{-10}$ m s^{-2}, the maximum equivalent tilt-induced acceleration that the integral feedback can cancel is, say, $3 \times 10^{7} \times 10^{-10} = 3 \times 10^{-3}$ m s^{-2} or $\sim 3 \times 10^{-4}$ rad, or ~0.02 ° tilt. Triaxially symmetric (Melton, 1965; Melton and Kirkpatrick, 1970) seismometers such as the STS-2 or T240 are limited by the maximum tilt of any individual sensor since the outputs are vector sums of all sensors. Integral feedback may be increased to increase the tilt range of the closed loop, although this increases the input-equivalent noise. Some portable instruments use this approach to extend the maximum operational tilt at the expense of small signal resolution. The best usage of data from EFFB sensors requires monitoring that the mass-position limit has not been exceeded. This information is recorded as ancillary data by most data acquisition systems but is frequently overlooked in analysis. A broadband sensor whose mass-position limit is exceeded may appear to produce seismograms until the point where the limit of its displacement transducer is reached, but the transfer function is no longer LTI. If one sensor of a triaxially symmetric seismometer is beyond its mass-position limit, all axes are affected.

The pressure fields associated with wind turbulence induce long-period but comparatively short-wavelength ground motion, resulting in rapid attenuation with depth, so that substantial low-frequency tilt reduction is achieved by installation at least 100 m below the surface (Sorrells, 1971; Sorrells and Goforth, 1973). The absolute decrease in pressure-induced tilt with depth is dependent on the rigidity of the site rock (Sorrells and Goforth, 1973). Underground installations (150 m) have shown tilt reduction by as much as 20 dB (compared to a surface installation) at periods from 30 to 50 s period (Murphy and Savino, 1975). Peterson et al. (1976) showed improvement at 100 m relative to 15 m depth of more than 10 dB at periods to 100 s. Hutt et al. (2002) depict a typical improvement in horizontal noise level as a function of frequency and depth in **Figure 24(a)**. Holcomb et al. (1998), however, point out that the improvement in tilt noise is highly installation-dependent. Current practice favors sand to stabilize the sensor in the borehole and to suppress convection currents acting directly on the package. In other experiments (Hutt, personal communication), partial evacuation of the borehole has reduced tilt noise. The published results at frequencies below a few mHz, however, may be instrumentation limited (**Figure 24(b)**), since instruments with intrinsic noise levels near minimum Earth noise have not been available for operation in a borehole.

1.02.3.3 Systems

1.02.3.3.1 A/D conversion

The early 1960s saw pioneering efforts in digital earthquake data acquisition and recording (Bogert, 1961; DeBremaecker et al., 1962; Haubrich and Iyer, 1962). The large-aperture seismic array project (Green et al., 1965) demonstrated digital recording on a large scale. At Caltech (Miller, 1963; Phinney and Smith, 1963), continuous operation of a seismograph suitable for general studies with a 'library' of digital tapes was envisioned at least a decade before such a system became operational in the SRO (Peterson et al., 1976).

Today, virtually all seismic systems employ 'wide' ($\geq$24 binary bits) data word A/Ds based on oversampling delta–sigma ($\Delta\sum$) architecture (Inose et al., 1962; Steim and Wielandt, 1989). Following the introduction to broadband global seismographic systems of $\Delta\sum$ A/D technology in the original Harvard system (Steim, 1986), 'gain-ranged' A/Ds

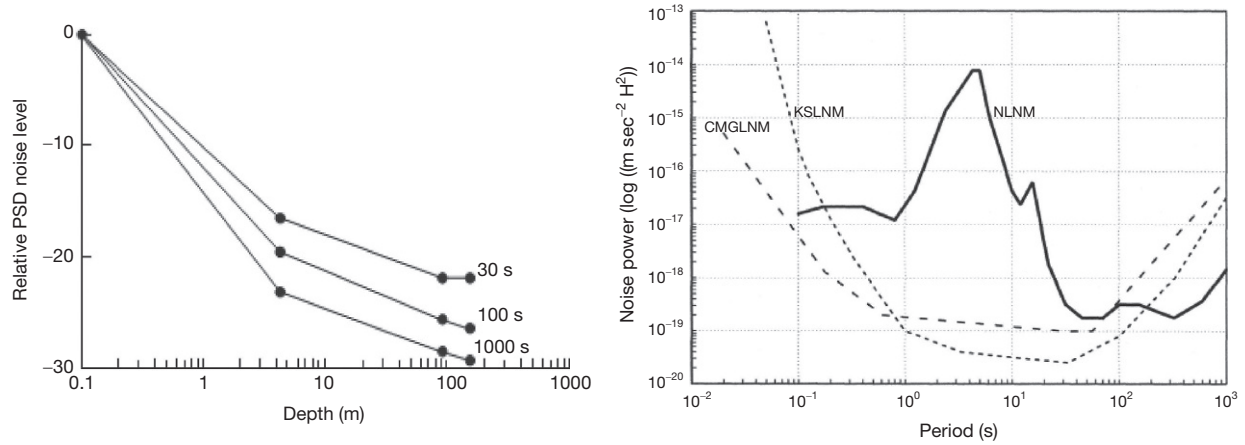

Figure 24 Left: Horizontal noise attenuation in a borehole as a function of depth at three selected periods. Depths 0, 4.3, 89, and 152 m. Reduction of nearly 20 dB is achieved at modest depths. The rate of improvement decreases with depth. The apparent improvement may be affected by changes in temperature variance as a function of depth. Right: Noise models of KS54000 and CMG-3TB borehole seismometers in use at GSN stations during the past decade. These borehole sensors do not resolve minimum low-frequency noise, suggesting that the measurements of borehole noise reduction may be affected by instrument noise. Adapted from Hutt CR, Bolton HF, and Holcomb LG (2002) US contribution to digital global seismograph networks. In: Lee W, et al. (ed.) *International Handbook of Earthquake and Engineering Seismology*. pp. 319–332.

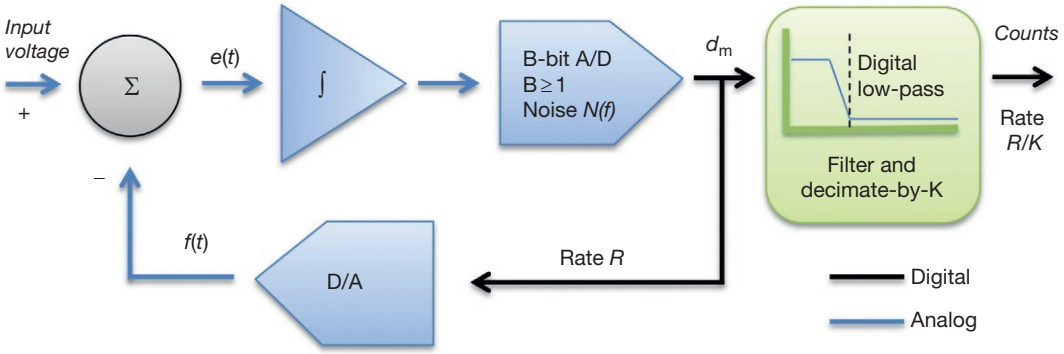

Figure 25 A first-order $\Delta\sum$ A/D converter. The input signal is summed with a feedback signal derived from a D/A converter. The difference signal is integrated and quantized to produce the digital output d_m which is fed back to the D/A converter. The integration boosts the ability of the quantizer to measure deviations in the average of the feedback signal from the input signal. The loop operates at a rate R much higher than the desired information bandwidth in the input voltage. Unwanted quantization noise outside the information passband is removed by the digital filter. Achievable SNR is defined by the noise and linearity of the D/A.

(Harjes and Seidl, 1978; Peterson et al., 1976), once popular in the exploration industry and global seismology, have essentially disappeared. They can be a source of demonstrable distortion in broadband systems (Steim, 1986).

$\Delta\sum$ A/D technology relies on *oversampling* and *noise shaping* to initially acquire digital samples of an analog signal at a sample rate that is highly relative to the information content, pushing the noise inherent in quantization to frequencies above the frequency band of interest. The resulting high-data-rate digital stream is low-pass-filtered and decimated (eqn [11]) to a sampling rate appropriate for the bandwidth delivered for analysis.

A $\Delta\sum$ system comprises a feedback loop containing an internal quantizer, a digital-to-analog (D/A) converter, and one or more integrators, as shown in Figure 25. The feedback tends to cause the time average of the digital output code d_m to represent the input voltage to the loop. The difference $e(t)$ between the input voltage and the D/A output $f(t)$ is integrated to give greater weight to lower frequencies in the comparison. This weighting achieves noise shaping. There are many loop topologies, although all rely on the same general principle. The most important element of a $\Delta\sum$ A/D is the D/A converter. As in the case of the force-feedback seismometer, the performance of the closed-loop system depends upon the linearity and noise of the element(s) that feeds back the output signal to the input. In a seismometer, these feedback elements over much of the frequency range are passive electronic components (resistors and capacitors) with high linearity and low noise. In the $\Delta\sum$ A/D, feedback is through a potentially complex active element, the D/A converter. Although an A/D may have an arbitrary data width (the number of bits in the output signal), the useful SNR of a $\Delta\sum$ A/D is defined by its D/A converter's actual electrical noise.

It can be shown (Aziz et al., 1996) that for a $\Delta\sum$ loop of order L (the number of integrations), setting the loop input voltage to zero leads to a description of the frequency dependence of the shaped noise power $N(f)$ of quantization of the B-bit A/D operating at rate R. For an input voltage range $\pm V$ and frequency f, $N(f)$ can be written:

$$N(f) = \frac{V^2}{3R \cdot 2^{2B-1}} \left(2\sin\left(\frac{\pi f}{R}\right)\right)^L \quad [34]$$

Figure 26 (with $V = R = 1$) shows that the shaped noise is increased beyond some signal passband of interest and decreased within the passband ($f \ll R$). The noise outside the passband is rejected by the low-pass digital filter. Equation [34] suggests that arbitrarily low noise within a defined passband is possible given high R and L; however, actual noise of a physical A/D is dominated by electronic noise, typically $1/f$ below some frequency and at some level. The measured terminated-noise spectrum (e.g., Figures 11, 28, and 29) is the only reliable specification of minimum A/D noise, that is, in the presence of no input signal. Noise may increase with signal applied. Tests discussed later address quantification of such signal-dependent noise.

Noise level, saturation level, linearity, signal bandwidth, and sampling rate define an A/D system. Noise and linearity

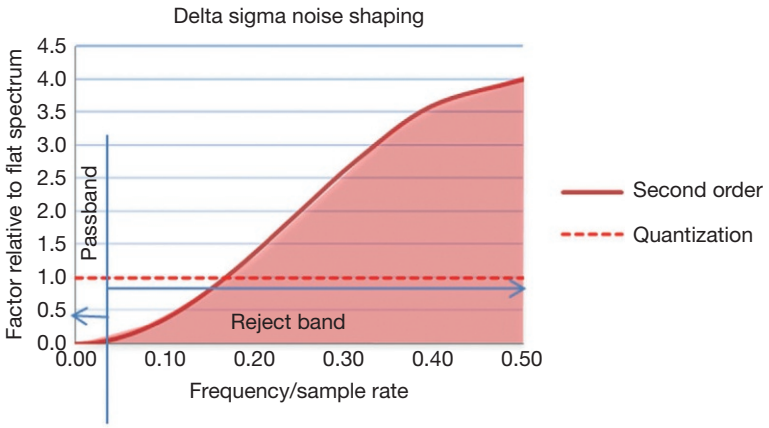

Figure 26 Noise shaping for a second-order $\Delta\sum$ A/D. The noise of quantization without shaping appears as the red-dashed line. Shaping forces quantization noise out of the passband, which is some small fraction of the $\Delta\sum$ loop rate. Quantization noise is increased above the passband of interest. Total quantization noise is actually increased. Noise above the passband is rejected by low-pass digital anti-alias filters. Noise shaping affects only quantization noise, not electronic noise in the shaping circuits, which limits the improvement achievable by a noise-shaped A/D.

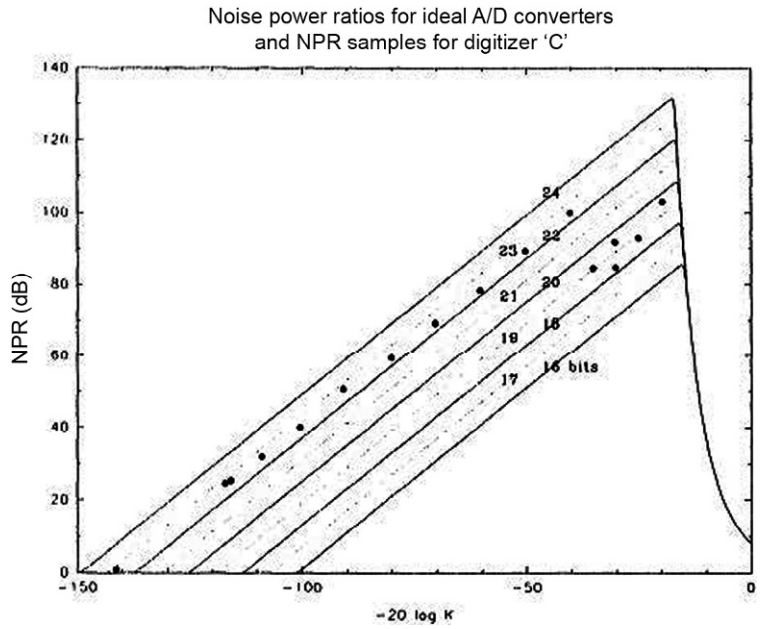

Figure 27 Results of modified noise power ratio (MNPR) test on a high-resolution digitizer. Dots indicate measurement of effective noise of an A/D with a signal applied. Horizontal axis is proportional to the amplitude of applied test signal. Vertical axis is proportional to SNR. In the case of this A/D under test, at a signal level well below its full scale, the effective noise of the A/D suddenly increases, resulting in a reduction of SNR. Adapted from McDonald T (1994) Modified noise power ratio testing of high resolution digitizers. *Sandia Report SAND94-0221*.

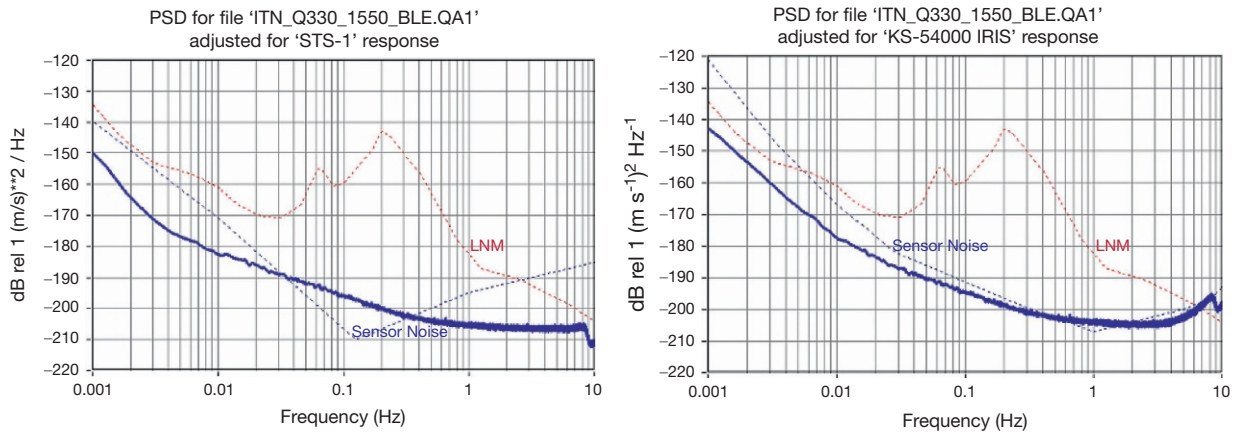

Figure 28 Engineering tests of the terminated-input noise of the A/D system used in global networks, represented as equivalent ground velocity PSD when connected with an STS-1/VBB seismometer, or a KS54000I. The input-equivalent noise is inversely proportional to the frequency-dependent magnitude of the seismometer transfer function. Adapted from Kromer RP (2006) *Technology Report Evaluation of the Kinemetrics/Quanterra Q330HR Remote Seismic System for IRIS/GSN Q330HR/GainX1 Configuration*.

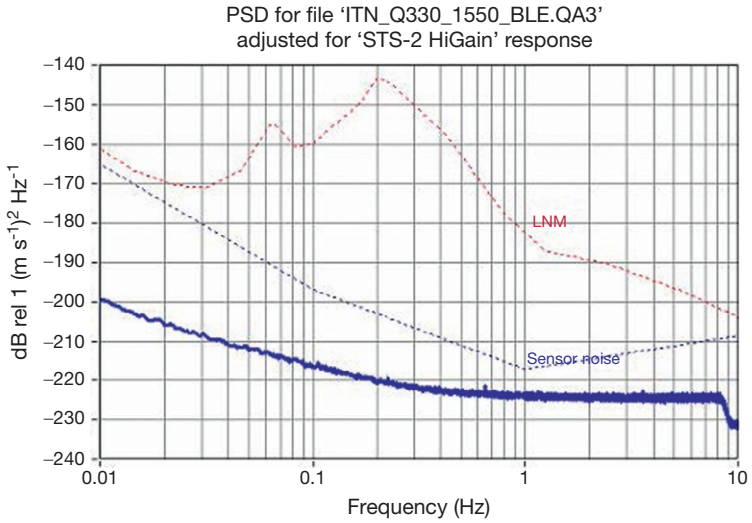

Figure 29 Similar to **Figure 28** for the large gain of the STS-2/high-gain seismometer. The excessive gain of the STS-2/HG wastes useful dynamic range, by reducing system clip level referred to ground acceleration. Digitizer input-equivalent noise is unnecessarily low when combined with a seismometer of such high gain. Adapted from Kromer RP (2006) *Technology Report Evaluation of the Kinemetrics/Quanterra Q330HR Remote Seismic System for IRIS/GSN Q330HR/GainX1 Configuration*.

are related, since if understood broadly, noise includes any digital output generated that is not strictly representative of the analog input signal. Such signal-generated noise may include products of nonlinear distortion in the A/D.

In the engineering literature, A/D behavior is often treated as having an essentially flat noise spectrum, since many applications of A/D converters involve frequencies above the $1/f$ corner of A/D noise. A/Ds with a comparatively small number of bits, say < 20, are typically dominated by quantization noise (white, uniformly distributed), since their quantization steps are large. Quantization noise (Bennett, 1948) is typically insignificant in digitizers for earthquake studies having 24 or more bits of resolution because the quantization steps are small; these systems are limited for small signals by their actual electronic noise. A nearly arbitrary number of bits may be included in the output words, sufficient to suppress quantization noise to an insignificant level. The number of bits in the output word of a $\Delta\sum$ A/D is nearly irrelevant, since that number is defined by the mathematics engines used to digitally low-pass filter the output data. An A/D with 24-bit arithmetic resolution, however, may produce many bits of actual noise.

Like sensors, the actual noise of A/D converters is frequency-dependent. The operating range of an A/D for earthquake seismology can be represented in an operating range diagram or the noise may be specified as a PSD spectrum along with the clip level. **Figure 11**, for example, shows A/D operating range expressed as equivalent peak noise and clip level. Such a representation shows the minimum A/D noise level in the absence of input to the A/D. These noise measurements are taken with a *terminated input*, that is, a resistance bridging the A/D inputs to

simulate the source resistance of a sensor. The A/D noise cannot be less than its terminated-input noise, although it can be higher in the presence of signal-related nonlinear distortion. The maximum potential dynamic range (MPDR) of an A/D is usually quoted in dB as the rms ratio of A/D output for a maximum continuous sine-wave input to its input-terminated noise. As with sensors, specification of bandwidth is required. For example, the A/D noise illustrated in Figure 11 is equivalent to an MPDR of 164 dB in an octave below 1 Hz. As Figure 11 shows, terminated-input noise is white to some $1/f$ corner frequency, below which power is constant in bands of constant relative width. Similar behavior appears to be common to many seismic A/Ds (Sleeman, 2006).

Terminated input noise tests are important for earthquake A/Ds because many signals are small compared to the available operating range. A complete characterization of an A/D, however, also requires measurement of the A/D noise level in the presence of large signals. There are several approaches. The simplest conceptually is to apply a signal of known characteristics, such as a sine wave, and measure the power of harmonics in the A/D output resulting from nonlinear distortion. Such a total harmonic distortion (THD) measurement (Kromer, 2006) is effective because most signal-dependent distortions generate harmonics of a comparatively pure input sine, although the method is difficult to apply for high-resolution seismic digitizers because signal sources with the required THD approaching −140 dB are not widely available. The known THD of the signal source must be significantly less than A/D THD to resolve A/D nonlinearity meaningfully. In addition, a standard A/D capable of verifying the signal source is required for reliable measurements over time.

Another approach to nonlinearity measurement is to inject an arbitrary signal into two nominally identical channels and calculate the incoherent noise power between the resulting digital outputs. Alternatively, one may analyze or model the arithmetic difference of the outputs. The latter approach is slightly less robust, since sample-wise subtraction of two potentially large signals is sensitive to small phase shifts between channels. Measurement of incoherent power is able to simultaneously resolve small phase differences, which can be corrected.

The incoherent power so calculated can be compared with the terminated-input noise or compared to the ideal noise of quantization for a digitizer with the same number of bits in the output word. If the arbitrary signal injected spans a wide range of amplitudes, the behavior of the A/D as a function of amplitude can be characterized. Nonlinear distortion may appear as an elevated ratio of incoherent power between the two channels at low or high amplitudes. McDonald (1994) applied the so-called modified noise power ratio (MNPR) method for the first time to the measure of nonlinearity of several then-current models of 24-bit A/D converter as a function of applied signal amplitude using a white noise source, finding in some A/Ds a strong knee-like dependence on amplitude. Figure 27 shows the result of such an analysis. McDonald described the behavior of this A/D:

> . . .this system has about 22 bits of linearity for low-level signals, but suddenly degrades to an erratic 18-to-20-bit performance level for large signals. The break occurs when the RMS input signal value is approximately 2% of positive full scale. This severe characteristic is typical of gain-ranged systems, which achieve a large dynamic range with limited linearity.

The MNPR test requires no special test equipment. A/D systems capable of generating a signal used for sensor calibration may use the same signal for the A/D. The characteristics of the input signal are unimportant, provided that a sufficient range of frequencies and amplitudes are driven, because the same signal is applied to both input channels. In principle, the method is unable to detect an error in the A/D that would generate identical distortion products for a given input signal input to two channels; however, application of the method has shown that results are generally correlated with THD measurements. THD measurements are preferred where available. IEEE Std-1057 (IEEE, 2001), standard for digitizing waveform recorders, and IEEE Std-1241 (IEEE, 2000), standard for terminology and test methods for A/D converters, define formalized test procedures for quantification of A/D systems.

From a system design perspective, one can today nearly assume that A/D noise will not limit system performance in combination with an active force-feedback sensor. Figure 28, for example, shows that digitizer noise in the GSN is uniformly below sensor noise within the sensor's passband. The positioning of noise of the digitizer relative to sensor noise is defined by sensor or digitizer gain. Generally, only sufficient gain should be used to result in the condition illustrated in Figure 28, where digitizer noise is slightly below sensor noise. Additional gain results in a loss of operating and dynamic range for large signals. The powers of uncorrelated noise sources add.

Figure 29 shows the positioning of digitizer noise relative to sensor noise using a sensor with high gain (the STS-2/HG, having a generator constant of 20 000 V m^{-1} s instead of the usual 1500).

In this case, the digitizer noise is unnecessarily below sensor noise – and farther still below actual ambient seismic noise at most sites. McNamara et al. (2005) concluded that the choice of high-gain sensors is likely to result in saturation on large events in North America. Excess gain in a sensor is generally a historical remnant from the time when A/D dynamic range was 100 times less than now. Present A/D systems typically incorporate the option to use modest additional gain where low sensor output requires better matching, or in applications requiring increased SNR, such as comparative instrument research or high-frequency/low-noise work. Gain within the digitizer is preferred because of the likelihood of a faster recovery time from saturation. A force-feedback sensor having high gain within its feedback loop, for example, may require many minutes to recover from saturation, whereas a digitizer will generally recover within the equivalent time length of its digital anti-alias filters – on the order of a few seconds for data rates on the order of 40 sps. Lower A/D noise permits the use of lower sensor gain, increasing operating and dynamic range. Lower gain in sensors and A/Ds moves the amplitudes of typical signals farther below the saturation level, which reduces the possible effect of power-law or threshold-driven amplitude-dependent nonlinearity, such as illustrated in Figure 27.

The sharp-cutoff frequency response of most low-pass digital anti-alias filters necessarily implies Gibbs-phenomenon (Scherbaum, 2001) overshoot on signals that contain substantial energy at the filter corner frequency, as may arise at regional distances. The response of a typical filter to a unit step is shown in Figure 30. This filter has about 25% overshoot

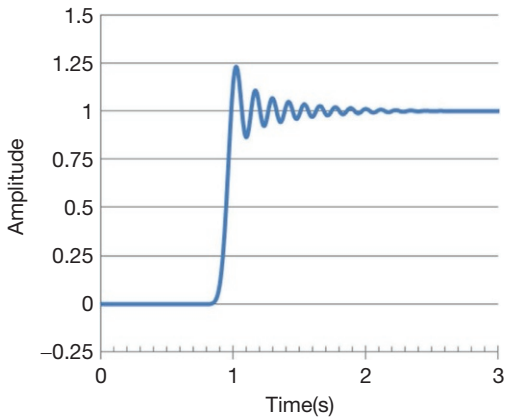

Figure 30 The response to a unit step of a typical high-order minimum-delay digital anti-alias filter used in A/D systems. The horizontal axis is time. The overshoot is ~25% of the step amplitude. Some A/D systems use arithmetic that cannot represent numbers larger than a nominal fixed value representing a full scale of 1.0. When overshoot occurs, such arithmetic may fail, or 'wrap' to a maximum value of opposite sign. This limitation is typically compensated by reducing effective gain so that a static signal can never reach more than, say, 1/1.25 of the nominal fixed value representing full scale. This approach wastes dynamic range. Other A/D systems can generate output codes significantly above the nominal full scale.

for a unit step input. Some integrated A/Ds use numeric accumulators with a fixed word length. In these A/Ds, the overshoot on dynamic signals may exceed the word length, resulting in clipping or amplitude 'wrapping' around the word length. Avoidance requires reduction of the signal level by the inverse of the overshoot factor, say to 80%. Systems so affected have an effective operating range reduction by the overshoot factor.

Another aspect of behavior at and above the nominal saturation level varies among various A/D systems. Each A/D's nominal saturation level is stated usually as a maximum peak bipolar voltage, for example, ±20 V for a specific digital code, say $\pm 2^{23}$ counts. When this value is exceeded, the output of the A/D may limit at the nominal maximum code, or it may wrap from maximum positive to maximum negative within some amplitude range, or it may be undefined if the A/D abruptly fails above the nominal saturation voltage. Another behavior is to continue to output a code representing the input signal exceeding the nominal saturation level by as much as 30%. This is a useful feature because many broadband sensors may produce output signals above their nominal maximum output voltages of, say, ±20 V, being limited only by higher power supply voltages. The linearity of both sensor and digitizer will be degraded in such an *overrange* condition, but these data may be useful if analyzed with caution. Analysts and code writers should be prepared to find signals above the nominal maximum A/D code expected for given systems. Many global and regional network systems operate this way.

1.02.3.3.2 Digital filters

Digital low-pass filters are an important element of digital broadband instrumentation. Many references address the topic of digital filters in general and with specific application to seismology (e.g., Oppenheim and Schafer, 2009; Rabiner and Gold, 1975; Scherbaum, 2001; Seidl, 1980). This section will treat one aspect of digital FIR filters that is important to both the problem of instrumentation and analysis of seismograms.

Whereas early analog systems required extensive use of electronic or electromechanical filters to shape frequency response to enhance small signals and reject 'noise,' filters are used within a broadband data system for only one reason: as anti-alias filters to reduce bandwidth accompanying decimation to a specified sample rate (Bennett, 1948; Blackman and Tukey, 1959; Oppenheim and Schafer, 2009; Shannon, 1949). Typically, a single data source is successively reduced in bandwidth to create compact data streams appropriate for long-duration analyses. For example, the GSN system records data simultaneously at 100, 40, 1, and 0.1 sps from the same sensor, reducing the data volume by as much as 1000 times for analyses requiring only low-bandwidth data. This would be cumbersome to do after the fact if only the highest-rate data were recorded. The required anti-alias FIR filters (eqn [10]) are applied in nearly real time in the time domain on a continuous input data sequence from the A/D.

Other types of digital filters may also be calculated in nearly real time for application-specific data processing. Examples include bandwidth limitation for event detection or simulation of Wood–Anderson seismometers (Anderson and Wood, 1925; Kanamori, 1999). These applications are not considered intrinsically part of the data system.

The principal guiding design of digital anti-alias filters is to pass a maximum band of frequencies for a given sampling rate, using a filter with a 'reasonable' time duration. An ideal filter would pass all frequencies with constant amplitude up to 1/2 the sampling rate at the output of the filter, would have a brief duration, and would contribute no phase distortion. Such a filter is unfortunately impossible, since the sharpness in the frequency domain is necessarily related to the duration of the filter's time-domain response. The filters used for anti-alias filtration, therefore, as in all engineering represent a compromise.

The most common anti-alias filter is a 'linear-phase' filter, which has a symmetrical response in time (zero-phase) shifted by 1/2 the filter duration to make the filter physically realizable. In many cases, this filter can simply be ignored in data analysis. The constant delay is compensated in the time labels of acquired data. The phase response of waveforms is not distorted by such a filter. Where substantial signal energy exists near the corner frequency of the filter, however, the symmetrical filter response introduces *acausal* effects in the filtered data that appear to originate before their associated signal. For many analyses, an appropriate procedure is to simply slightly reduce the bandwidth of observation with an additional causal filter, such as a Butterworth low-pass filter. In general, information near the corner frequency of sharp filters should be treated with caution because of the steep roll-off. Deconvolution of data near the corner frequency is unreliable because of the rapid loss of SNR near and above the corner frequency.

The problem of ex post facto elimination of such acausal effects has been considered (Haney et al., 2012; Scherbaum and Bouin, 1997). As Scherbaum and Bouin (1997) has pointed out, a generalized approach is tedious and error prone – if not impossible – without detailed knowledge of each filtration and decimation step occurring inside a data acquisition system.

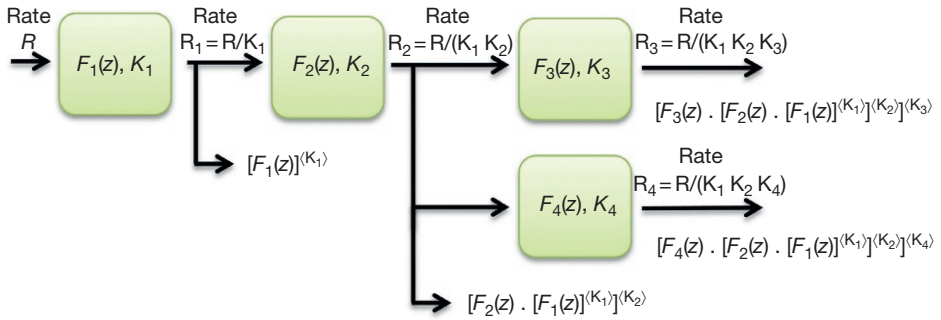

Figure 31 A digital anti-alias filtration and decimation 'chain.' Each filter stage has a Z-transform response $F_n(z)$ and a decimation factor K_n. The output from successive stages combines the effect of each prior stage, including phase shifts corresponding to time intervals less than one sample of the output rate. Such phase shifts result in difficulty modeling the filtration decimation process (Scherbaum, 2001). Consider the case where $K_3 = K_4$, and filters F_3 and F_4 have an identical length and amplitude response. If one filter has a minimum-delay response and the other has a linear-phase response, the resulting decimated filters represent a complementary *composite* pair. Such a pair concisely contains the information necessary to deconvolve acausal effects from data acquired with the linear-phase member of the pair, or to remove the phase from data acquired with the minimum-delay member of the pair (see text).

1.02.3.3.2.1 Composite responses and correction of acausal effects

In an A/D system, digital anti-alias filtration and decimation are successively applied in stages, comprising a chain. The response at the output of each stage builds upon the preceding stage. Figure 31 illustrates a filtration/decimation chain with four simultaneous output sampling rates, R_n. The notation $[F_1(z)]^{\langle K_1 \rangle}$ describes filtration by filter F_1 having Z-transform response $F_1(z)$ followed by decimation by factor K_1. At the output of each stage of filtration and decimation, the effective response incorporates the response and effect of decimation in all preceding stages.

The effective responses corresponding at each filter output are compact, since they are decimated. There is no information in the decimated responses describing the bands of frequencies rejected. Such a response description can be called a *composite* response.

The widely used Standard for the Exchange of Earthquake Data (SEED) format (IRIS, 2012) includes features to describe analog and digital filters within instruments, however, is not well suited to a detailed description of implementation-dependent operations internal to a data logger, such as in a decimation chain. Most of the information contained in the internal filters pertains to frequencies that are filtered out in the data delivered to the seismologist. If the anti-alias rejection is assumed to be adequate by design, the response at frequencies not present in the output has no value in seismological analysis. The response in the remaining passband, represented in the composite response, is of seismological interest.

Consider the example of Figure 31 where filters F_1, F_2, and F_3 have minimum delay, while F_4 has linear phase. In addition, specify that the $|F_3(z)| = |F_4(z)|$, $K_3 = K_4$. The resulting responses from stages 3 and 4 are a complementary pair differing only in phase. The two members of the pair incorporate identical inter-stage fractional-sample phase shifts accompanying decimation described by Scherbaum (2001) that are necessary to understand for accurate deconvolution of acausal effects. An A/D system would not typically actually record data simultaneously with two different phase responses; the choice to record linear-phase or minimum-delay filtered data would be made by a network operator. The availability of complementary composite pairs, however, enables a simple method to remove acausal effects in recorded data.

For example, the Quanterra Q330 defines seven possible selectable sample rates and four possible combinations of filters: all linear-phase filters or minimum-delay filters to reach 100, 40, or 20 sps followed by linear-phase filters for lower sample rates. Higher-rate data using minimum-delay filters may be used, for example, for seismic arrival picking, while lower-rate data, with a simple phase response, may be used for whole-waveform modeling. Twenty-eight possible filters comprise the canonical set of composite responses of the A/D system within the signal passband pertinent to the associated sample rate.

Figure 32 shows one complementary pair from the canonical set of FIR filters for a Q330. In blue is the A filter, having K elements a_k, for 20 sps output with linear-phase response; in red is the minimum-delay filter B, having K elements b_k for 20 sps data. The pair of filters has identical length $K = 67$ and amplitude response that is flat to roughly 80% of the passband and rolls off steeply. A filter C comprising a sequence c_n of arbitrary length N may be defined to filter a sequence $\{x_m\}$ originally acquired using A to the sequence $\{y_m\}$ as if it were acquired with B:

$$y_m = \sum_{n=0}^{N} c_n x_{m-n} \qquad [35]$$

Equation [35] can be recognized as description of a FIR filter, as in eqn [7]. Delay of the result y_m is ignored for the present discussion. The filter C can be derived from only the A, B filter pair and can be considered to be the convolution of B with a filter $\widetilde{A}$, where $\widetilde{A}$ represents a filter with a response inverse to A, such that convolution of $\widetilde{A}$ with the sequence $\{x_m\}$ deconvolves the response of A from $\{x_m\}$. Physically, such a filter $\widetilde{A}$ cannot be realized, since the frequency response of A sharply reduces the SNR in $\{x_m\}$ at frequencies above the filter corner. The application of $\widetilde{A}$ can be viewed as equivalent to the unstable division of the spectrum $\mathcal{D}\{x_m\}$ of $\{x_m\}$ by arbitrarily small numbers as 1/2 the sample rate is approached. However, the amplitude spectrum of A and B

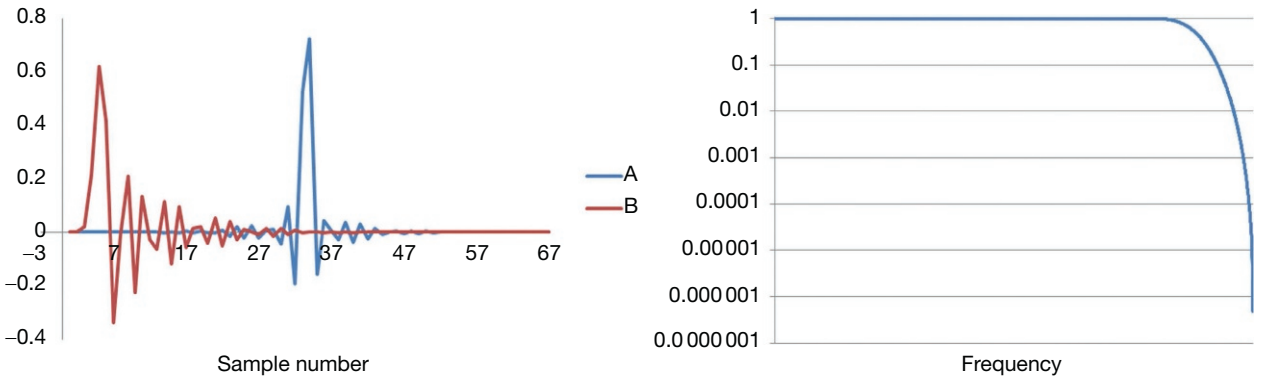

Figure 32 Left: The minimum-delay (B, red) and linear-phase (A, blue) members of a complementary composite pair of digital low-pass filters, each having 67 coefficients. This pair is used to generate 20 sps data in a Quanterra Q330. The apparently slightly asymmetrical appearance results from subsample phase shifts in earlier filtration stages. Right: The identical amplitude response of both filters.

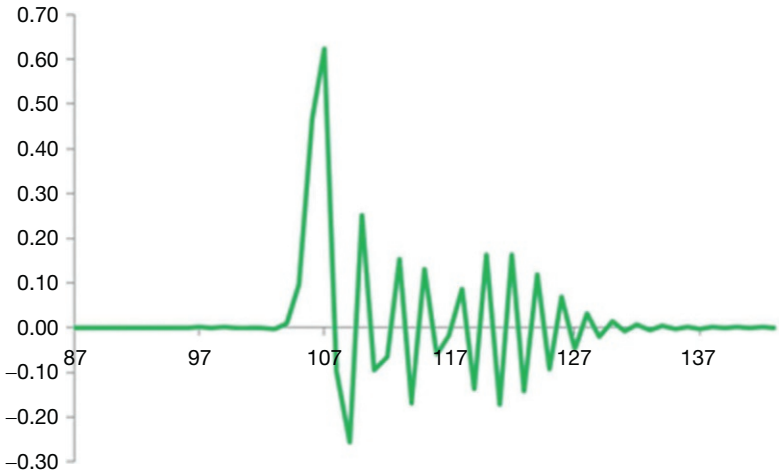

Figure 33 The time-domain filter derived from the complementary composite pair in **Figure 32** used to deconvolve acausal effects from data recorded using the linear-phase member of the pair.

are defined as identical. Therefore, a division of the finite spectra

$$\frac{\mathcal{D}\{b_k\}}{\mathcal{D}\{a_k\}} \qquad [36]$$

is stable and in principle represents the discrete phase-only, unit-amplitude spectrum of C if $N = K$, that is,

$$\mathcal{D}^{-1}\left\{\frac{\mathcal{D}\{b_k\}}{\mathcal{D}\{a_k\}}\right\} = \{c_k\} \qquad [37]$$

The filter $\{c_k\}$ calculated by eqn [37] would exhibit Gibbs-phenomenon oscillations caused by end effects. A numerical procedure to reduce such 'ringing' is to define sequences a'_n and b'_n of length N where $N > K$, for example, $4K$, and the elements $a'_{k+2K} = a_k, b'_{k+2K} = b_k$ with all other elements of $a'_n = b'_n = 0$. The actual sequences a_k and b_k therefore are padded with leading and trailing zeros to reduce wrap-around effects. The amplitude of the spectral ratio in eqn [37] can be set to unify at all frequencies to further suppress ringing at the sample rate.

Figure 33 shows the resulting all-phase FIR filter, arbitrarily shifted for clarity. Figure 34 shows application of the all-phase filter to the removal of acausal precursors in recorded data; the horizontal axis is sample number at 20 sps. The blue trace in the left panel of Figure 34 shows the data from a local magnitude 2.5 earthquake at about 9 km epicentral distance recorded on an STS-2 at 20 sps using the A linear-phase filter shown in Figure 32. The peak amplitude is 1.6×10^{-4} m s^{-1}, dominated by 25 Hz. This was a strong signal with rich high-frequency content. Overlain in the red trace are data simultaneously acquired from a preceding 100 sps output rate in the filter chain. The 100 sps data are casually filtered to the same ~7.5 Hz bandwidth as the 20 sps data. An oscillatory acausal precursor on the 20 sps data is obvious. The right panel of Figure 34, magnified, shows the application of the correction FIR filter in Figure 33, using eqn [35], to the 20 sps data from this event. The trace in black shows the corrected data with no precursor and agreement with the data derived by causal filtration from 100 sps. The trace in black, after application of the correction filter, has the effective response of the B filter in Figure 32.

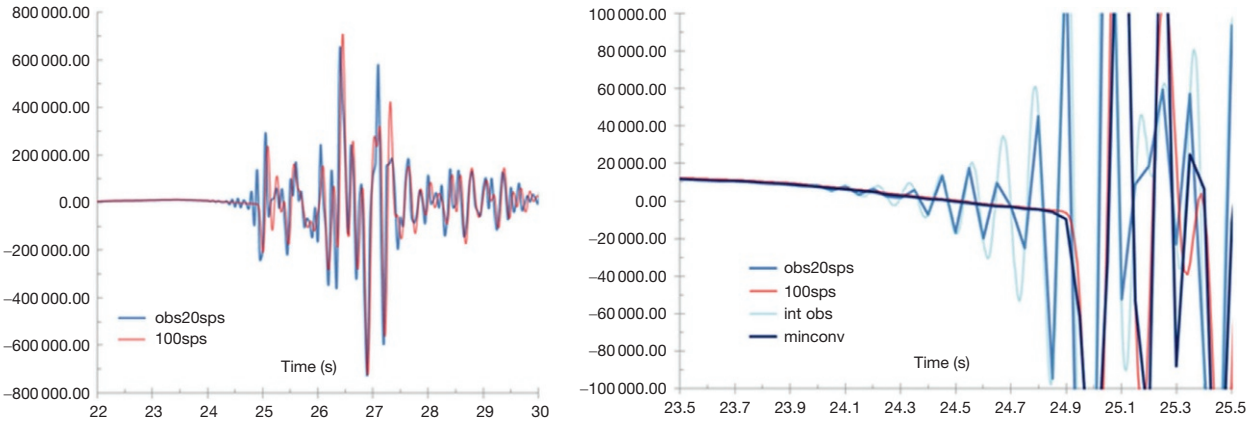

Figure 34 An example of the removal of acausal ringing using the all-phase filter shown in **Figure 33**. Left: The original 20 sps data (blue) for an M2.5 event at about 9 km distance are shown with data simultaneously acquired from an earlier stage in the filtration chain at 100 sps (red). The sharp linear-phase filter used to produce the 20 sps creates a strong acausal effect not present on the 100 sps data. Right: The initial onset is magnified ×8, with two additional traces. The light blue (int obs) is the observed 20 sps data interpolated to a higher sample rate to remove distortion of the plotted waveform. The black trace (minconv) is the observed 20 sps after passing through the filter of **Figure 33**, showing removal of the acausal precursor. The onset of the deconvolved data agrees closely with the data originally acquired at 100 sps using causal filtration.

1.02.3.3.3 Timing

Timing to a seismologist processing digital data is generally understood to describe the accuracy of time labels applied to acquired data sequences. To an instrument designer, timing implies the coordination of several elements necessary to result in the continuous delivery of accurately timed data.

1.02.3.3.3.1 Time reference

A system requires a time reference, traceable to universal time (UT). For most land-based instrumentation over the past 20 years, GPS has become the *de facto* standard time reference, provided through a small receiver. GPS receivers provide three necessary pieces of information to enable their use as a time reference:

1. A fiducial pulse, such as 1 pulse s^{-1}, occurring on transitions of UT. The pulse is derived from a local oscillator inside the receiver that is phase-locked to information derived from the radio signal. Without radio reception, the receiver's oscillator stability is typically fairly poor and the 1 pulse s^{-1} is not UT-synchronous.
2. A digital label identifying the UT represented by each pulse.
3. *State-of-health* (SOH) information on the potential errors that may arise with variations in or loss of radio reception. This information is necessary to provide to users of the reference information provided in points 1 and 2, because when radio reception is degraded, the time reference may rapidly become very inaccurate.

Sites such as those on the ocean bottom or deep underground may be unable to use a radio-based time reference and may depend on a local time reference that is periodically synchronized to UT. Such a local time reference depends on a very stable oscillator and accurate initial (and final) synchronization with a known reference. The accuracy of such a reference depends on minimum and predictable frequency error. Recently, low-power atomic-standard oscillators have become available, making possible the construction of a local time reference that has been shown to accumulate an error that can be much less than 10^{-4} s day^{-1} (Gardner and Collins, 2012). This compares with a typical 10^{-6} s rms time reference stability from common C/A code GPS receivers, independent of duration.

Although GPS receivers have become remarkably reliable, errors in their internal data processing, and possible occasional errors in the signals transmitted from the GPS ground management system, occur with finite probability. Some receivers have been observed to randomly, and persistently, emit erroneous codes for long intervals. In some cases, the errors are immediately obvious, such as incorrect management of 19-year GPS epochs, while in other cases, errors of 1 s are essentially undetectable by equipment dependent on the receiver as a reference source. Because the probability of an error is finite, and the operation of GPS receivers in global and regional seismic networks is continuous, the likelihood of inaccurately timed data is not insignificant. The probability of an error can be reduced to a manageable level by the application of further heuristic qualification of the time reference signals provided by receivers in the A/D system. A common tool, for example, is to ignore the time reference if a phase discontinuity is detected in the sequence of time reference pulses.

1.02.3.3.3.2 Time base purity

Oversampling A/Ds in ubiquitous use require a constant frequency *clock* (not to be confused with a clock giving the time of day) signal, from which the initial high sampling rate is derived. In these types of A/Ds, clock *jitter*, that is, variation in the width of sample periods Δt, can significantly elevate noise of the A/D. The local clock, therefore, must typically be derived from a stable local oscillator. This oscillator may or may not be the same local oscillator used to provide a time reference. For the time reference oscillator, the integrated stability is important: over a long period such as a day, the number of cycles should be constant and predictable. For the A/D clock oscillator, the jitter must be low, although the frequency need not necessarily be precisely known or stable over long times in order to attach an accurate time label.

1.02.3.3.3.3 Static time corrections and time label management

Every system includes fixed, known delays that may depend on physical circuit elements or digital data processing, such as digital filters. Known delays are compensated for in-time labels attached to acquired data or described in some accompanying embedded metadata. Minimum-delay anti-alias filters, in which the group delay is a function of frequency, require an arbitrary definition for delay compensation. One approach is not to compensate at all for delays of minimum-delay filters and require that data consumers calculate the group delay. Another approach is to estimate the filter group delay in the limit of zero frequency (as in the GSN system) or some reference frequency. Ambiguity for data consumers can be reduced by introducing a known waveform such as a step into the input of the A/D system at a defined time, such as a 1 min transition of UT. This approach was used many years ago in the WWSSN and remains a useful check on the management of static time corrections in complex digital systems. Uncertainties arise in each element of a potentially long chain of operations associated with time label management.

1.02.3.3.3.4 Time labels and sampling

Time labeling is defined as the attachment of a UT time label to a specific data sample. An A/D may free run – the samples of the A/D may be taken at any time offset τ with respect to UT and the offset τ measured (case A in Figure 35) – or the samples, taken at intervals Δt_{nom}, may be sampled at fiducial transitions of UT (case B in Figure 35). In Figure 35, the heavy black arrows represent the occurrence of a time reference pulse. The figure depicts, for example, an interval of four samples between time reference pulses. Ideally, the A/D clock oscillates at a frequency resulting in as close as possible to, for example, 86400.0 samples taken at 1 sps during a 24 h period. The green arrow indicates an active *phase lock* process to drive the sampling transitions to coincide with the transitions of UT. The data represented in case A are accurately timed, but do not occur at UT transitions. The time, for example, in case A of sample zero following the reference pulse T_n, is $T_n+\tau_1$. At constant clock frequency, $\tau_1=\tau_2=\tau_3$. A *time tear* is defined as the difference between the time label of a sample and the time of the sample calculated by counting samples from a previously labeled sample. By definition of Δt_{nom}, $T_{n+4}=T_n+4\Delta t_{\text{nom}}$. If the frequency of the clock in case A is such that, for example, $\tau_1\neq\tau_2\neq\tau_3$, there may be small apparent time tears, for example, between the samples taken at time $T_n+\tau_1$ and $T_{n+4}+\tau_2$. If, for example, $|\tau_1-\tau_2|\ll\tau_1$, the time tear can be considered insignificant. Typically, data segments are analyzed using the time label nearest the start of the

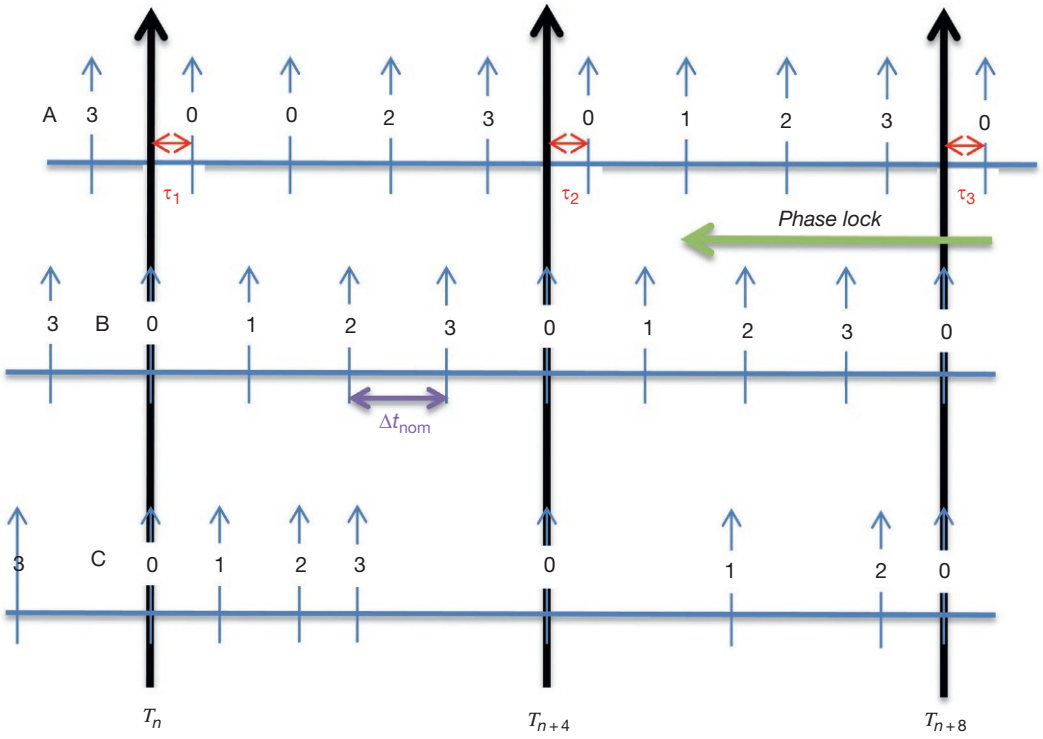

Figure 35 Three cases showing time labeling and sampling. The heavy black lines represent universal time (UT) transitions occurring, for illustration purposes, at intervals of 4 s. The thin blue arrows indicate the times at which samples are taken. Case A shows a system in which the samples are taken at an arbitrary offset τ with respect to UT. At each transition of UT, τ is measured and used to create a time label. For example, the time label of the second sample after UT transition T_n is $T_n+\tau_1+2\bullet\Delta t_{\text{nom}}$ where Δt_{nom} is the nominal sample interval. The accuracy of time labels diminishes with increasing time between measurements of τ. A sampling interval slightly different than Δt_{nom} creates small 'time tears' of magnitude $\tau_{n+1}-\tau_n$. The sampling times may be aligned with transitions of UT, and τ made arbitrarily small by *phase locking* A/D sampling to UT, as shown in case B. All stations in a network sample synchronously in this case. Case C, highly exaggerated, shows an system in which a sampling clock with poor stability is periodically 'jam set' to UT transitions, and actual offset τ is not measured. Such a sampling system can exhibit low-phase purity that can degrade high-resolution A/Ds and accumulate time errors that are unreported.

segment. If no significant time tear occurs within the segment, all samples in the data segment can be considered uniformly sampled and timed as accurately as the first time label.

Case C represents two scenarios using exaggeration: an A/D clock of poor stability and the *jam setting* of an A/D timing system. In this case, the A/D is forcibly resynchronized to the time reference at every reference occurrence. Data samples at the reference times are labeled correctly and are taken at fiducial transitions of UT. As time from the nearest reference pulse increases, however, the accuracy degrades because of variation and error in the sample interval. In extreme cases, samples may even be missing. This approach was frequently used before the appearance of oversampling A/Ds, which cannot tolerate excessive clock phase variance. A system such as C in which sample alignment with the time reference is assumed, but not measured, can lead to a false appearance of accurate timing.

1.02.3.3.5 Phase lock

The A/D sampling clock may be phase-locked (case B **Figure 35**) to a UT reference using a PID feedback loop. **Figure 36** (right) shows the PID loop used in GSN systems to maintain sampling in UT synchrony and to generate time quality information. **Figure 36** (left) shows that the sampling clock frequency control is forced to follow ambient seasonal temperature variation and secular aging of the sampling clock oscillator. In a network of such systems, each data sample throughout the network is taken simultaneously. Array processing is simplified with network-wide UT-synchronous sampling (IRIS, 2012).

1.02.3.3.6 Time quality and the time label vector

The PID control loop used to phase lock the A/D clock generates as a by-product significant amounts of SOH information that describe the *quality* of time labeling. Time quality quantifies in some way confidence in time label accuracy. Time quality uses all available information, including the SOH information available from the time reference, and internal measures, such as the variance of the sequence of phase measurements τ_n of the A/D clock to determine if the oscillator quality and time label accuracy are within defined limits.

With a quality measure available, the time labels applied to data may be considered to be a vector-valued function representing the notion of time in the A/D system. The components of the vector for each time label include one or more measures of time quality and the value of time label. Time labels in an A/D system should not be considered without evaluation of the quality components. The time quality concept was developed in the original Harvard system. Data management facilities make an abbreviated time quality available to users in the SEED *data extension blockette* (IRIS, 2012) as a percentage 0–100 that can help the user detect data that may be unreliably timed. The quality components of the time label vector may also be treated as independent time series synchronous with data. Some data management systems now make available several quality components of the time vector as uniformly sampled time series (e.g., the SEED channels LCE, τ_n, in **Figure 35**; LCQ, time quality; LCL, time since the loss of acceptable time quality; and VCO, the frequency control value used by the A/D sampling clock).

1.02.3.3.4 Ancillary data

Broadband data systems typically have the ability to collect multiple data sources in addition to the output of one or more seismometers. While in principle the measurement of temperature could be used to improve the quality of low-frequency seismic data in post processing, the required resolution of the order of 10^{-6} K is not feasible, although resolution of 10^{-4} K has been reported in some GEOSCOPE (Romanowicz et al., 1985) stations (Roult et al., 2010). A seismometer responds not only to uniform variations in temperature, but also the gradient throughout the structure. A low-frequency seismometer, in fact, is a sensitive and very high-resolution averaging temperature transducer. Contemporaneous recording of quantities such as atmospheric pressure and temperature and other meteorological data, information

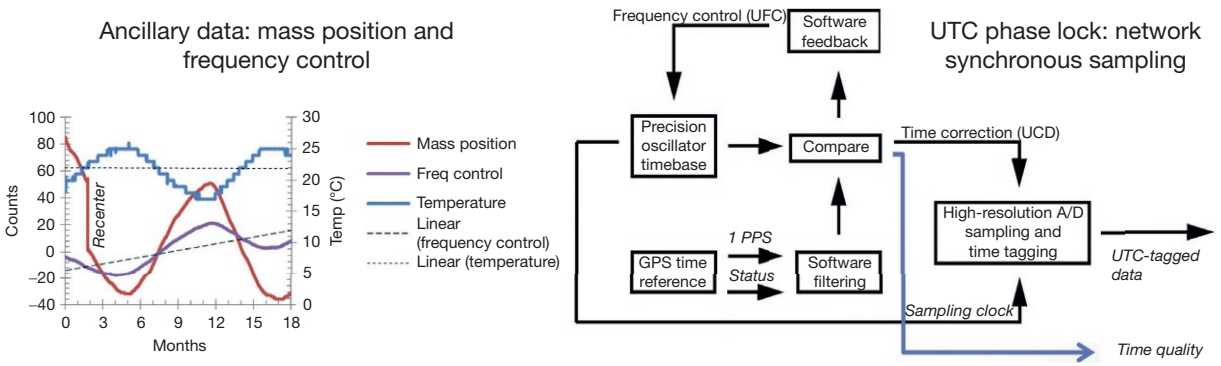

Figure 36 *Right*: The system for sampling clock generation and phase locking in GSN stations. A local sampling clock is derived from a frequency controllable temperature-compensated oscillator. The small time offsets (τ_n in **Figure 35**) between the sample times and UT are driven toward zero by controlling the oscillator frequency. The software-driven phase-locked loop assigns the *quality* of time labeling based on information provided by the UT time reference and variance of the sequence τ_n. When phase-locked, the sample times of stations in a network are simultaneous at UT transitions. Time labels and time quality constitute the *time vector*, fully describing data timing. *Left*: 18 months of ancillary data from GSN station HRV including the phase-locked frequency control (violet) and sensor mass position (brown) as a function of temperature (blue). During this period, the temperature changes seasonally with an amplitude of $\pm 3.5\,^{\circ}$. The 'time correction' (τ_n) during this interval did not exceed 4 μs. The frequency control is adjusted by the PID loop to compensate for seasonal temperature change and aging-induced secular change of the sampling clock. The STS-1/VBB sensor was recentered at month 2 to correspond with seasonal temperature zero-crossing.

on power supply voltages or other states of health, and even quantities such as efficiency of communications, however, can be valuable in analyzing the causes of noise or disturbances in the seismic data. Such analyses are particularly helpful if ancillary data are recorded as a time series with accurate time labels. Systems such as the GSN, for example, typically record 40 or more independent time series including the ancillary data, co-sampled with seismic data.

Atmospheric pressure deserves consideration because of its strong effect on low-frequency measurements (Figures 18–22). Seismographic observatories have long recorded meteorological background data. The value of digital barometric data for low-frequency seismology was recognized early (DeBremaecker and Sitton, 1963). Figure 37 shows the barometric pressure spectrum spanning the frequencies of broadband systems. Various typical and low-level observed spectra

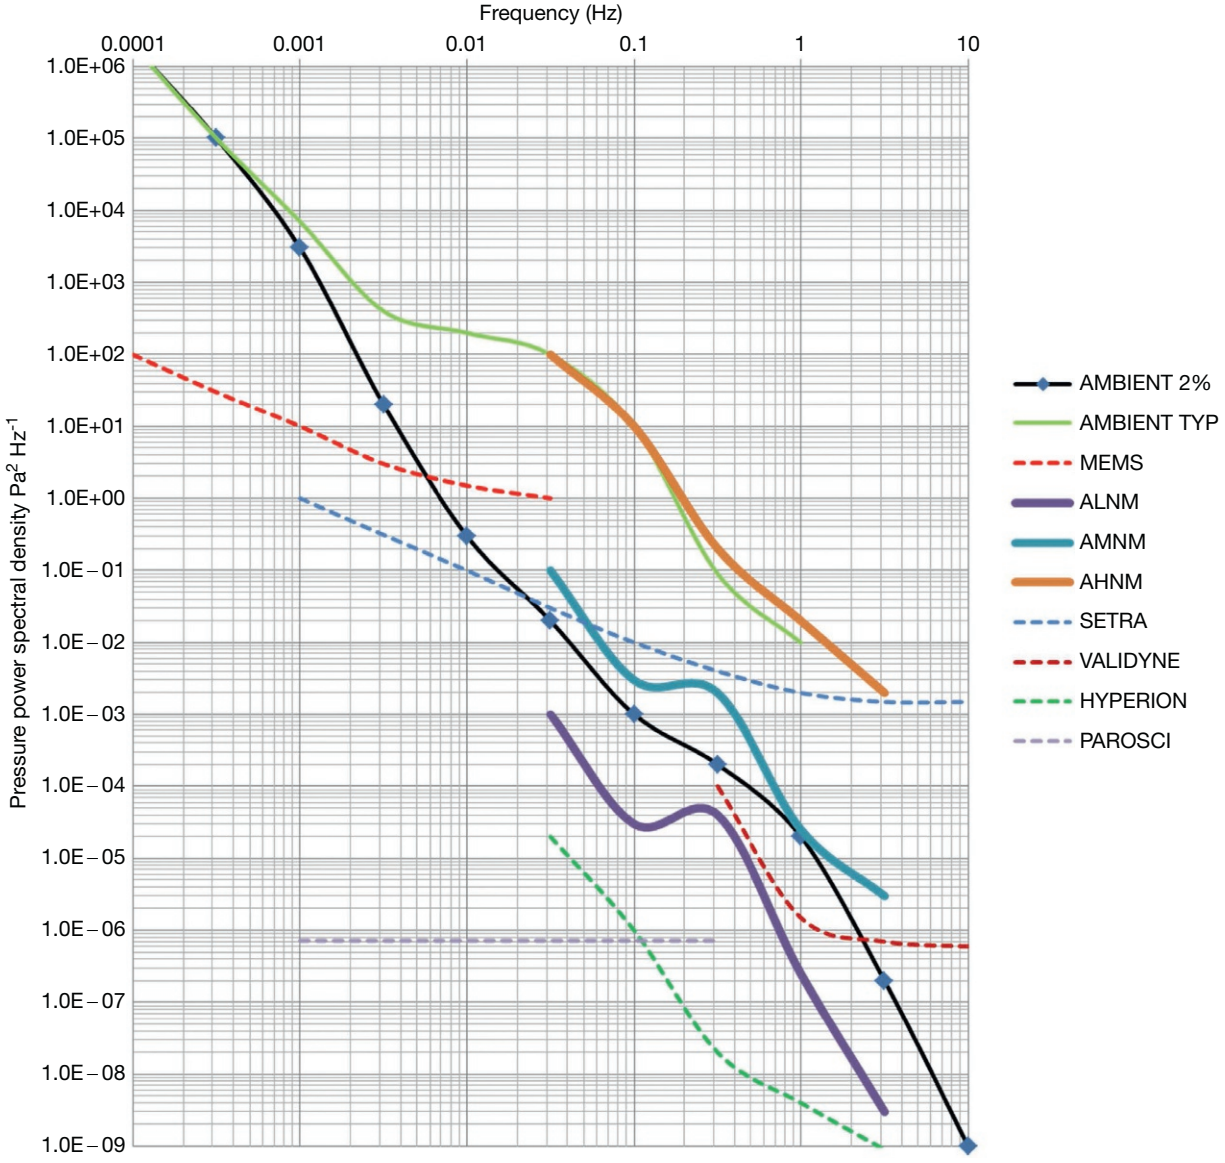

Figure 37 The spectrum of ambient low and typical barometric pressure, the intrinsic noise of several barometric sensors, and the low (ALNM), median (AMNM), and high (AHNM) infrasound noise models of Bowman et al. (2005). The measurements of intrinsic sensor noise are based on incoherent or arithmetically differenced time series using two or more identical instruments of the same type. The instruments compared are pressure sensors manufactured by VTI (now Murata, labeled MEMS), Setra Systems, and Paroscientific, and infrasound sensors, which are high-sensitivity pressure sensors typically with a high-pass frequency response, from Validyne and Hyperion, the latter originally developed by the National Center for Physical Acoustics (NCPA). The MEMS, Setra, and Hyperion sensors are deployed in hundreds of stations of the USArray Transportable Array. Combined, the three sensors are capable of resolution of minimum ambient pressure noise over more than five decades in frequency. Ambient typical and ambient two-percentile measurements were made at GSN station HRV. Noteworthy features of the barometric spectrum are the steep decrease in pressure noise with increasing frequency, and the level at frequencies <4 mHz, resolvable using low-cost MEMS barometers. These data are useful for pressure correction of low-frequency seismograms. See manufacturer's data on barometric pressure sensors (VTI, Setra, Validyne, Hyperion, Paroscientific, not dated).

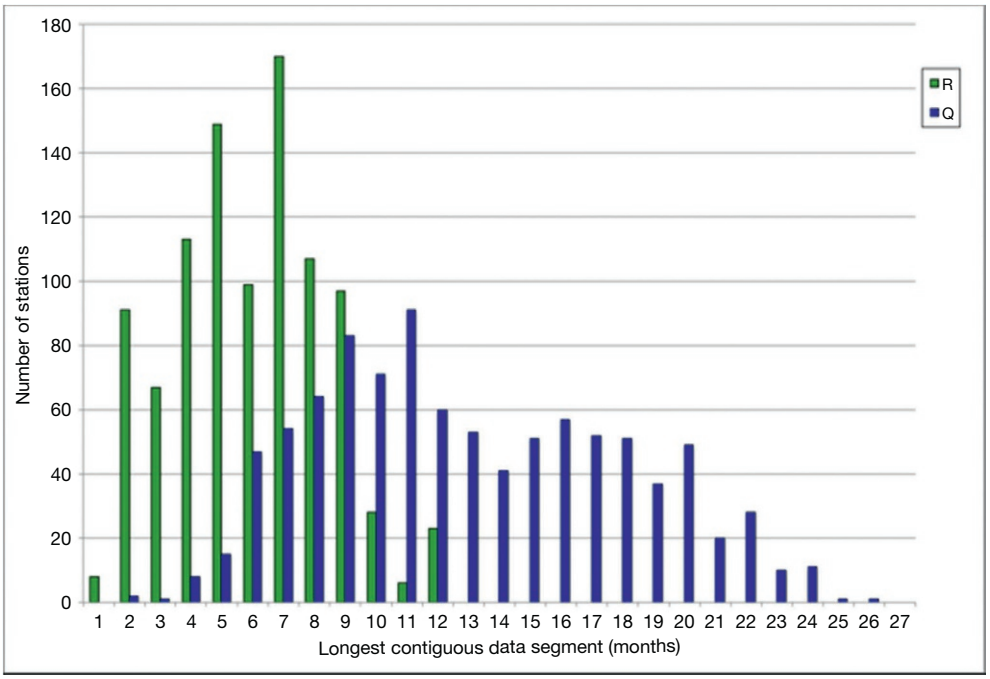

Figure 38 The effect of multiple independent data archives on data completeness over 958 stations of the USArray Transportable Array. The horizontal axis shows one measure of data completeness: the longest *contiguous* data segment (months) acquired during the station's 2-year deployment (nominal maximum 24 months). Contiguous is defined as zero missing data. The ordinate is the number of stations. The green bars represent the SEED 'R' (raw) data obtained via the real-time telemetry path only. The blue bars represent a merged 'Q' (quality-controlled) data set including both real-time telemetered and on-site recorded data. The mean length (on the order of 1 year or more) of contiguous Q data is roughly double the mean R data. No R data exceed 1 contiguous year. (Figure courtesy of R. Busby, unpublished) Some data breaks are planned, such as during firmware upgrades or system reconfiguration.

are shown, along with acoustic noise models (Bowman et al., 2005; Brown et al., 2012) and the intrinsic noise level of a number of barometric sensors. Barometric minimum ambient PSD varies on average over the five decades from 0.1 mHz to 10 Hz as $\sim 1/f^3$, although the slope is steeper at high frequencies. Ambient barometric pressure PSD varies over more than 150 dB over this frequency range. Ambient barometric noise below about 10 mHz, where coherence exists with waveforms observed on seismometers, is high and increases rapidly with period, and so can be measured with relatively simple and low-cost MEMS barometric pressure transducers. Hundreds of stations of the IRIS USArray Transportable Array program use three barometric sensors (VTI, now Murata, MEMS; Setra; and Hyperion, Hart et al., 2011) with overlapping operating ranges capable of resolving minimum ambient background levels over the frequency range of Figure 37. Multiple sensors facilitate cross-checking their calibration and operation *in situ*.

1.02.3.3.5 Archival methods: impact on quality and longevity of data set

A few design aspects developed in the original Harvard VBB system have improved the usefulness and longevity of broadband data. Perhaps, the most important feature is continuous recording rather than event-based. Contemporaneous resampling and reduction of broadband data rates in the A/D system to time series sampled at 1 and 0.1 sps makes more convenient data usage and quality analyses based on low-frequency data. In addition, the likelihood of successful telemetric transmission of complete low-frequency data sets is improved. Resampling to produce lower-rate time series requires 100% complete data at the initial rate, the likelihood of which is diminished as bandwidth, data volume, and time duration are increased.

Recording and telemetry systems fail. Multiple independent data archives, on-site and off-site through telemetry links have improved overall data integrity. Two or more independent and redundant data sets increase the likelihood of recovery of an intact and complete merged data set (Figure 38). The systems of the GSN and many regional networks incorporate this capability. The seismic data and ancillary data can be considered to comprise a 'station data vector' representing a broad view of the physical environment and configuration of the station at the time the seismic data are acquired.

Lossless data compression has reduced the data volume required for storage (essential in the 1980s and 90s) and telemetry (still important through bandwidth or volume-limited radio links or some commercial services such as cellular and satellite). The Steim1 and Steim2 (IRIS, 2012) compression techniques have become a *de facto* standard for many seismic networks and A/D systems, as a reasonable compromise of efficiency and complexity.

The method exploits the high correlation over 1–2 samples in seismic time series by storing differences only in a compact binary representation. Figure 39 shows a typical broadband 1 sps data stream along with the first and second differenced series superimposed, with a reduction in amplitude and whitening. The resulting series of differences can be coded in a tightly packed representation. Such compression is efficient

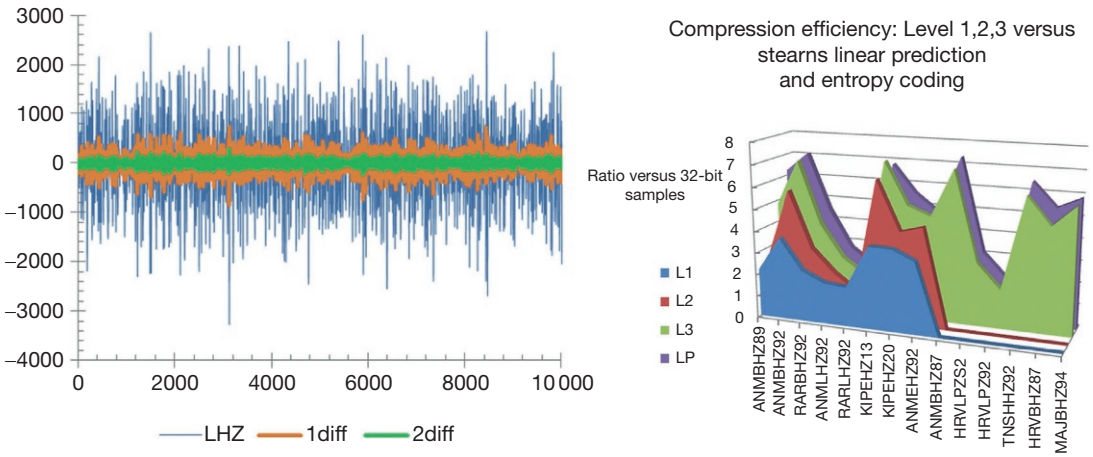

Figure 39 The basis of differencing data compression. *Left*: The reduction in amplitude of 1 sps broadband noise dominated by microseisms (LHZ, blue) when first (brown) and second (green) differenced. The smaller and relatively uniform amplitudes approximate a maximum-entropy residual and are encoded with smaller storage space than the original data. *Right*: The efficiency of three levels of 'Steim' data compression (IRIS, 2012) compared to the linear prediction and entropy coding (LP) method of Stearns (Peterson and Hutt, 1994). The ordinate is the ratio of 32 to the average number of bits required per sample. The data set comprises 14 segments (horizontal axis) representative of various ambient noise and earthquake signal characters; each data segment exhibits a different compression ratio. The stations are ANMO, RAR, KIP, HRV, and MAJO of the GSN and TNS of the German regional seismic network. Level 1 and level 2 results are shown with only eight segments of the complete data set. Level 2 is the most commonly used compromise of efficiency and complexity. Storage efficiency of level 3 is nearly equivalent to the method of Stearns, but is ~50 × more computationally efficient.

on many of the station vector 'state of health' data streams, which are often slowly varying compared to the sample rate, and therefore highly predictable. The SOH data are therefore acquired at little marginal cost in storage or bandwidth.

A further Steim3 extension (Steim, 1994), having additional coding groups and the automatic adaptive usage of first or second differences was defined and implemented in 1993 (Peterson and Hutt, 1994), but not deployed in operational networks. The method compares favorably with the maximum-entropy linear prediction coding developed by Stearns (Stearns et al., 1993), while using only integer arithmetic and about 2% of the computational effort. While potentially much larger compression efficiencies are possible using lossy techniques, these are generally destructive to broadband data because the instantaneous amplitude of the full-bandwidth signal that drives the compressor is not correlated with low-frequency signals. Although ambient noise drives the time-averaged effectiveness of compression of continuous data, earthquake data, particularly at sample rates 40 sps and higher, are generally effectively compressed. Compression is therefore effective in reducing average telemetry rates during both ambient and event conditions.

Because these compression techniques are lossless, that is, all bits of the compressed time series are preserved, the effectiveness depends on the number of bits remaining to be coded after the redundancy has been removed. Therefore, compression efficiency is inversely correlated with gain. System gain in excess of the amount required to overcome seismic noise is generally superfluous and detrimental to storage efficiency.

Small additional marginal storage reduction (10–20%) is often possible with commonly used general lossless compression methods (e.g., 'gzip'), mainly through exploiting redundancies in header information.

1.02.3.4 Calibration

Calibration is usually thought of as a means or process to measure and describe the transfer function of the sensor to ground motion. Calibration can be thought of more broadly to include measurement and verification of several other important aspects of network systems that affect the accuracy of acquired data, including orientation and location, and validation of the data processing that may affect accuracy following acquisition in the A/D system.

1.02.3.4.1 Sensor

Most sensors in current use in global and regional networks are commercially produced and are standardized; units of each make and model have nominally identical transfer functions within typically of the order of 1% accuracy. The transfer functions primarily require verification of conformance to nominal behavior while deployed. Calibration analyses may be considered to divide into 'research,' for characterization of new systems or detailed investigation of behavior using new methods, and 'operational.' Operational calibration analysis is typically used in global and regional networks. Research calibration may require special equipment or test configurations and cannot easily be performed longitudinally. Operational checks should therefore be able not only to verify nominal conformance to known behavior, but also to detect deviations requiring further study.

A sensor transfer function, say, relating output voltage $E(s)$ to ground acceleration $A(s)$ can be written as the product of a constant G_C, the gain or absolute responsivity, and a frequency-dependent $H(s)$. The factors can be identified in eqns [29] and [30]:

$$\frac{E(s)}{A(s)} = G_C H(s) \quad [38]$$

For an EFFB sensor where an electrical calibration signal is applied, either, for example, as a voltage or current summed into the drive of the feedback force transducer, or through a separate *calibration coil* that applies a force to the suspended mass by acting on the force transducer's permanent magnet, the constant G_C cannot be determined. This is because any force so applied to the suspended mass is always countered by an opposite force applied to the mass that is generated against the same magnet. This is expressed in eqn [39] simplified for zero frequency:

$$i_{cal} \cdot B \cdot K_{cal} = i_{fb} \cdot B \cdot K_{fb} \quad [39]$$

where i_{cal} is a current applied to the calibration coil, K_{cal} is a constant for the calibration coil relating the force generated for an applied current through the coil in the field of a magnet with flux density B, and K_{fb} is a similar constant, usually much larger, for the coil through which feedback is applied. On rearrangement, the balancing feedback current i_{fb}, which is proportional to the observed output signal resulting from application of the applied calibration current, can be written

$$i_{fb} = i_{cal} \cdot \frac{K_{cal}}{K_{fb}} \quad [40]$$

and measures only the ratio K_{cal}/K_{fb} in which information related to the sensor's response to ground acceleration is not present. The behavior can be seen to be equivalent if different magnets are used or a voltage is applied to the closed loop. A change from a previously measured ratio is cause for investigation, but measurement of G_C using inputs to the calibration coil is not possible.

Application of a calibration signal to a calibration coil can, however, illuminate $H(s)$, the frequency dependence of the transfer function. Most A/D systems in global and regional network use are capable of generating some type of electrical calibration signal, such as steps, sine waves, or random functions, and various methods have been extensively described (Berger and Agnew, 1979; Farrell and Berger, 1979; Fels and Berger, 1994; Peterson et al., 1980; Wielandt, 2011a,b) to derive $H(s)$ from the response to various electrical stimuli. These methods can be used for the operational determination of $H(s)$. $H(s)$ may be described in terms of a parametric model that may correspond to the physical design of the sensor, or $H(s)$ may be represented as tabulated amplitude and phase measurements as a function of frequency. A system, such as used in global networks, capable of simultaneous A/D sampling on multiple channels and synchronous with the calibration signal source can be used to derive an estimate of $H(s)$ using spectral division (Ringler et al., 2012b; Wielandt, 2011a,b). A requirement is that the calibration signal source must have sufficient energy at the frequencies where the transfer function is to be measured. To reduce variance of the estimate, multiple measurements may be stacked, and the contemporaneous ground motion input may be subtracted if available on another sensor (**Figure 40**).

Measurement of $H(s)$ using electrical inputs tests primarily the feedback system, since forcing inputs are not applied through the sensor's coupling to the ground and the sensor's feet, frame, and mass supports. Such measurements not only quantify $H(s)$, but also can detect some mechanical failures, such as defective elements of the inertial suspension. Maximum allowed electrical calibration input amplitudes and frequencies are often limited by the sensor or calibration generator, and calibration force transducers apply only a uniaxial signal aligned with the sensor's sensitive axis.

The determination of the gain constant G_C, that is, 'absolute' calibration, is more difficult requiring traceability of a stimulus signal to actual ground acceleration. Many

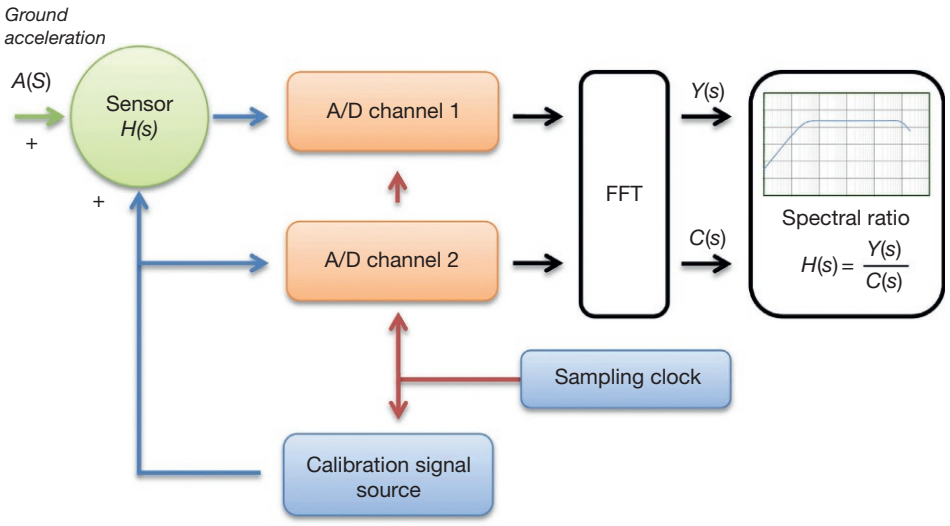

Figure 40 Measurement of the frequency-dependent part of sensor transfer function using spectral division or linear modeling. Synchronous sampling of the A/D and calibration signal source allows stable recovery of sensor transfer function from spectral division. The transfer function of the A/D is identical on both channels and does not affect the ratio $H(s)$. Sufficient SNR must be present in the input signal $C(s)$. The sensor output on channel 1 may also be linearly modeled for a known input signal measured on channel 2. Linear modeling in the time domain can provide insight into possible mechanisms of nonlinearity.

approaches have been developed, including the use of the gravity field of an external nearby rotating mass (Bernard and Karczewski, 1991), comparison against a known reference sensor using ambient seismic noise as a stimulus (Pavlis and Vernon, 1994), measurement on a motion table (Wielandt, 2011a,b; Wielandt and Zumberge, 2013), analysis of signals having well-known amplitudes such as solid Earth tides and the free mode ${}_0S_0$ (Davis and Berger, 2007, 2012), and comparison against expected synthetic signal amplitudes (Ekström et al., 2006).

Global and regional networks have recently adopted systematic programs to regularly compare, using an approach similar to Pavlis and Vernon (1994), the output of installed sensors with that of a portable transfer standard whose calibration has been independently verified (Davis and Berger, 2012). In addition, since most global and many regional network stations are equipped with multiple sensors, the consistency of records from multiple sensors for events with large SNR can be regularly analyzed (Ringler et al., 2012a), including verification against synthetic seismograms.

Both the absolute and frequency-dependent parts of the transfer function are measured by comparison to a calibrated reference sensor. The accuracy of this approach, however, diminishes at frequencies where SNR is low, such as extreme low or high frequencies where signals are small, and temporary installation of the reference sensor may limit SNR. However, the frequency-dependent $H(s)$ may be determined reliably using high-SNR electrical drive signals, and the gain G_C may be determined using the reference sensor at frequencies, such as the microseism band, and at times, such as during large events, where SNR is high.

Acquisition and recording systems are indirectly verified during network operational calibration checks. Some acquisition equipment performs automatic self tests and adjustment of gain within $<1\%$. A/D systems may fail or degrade, however, in ways similar to sensors. Observed failure modes include sudden increases in noise or changes in gain.

1.02.3.4.2 Orientation and location

Two historically difficult aspects of station operation on land, precise timing and location, have been solved nearly universally using GPS. Many global and regional seismic network stations are equipped only with C/A code, single-frequency receivers capable of precise timing and only moderate location accuracy. Multiple-frequency and code receivers capable of higher-precision location measurement are increasingly being colocated with seismic stations and promise to complement seismic data in the rapid measurement of static displacements accompanying large nearby events (Emore et al., 2007; Bock et al., 2011; Houlié et al., 2011). Commercial demands on increased location accuracy and miniaturization will drive high-accuracy global navigation satellite system technology into low-power products suitable for incorporation in seismograph systems.

Another important aspect of station operation is azimuthal orientation of three-axis sensors. This has historically been difficult, requiring astronomical sighting or other geodetic surveys. Surveyed azimuths then require transfer to an underground instrument site, with multiple opportunities to accumulate error. GPS survey instruments have also increasingly replaced historical methods for orientation measurements, although this approach still typically requires the transfer of a measured azimuth to an underground site because GPS reception requires unobstructed sky view. Small fiber-optic gyro (FOG) systems (IXBLUE) have recently enabled measurement of actual instrument orientation to $<1^\circ$. This technology does not depend on a sky view and hence can directly measure the azimuth of an instrument. The EarthScope Transportable Array first used this approach to measure the orientation of sensors directly in their instrument vaults. The known orientations were checked (**Figure 41**, Ekström and Busby, 2008) against orientations derived from polarization of observed surface waves compared with synthetics, finding close agreement. This controlled experiment confirmed the validity of polarization measurements as a routine tool in global and regional network operations.

Polarization analyses of other networks (**Figure 42**) show that the orientations of TA stations generally fall within a somewhat narrower distribution than most other networks, although orientation accuracy remains a challenge. Ringler et al. (2013) show that sensors installed by experienced field engineers can be expected to fall within 2° of an available azimuthal reference.

Just as the transfer function of a sensor may be verified using a transfer standard, the azimuthal orientation of maximum sensitivity of the sensor may be determined by measurement of coherence with a reference sensor having known orientation (Holcomb, 2002). This approach is particularly useful for determination of orientation of borehole sensors,

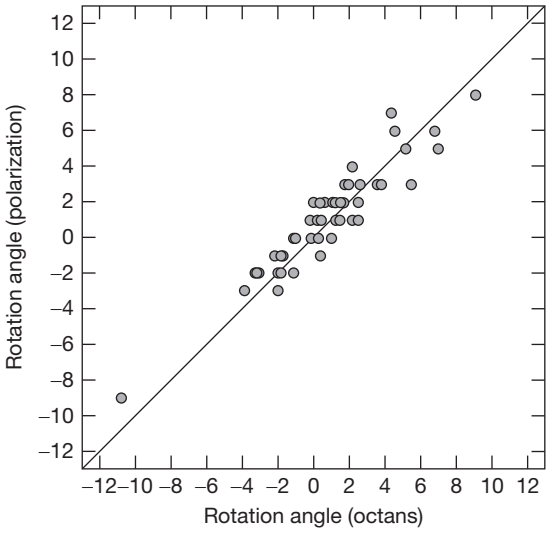

Figure 41 Comparison between two types of measurements of rotation angle. The horizontal axis corresponds to high-precision field measurements of seismometer orientation obtained at 49 TA sites at the time of station removal. The measurements were obtained using an IXSEA Octans IV interferometric fiber-optic gyroscope. The vertical axis corresponds to the rotation angle obtained from surface-wave-polarization measurements. The thin line indicates equal values of the two measurements. The difference between the two measurements is less than 3° for all stations. From Ekström G and Busby RW (2008) Measurements of seismometer orientation at USArray transportable array and backbone stations. *Seismological Research Letters* 79(4): 554–561.

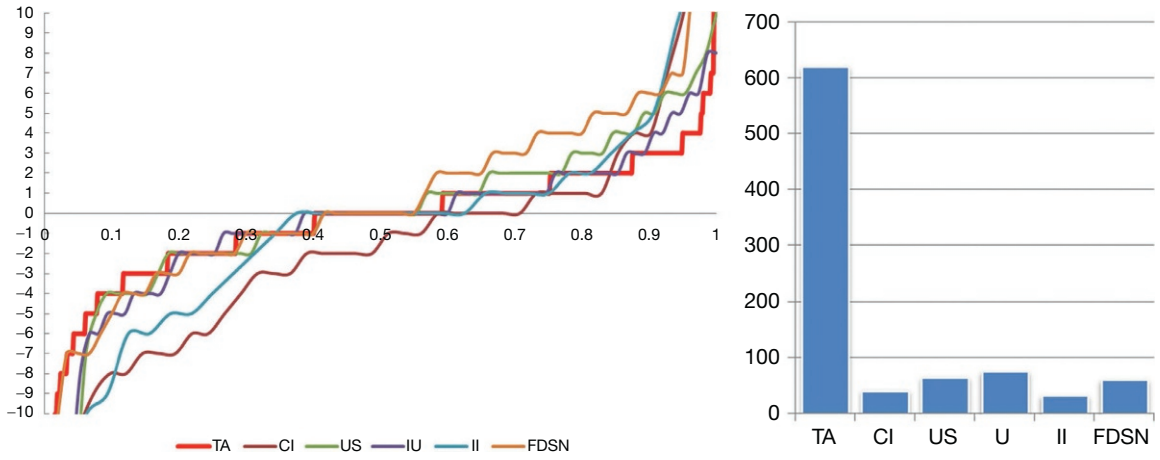

Figure 42 At left, the deviation in degrees of orientations of horizontal axes from reported values based on comparison of data with synthetic seismograms. FDSN network codes identify all networks except 'FDSN' which includes various contributing regional and global stations. The abscissa is the fraction of stations per network code. At right is the total number of stations in the analysis by network code. TA stations have been installed using a fiber-optic gyro. Data from http://www.ldeo.columbia.edu/~ekstrom/Projects/USARRAY/POLARIZATION/index.html.

where physical rotation of the instrument package to a specified azimuth may be impossible. This method can also detect faulty wiring, polarity inversion, or misalignment of the sensor's actual sensitive axis with package markings. Zha et al. (2013) have measured orientations of ocean-bottom sensors using correlations on multiple sensors of ambient noise.

1.02.3.4.3 Network calibration

Although 'calibration' has traditionally been viewed to refer to station equipment, and most specifically seismometers, increasing reliance on automatic processing chains beyond the direct view of researchers creates a need to calibrate not only the sensors, but the entire end-to-end data acquisition and delivery process. Data distributed by data management facilities in general is not identical to that acquired by field equipment, further necessitating the end-to-end verification particularly of potential time delays or errors in data center processing. MiniSEED data routinely distributed by the IRIS data management system, for example, are identified with the SEED data record type 'M' indicating 'data center modified.' Laske (2004, unpublished report), for example, shows a case where data center operations introduce a timing error. McNamara et al. (2009) show the effect of minor errors in instrument response on noise PSD calculation. Quality control analysts associated with most network operators carefully monitor acquired data for indication of timing or response errors, although in some cases, the potential errors may occur after quality control processes are applied.

Many GSN and regional network station A/D systems incorporate the ability to generate a 'network calibration' signal. In some equipment, the electrical sensor stimuli used for transfer function calibration start at precise UTC times, synchronized by the station's GPS time reference. The GSN system also includes the ability to introduce a signal only into the A/D system (and hence the subsequent data path through all data management facilities) at UTC-defined times. Just as regular sensor calibration measurements are necessary, so are 'network calibration' measurements to assure that data collection and distribution do not introduce errors in timing or data completeness. Calibration pulses at known times were used in the WWSSN.

1.02.3.5 Quality Assessment and System Characterization

When broadband instrumentation began to be deployed in the late 1980s, network operators phased out the daily calibration pulses that ruined the ability to acquire long undisturbed time series needed for some analyses (Woodward and Masters, 1989). By the mid-2000s, many sensors that were installed during the initial wave of broadband installations had been in use for nearly two decades. Sufficient data had accumulated to enable critical review of instrumentation performance. Some cases of significant deviation from assumed parametric models became apparent in the mid 2000s (Davis et al., 2005; Ekström et al., 2006). A regular and adequately frequent application of various methods to verify the system transfer function improves the accuracy of instrument models, as well as timeliness to correct a problem.

Systems are initially characterized at design time. Longitudinal analysis helps maintain network quality. Hutt et al. (2009b) and have described laboratory tests to quantify the behavior of seismic sensors. Most manufacturers and instrumentation developers have generally adopted these or equivalent methods. In general during the past three decades, designers, manufacturers, and network operators have converged on meaningful representations of noise and signal over the large potential operating range of brand band systems. Near universal adoption of Peterson's LNM and successors and refinements has facilitated comparison of diverse broadband instrumentation to an absolute reference. The level of noise and signals yield much of the operational quality information in global and regional networks.

1.02.3.5.1 Noise

Where one sensor is available, only total observed noise, including the ambient seismic noise of the site, intrinsic sensor

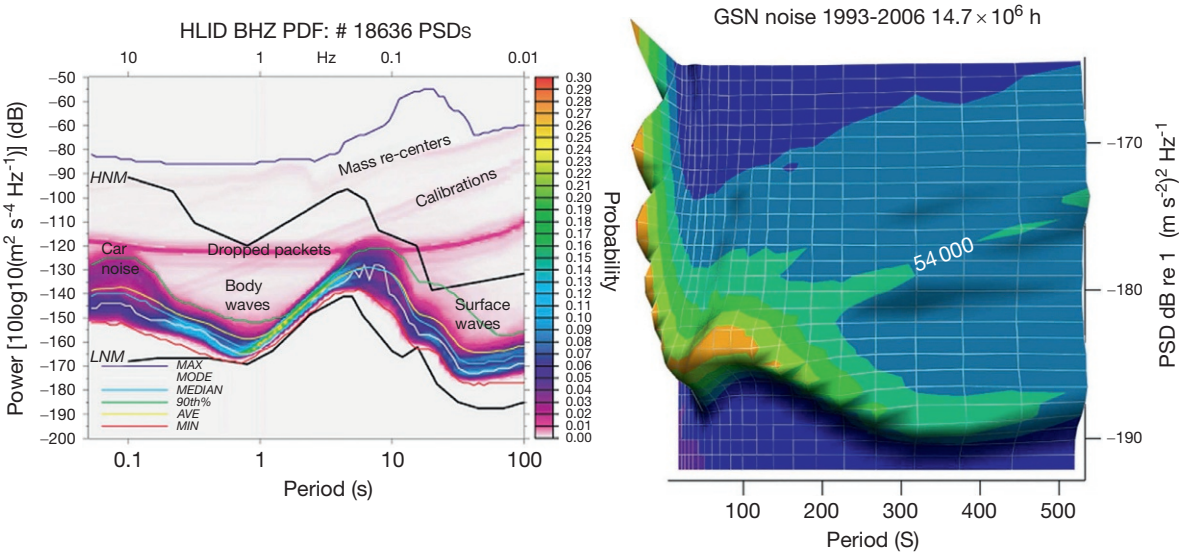

Figure 43 Left: PDF for station HLID using 18236 PSDs from 2000–09 through 2003–09. Recording system transients are observable. From McNamara and Buland (2004). Right: Cumulative noise-only vertical PSDs for GSN 1993–2006 using 1.47×10^7 1 h data segments. The 'surface' may be rotated to view features, such as the 'ridge' produced by KS54000 seismometers. Compare **Figure 50**. The depth/color axis represents number of observations. One-hour spectra to build the image from http://www.ldeo.columbia.edu/~ekstrom/Projects/WQC/MONTHLY_HTML/index_time.html.

and A/D system noise, and the effects of installation and environment is measurable, and is usually presented as PSD compared with an accepted LNM. Low noise models have been based on the lowest observed noise levels in many observations, representing the smallest percentiles of a distribution. McNamara and Buland (2004) and McNamara and Boaz (2005) introduced the routine calculation and color presentation of PSD PDFs, allowing a rapid visual assessment of typical station noise levels. The PDF plots continuously calculated at data management facilities typically extend from ~0.01–10 or 20 Hz, and hence do not cover the lowest frequency range of global instrumentation. Data segments spanning 1 h are used in construction of the routinely generated PDF plots. Features in PDF representations can be associated with scenarios that elevate apparent noise level, including sensor adjustment or missing data (**Figure 43**). McNamara et al. (2009) have proposed development of automated screening of noise PDF results to assist in quality assessment. Because PDF representations of PSD lose phase information, multiple phenomena may degenerate to produce similar spectra. Recognition of common occurrences such as clipping, mass recentering, missing data, etc., may be more effectively done using a time-domain correlation with the signature of such scenarios. Cumulative spectra also reveal persistent features related to specific sites and types of instrumentation.

Where multiple sensors are available on-site, many techniques may be used to separate apparent ambient noise from sensor intrinsic noise or the effect of installation methods on a particular sensor. Some of these approaches were discussed in connection with calibration. Spectral coherence is a common tool in deriving estimates of the PSD of noise that is uncorrelated on multiple colocated sensors (Holcomb, 1989, 1990; Ringler et al., 2011; Sleeman, 2006). **Figure 44** (Sleeman and Melichar, 2012), for example, shows estimates of the intrinsic noise of thermally insulated STS-2s compared with total observed noise. The measurement of intrinsic noise using coherence cannot distinguish between multiple sources of coherent energy, including nonseismic inputs such as thermal, barometric, or magnetic. A combination of low total observed noise, low apparent intrinsic noise derived through coherence measurement, and low correlation with environmental inputs provide reasonable confidence in the measurement of sensor performance. The analysis of arithmetic sample-by-sample differences between the outputs of nominally identical sensors can yield equivalent results. Time-domain analysis of the correlation of transient phenomena can yield physical insight into the origin. Examples include correlation with barometric or magnetic pulses (Forbriger, 2007a,b; Forbriger et al., 2010)

Routine noise PSD calculation by Lamont–Doherty Earth Observatory for global and regional stations (http://www.ldeo.columbia.edu/~ekstrom/Projects/WQC/MONTHLY_HTML/index_time.html) provides a valuable resource for longitudinal and network-wide noise studies and station quality assessment. These data comprise millions of 1-h PSD measurements in 25 frequency bands with center periods of 518–10 s, derived from 1 sps data, spanning up to 20 years of operation. Ringler and Hutt (2010) have examined temporal noise variation in the GSN. Seasonal noise variations in some period bands are common, while very low-frequency noise, particularly vertical, is relatively constant. **Figure 45**, for example, shows seasonal variation at GSN station HRV of several dB in noise PSD at 27 s period, with <1 dB variation at 100 s period. Significant departure from seasonal norms is cause for investigation.

1.02.3.5.2 Signals

Noise measurement is an important component of station quality assessment, but insufficient alone. Noise may appear to diminish over time, for example, if absolute gain decreases, or if the frequency-dependent part of the transfer function changes reducing gain in a specific range of frequencies. Such

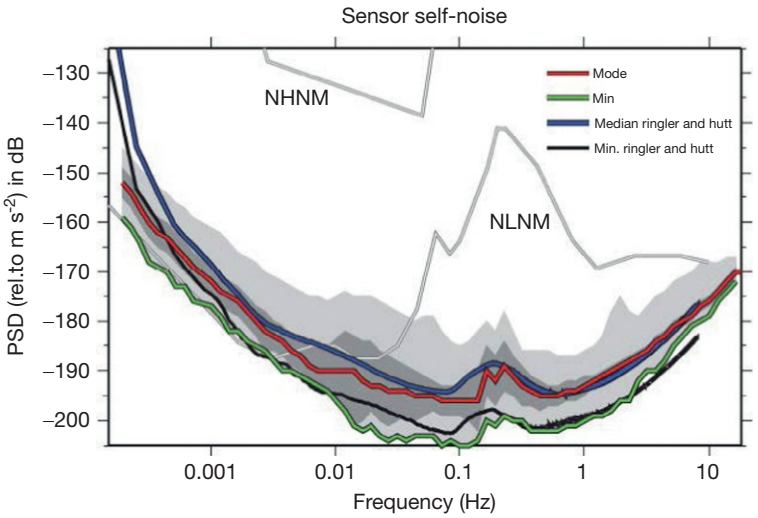

Figure 44 Mode (red) and minimum (green) values of STS2 self-noise PSD from an experiment with insulated sensors compared to results from Ringler and Hutt (2010; blue and black). The light gray and dark gray bands contain 95% and 68% of our PSD estimates. Adapted from Sleeman R and Melichar P (2012) A PDF representation of the STS-2 self-noise obtained from 1 year of data recorded in the Conrad observatory, Austria. *Bulletin of the Seismological Society of America* 102(2): 587–597.

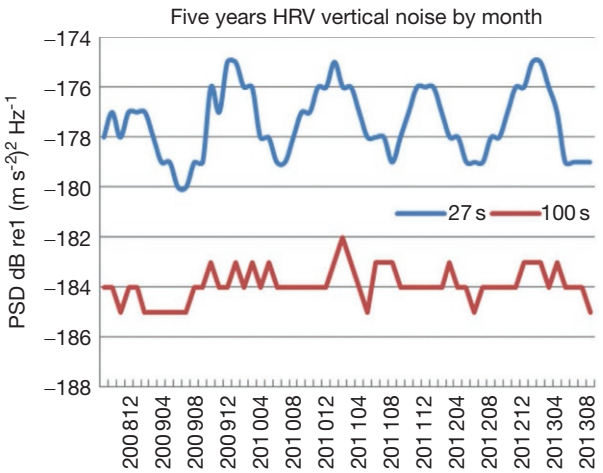

Figure 45 Monthly averaged noise (acceleration PSD) at GSN station HRV over a period of 5 years at 27 s and 100 s period. Noise at 27 s shows seasonal variation of several dB.

changes have been detected in longitudinal studies by comparing signal amplitudes between multiple colocated sensors where available, or with the amplitude of synthetic seismograms (**Figure 46**). In some cases, these problems have been caused by deterioration of electrical connections of broadband sensors after many years in service in humid environments (Hutt and Ringler, 2011; Yuki and Ishihara, 2002).

1.02.3.5.3 Instrument nonidealities

Rotations accompanying seismic signals in the far-field are not significant (Forbriger, 2009; Rodgers, 1969). Low-frequency instrumentation can be plagued by 'glitches' or brief impulses and steps. These may arise from chemical or electrochemical processes, aggravated by the high humidity environments common in seismic observation. Inherent mechanical stresses in instruments may also relax episodically over long periods – days to years. Formerly 'quiet' instruments may slowly or suddenly develop episodic noise, or the opposite. Manufacturers attempt to relieve stress through selection of materials and assembly processes, including accelerated thermal aging, and enclosure of sensitive mechanical systems in hermetic environments.

Linearity of sensors and A/D systems is often cited. Given as a single number without reference to the amplitude or type of applied signals, the type of apparent nonlinear result generated, and the band of frequencies, such a description is not meaningful. A common measure of nonlinearity is the familiar 'two-tone' intermodulation (IMD) test (Peterson et al., 1980) for mixing of the frequencies of applied electrical test signals. This test is applicable for A/D systems; however, the value is unclear as a predictor of the operation of sensors. Sensor gains and transfer functions vary widely, so that an electrical 'full scale' test of one sensor may refer to a very different equivalent ground motion input than the same test with another sensor. Importantly, the application of an electrical stimulus for linearity measurement does not duplicate the actual forces present on the inertial system in an earthquake, particularly when a test signal is uniaxial. Wielandt and Zumberge (2013) have applied uniaxial mechanical test signals on a shake table to broadband sensors, while independently measuring the shake table motion using optical interferometry. The resulting sensor outputs are linearly modeled for the known, measured table input including the table's own nonlinearity. The results show for several different types of EFFB sensor that for input signals in the range 0.25–8 Hz of nearly half the maximum input signal of the sensor, IMD products are, in terms of ground accelerations, of order −90 to −100 dB, but vary over a 30 dB range for various instruments. Expression of low-frequency distortion products as ground velocity or displacement results in an apparent distortion much higher, by the ratio of applied frequency to frequency of the mixing product. Is this 'good enough?' What is an appropriate representation? How is this

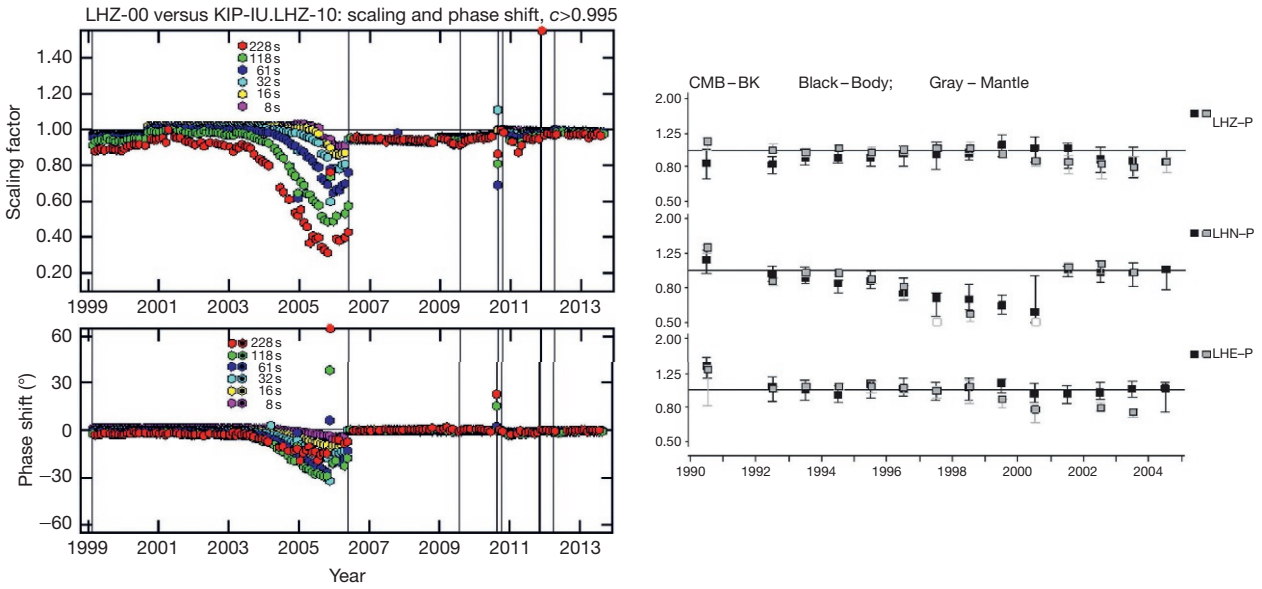

Figure 46 Left: Comparison of amplitude and phase of signals measured on two seismometers at GSN station KIP over a 14-year period. Beginning as early as 2001, low-frequency data from LHZ-00 began to decrease relative to a colocated instrument. The instrument was replaced in 2006. Such longitudinal studies are an important quality assessment tool (http://www.ldeo.columbia.edu/~ekstrom/Projects/WQC/COMB_QC/COH/cohfig.html#KIP-IU.LHZ-10_LHZ-00). Right: The amplitudes of observed and synthetic long-period signals are compared over a period of 14 years at station BK-CMB, showing a gradual deterioration on the LHN sensor beginning in 1996 and ending in 2000 when the sensor was replaced. Adapted from Ekström G, Dalton C, and Nettles M (2006) Observations of time-dependent errors in long-period instrument gain at global seismic stations. *Seismological Research Letters* 77(1).

measurement related to the apparent distortion using only an electrical stimulus to an instrument's calibration coil? Wielandt and Zumberge find that the distortion for inputs on the shake table is much higher than with electrical stimuli. The principal requirement on the type of linearity the 'two-tone' test seeks to measure is that significant high-frequency or microseismic ambient noise should not significantly affect the simultaneous low-frequency resolution of a broadband sensor or system. Apparently, this goal has been achieved with the present generation of global instrumentation, or measurements of minimum seismic noise or long-term observations of very small low-frequency signals such as free modes or hum would not be possible. Despite no obvious quantifiable association with multiaxial ground motion input, the electrical linearity test can detect certain failures (e.g., bent hinges, Hutt, personal communication), and remains a helpful engineering tool. Hutt and Ringler (2011), for example, describe 'amplitude-dependent amplitude' in an instrument sensitive to humidity, which would be expected to produce a high apparent distortion in a two-tone electrical test. Reasonable behavior in the electrical linearity test may be considered a necessary but insufficient indicator of correct operation.

Other nonlinear effects that have been observed may be less deterministic than the distortion measurable in a two-tone test. Phenomena have been observed (Delorey et al., 2008; Zahradník and Plešinger, 2005) where moderately strong high-frequency signals apparently well below the nominal clip level of broadband instruments appear to be correlated with low-frequency transients. In many cases, these signals may be explained by small permanent tilts that may arise in the sensor installation or in the local environment. Figure 47 shows an example of an apparent transient equivalent to a step in acceleration that would arise from a small tilt coincident with signal onset.

Zahradník and Plešinger (2010) suggest that some apparently unexplained nonlinear effects observed during moderately strong signals that are well below nominal clip level may be the result of saturation embedded within sensor feedback systems at frequencies outside the recorded signal passband. Such phenomena may, however, in some cases be explained by exceeding sensor clip level (Egli, 2011). An estimate of the dominant frequency of the full-bandwidth acceleration (as used in estimates of peak signals in this chapter) seen by the sensor is necessary to determine the proximity to the frequency-dependent clip level of broadband sensors. For example, Zahradník and Plešinger (2010) show a signal (their Figure 2) with peak displacement $\sim 1.5 \times 10^{-4}$ m. If this occurs at a dominant frequency ≥ 13.8 Hz, the sensor's published limit of 0.1 g is exceeded, without the need to resort to a more complex explanation. Such large acceleration amplitudes at high frequencies generated from relatively small events support the concept of low-gain velocity sensors (Clinton and Heaton, 2002) for general-purpose use at local and regional distances. New lower-gain sensors may take advantage of current A/Ds that are lower noise than those prevalent when the *de facto* gain near 1500 V m^{-1}s for sensors was chosen for general-purpose broadband sensors two decades ago.

1.02.3.6 Instruments in Global and Regional Networks

A descriptive summary of current sensors grows rapidly out-of-date. After a period of relative stability in the preceding two

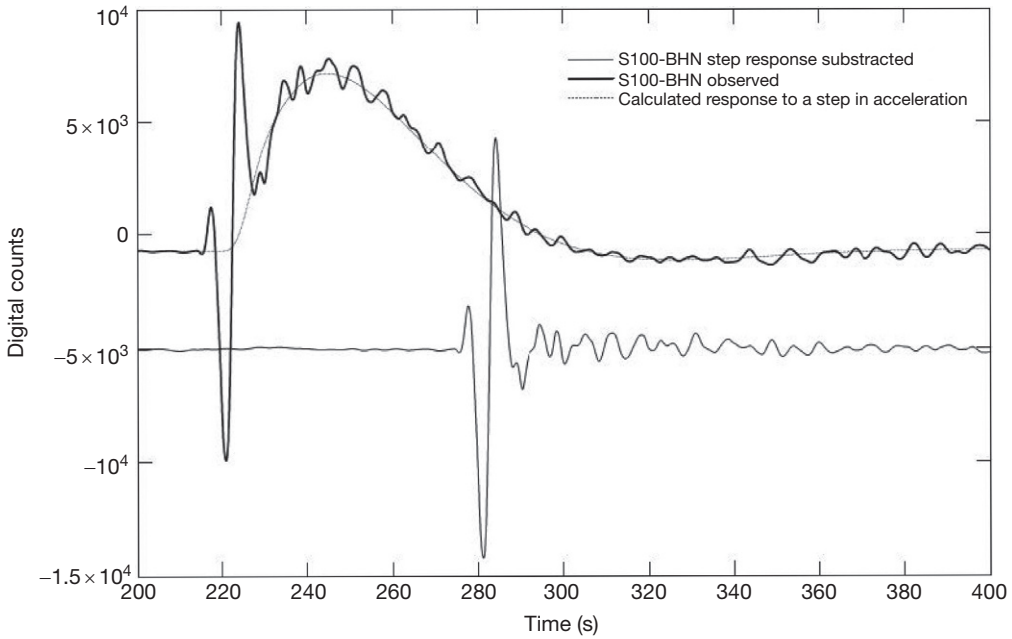

Figure 47 Small tilts on a broadband seismometer seen at regional distances accompanying felt ground shaking. The low-pass filtered signal, well below clip level, recorded on station S100 in NW United States includes an almost ideal acceleration step response that is removed in the lower trace (time shifted for clarity). Adapted from Delorey et al. (2008) Broadband sensor nonlinearity during moderate shaking. *Bulletin of the Seismological Society of America* 98(3): 1595–1601.

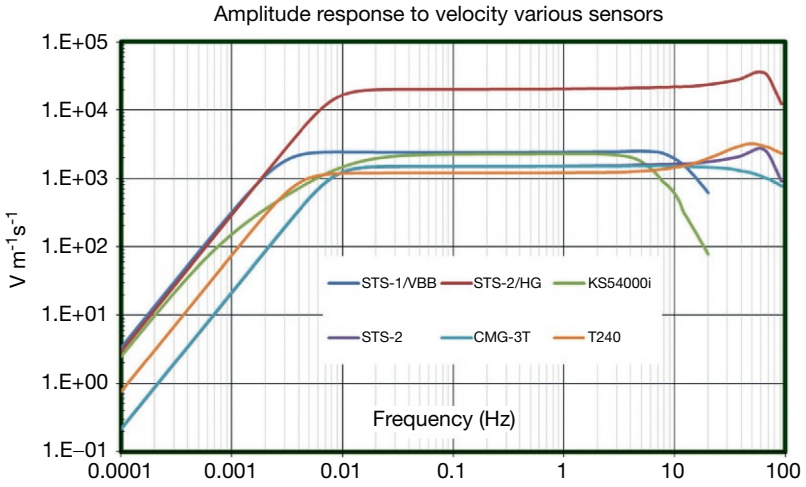

Figure 48 The amplitude response to ground velocity (volts per meter per second at the output) of the sensors providing the majority of data in global and regional networks currently and during the past two decades. These responses are approximately inverse to the spectrum of ambient Earth noise shown in **Figure 10**.

decades, resurgent interest in new instrumentation is driving rapid development. Figure 48 compares the response to ground velocity of the existing sensors responsible for the majority of high-quality data in current global and regional networks over the past two decades:

- Streckeisen, AG STS-1/VBB (replaced by Metrozet, LLC M2166-VBB sensor; Figure 49)
- Streckeisen, AG STS-2 (replaced by Streckeisen GmbH STS-2.5)
- Nanometrics, Inc. T240
- Güralp Systems, Ltd. CMG-3T
- Geotech Instruments, LLC KS54000I

The STS-1/VBB and STS-2 sensors are no longer produced and, however, have been replaced by new sensors with equivalent characteristics and performance, which are included in this brief overview. The standout feature of the frequency responses of all of these sensors, except the STS-2HG and a similar CMG-3T variant with high gain, is the similarity, having

been designed following the development of the original VBB concept (Steim, 1986; Wielandt and Steim, 1986). The STS-2 and CMG3T sensors have been produced in special 'high-gain' models for incorporation in some networks, in principle, to improve the high-frequency (>>1 Hz) match to digitizing equipment. The gain of these variants is excessive in view of actual global surface high-frequency noise levels and presents digitizer capability (McNamara et al., 2005), causing saturation on moderate events at regional distances.

The performance of the sensors in **Figure 51** can be comparable (Ringler and Hutt, 2010). All can provide high-quality broadband data in a wide variety of environments, if careful

Figure 49 Left: The STS-1/VBB vertical seismometer, viewed as it is installed in the original glass vacuum enclosure. A warpless baseplate (Holcomb and Hutt, 1992) is used in current installations. The STS-1/VBB has a response flat to ground velocity from 360 s to 10 Hz and provides the majority of high-quality very low-frequency data in global networks. Center: IRIS (2004) articulated a need to replace the STS-1/VBB, not produced since the 1990s. An industry-academic program (VanZandt et al., 2010) produced an equivalent replacement. The M2166-VBB, manufactured by Metrozet, LLC (Metrozet, 2011), comprises three mutually orthogonal sensors on a common all-metal warpless baseplate. In both the STS-1/VBB and M2166-VBB, heat-producing feedback electronics are external to the sensor vessel. Right: A comparison of free mode ${}_0S_0$ visible in 2 weeks of data following 1 month after the 2011 Tohoku Mw 9.0 earthquake recorded at the USGS Albuquerque Seismological Laboratory on an STS-1/VBB and M2166-VBB. The incoherent noise (green) between the two recordings is below the GSN (solid red line, Berger et al., 2004) low-noise model. The rms amplitude of the mode is 1.6×10^{-10} m s^{-2}, or 6.5 μV at the output of the sensors. The logarithmic scale shows the signal to be about 30 dB above the ambient seismic noise and nearly 50 dB above the noise incoherent between the two sensors. See manufacturer's data (Streckeisen G.; Metrozet, 2011)

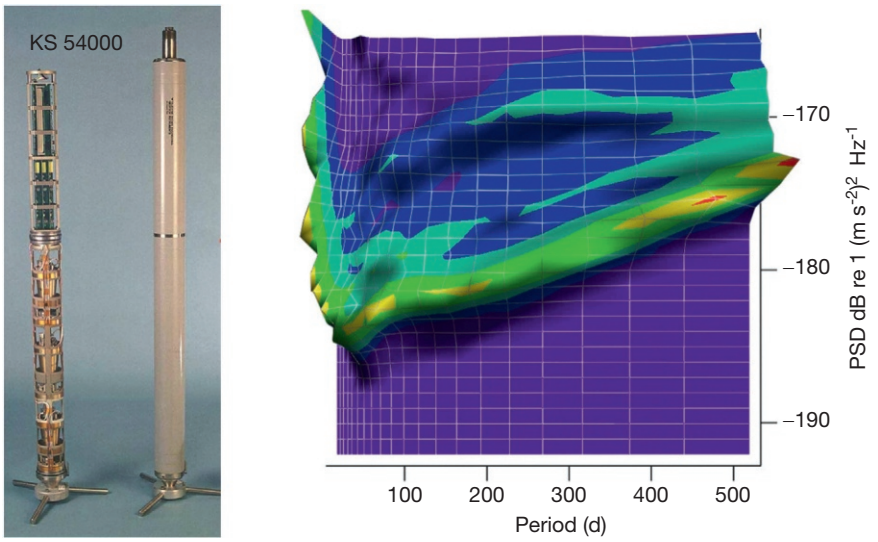

Figure 50 *Left*: The Geotech Instruments KS54000I (http://www.geoinstr.com/ks54000i.htm) very broadband borehole seismometer provides all of the high-quality low-frequency data from borehole installations in the GSN. The frequency response is nearly flat to ground velocity over a broad range from 4 Hz at 100 s, with an asymptotic response at frequencies <1 mHz similar to an STS-1/VBB. *Right*: Cumulative vertical low-frequency acceleration PSD representing about 3×10^6 1-h spectra for stations of the GSN equipped with KS54000I sensors obtained from http://www.ldeo.columbia.edu/~ekstrom/Projects/WQC/MONTHLY_HTML/index_time.html. The depth (color) axis shows number of observations. The KS54000I does not resolve levels of minimum vertical Earth noise at frequencies <5–10 mHz. Most noise observations are tightly grouped along a line roughly −182 dB at 100 s to −174 at 500 s. Several 'ridges' at higher noise levels identify significant atypical modes of operation or behaviors. Compare **Figure 43** including data from all GSN vertical sensors. See manufacturer's data (Geotech Instruments).

Figure 51 Three of the sensors providing the majority of broadband data worldwide during the past two decades. Thousands of these sensors have been produced. All three sensors have similar responses, flat to ground velocity over a broad range, extending to higher frequency (tens of hertz) than the STS-1/VBB. These sensors are typically not used for nor are capable of resolution of minimum signals at frequencies <5–10 mHz. All three sensors house their heat-producing feedback electronics inside the sealed sensor vessel. Left: The Streckeisen, GmbH, STS-2.5 is pictured, the current-production successor to the STS-2. Externally, the STS-2.5 is distinguished from the STS-2 only by the color (gray, not green), and the absence of mechanical controls to lock the sensor for transport, although the internal design is entirely new. The STS-2.5 is locked electrically. Center: The Nanometrics, Inc., T240. The STS-2, STS-2.5, and T240 are triaxially symmetric (Melton and Kirkpatrick, 1970), comprising three identical matched sensors with sensitive axes oriented at 120° azimuths and ~54 ° to the vertical. The familiar XYZ outputs are derived through a coordinate rotation performed electronically in the sensor. Right: The Güralp Systems, Ltd. CMG-3T. The CMG-3T comprises independent vertical and horizontal sensors in a common package. See manufacturers data (Guralp, 2013; Streckeisen, 2013; Nanometrics).

attention is paid to physical stability of the installation and thermal isolation. The EarthScope Transportable Array project over the last decade has deployed all three sensors in over 2000 installations using a uniform model of station construction achieving consistent noise levels within the sensors' design capability (Figure 52).

1.02.3.7 Instrumentation Directions

Hutt et al. (2002) cite some remarkable goals for a hypothetical broadband system. As yet and likely for more than the next decade, this vision of a 'super sensor' will remain unrealized. Some near-term areas in instrumentation development research are currently active, however, and will benefit new initiatives in proposed broadband array deployments (Dziewonski, 2013).

1.02.3.7.1 Renewed interest in boreholes

As cultural noise has encroached on many sites and difficulty in securing siting for installations with a large surface 'footprint' grows, borehole broadband instrumentation is receiving new attention (Busby et al., 2013a,b). Recent developments by several manufacturers will bring capable and cost-effective borehole broadband instruments into service during the next decade. The advantages of burial have been well known, but availability of reliable, cost-effective instruments has limited the deployment of this technology. Borehole systems promise a smaller surface footprint, simpler deployment, a lower-noise environment, and better physical security. New instrumentation preserves three-axis mutual orthogonality and

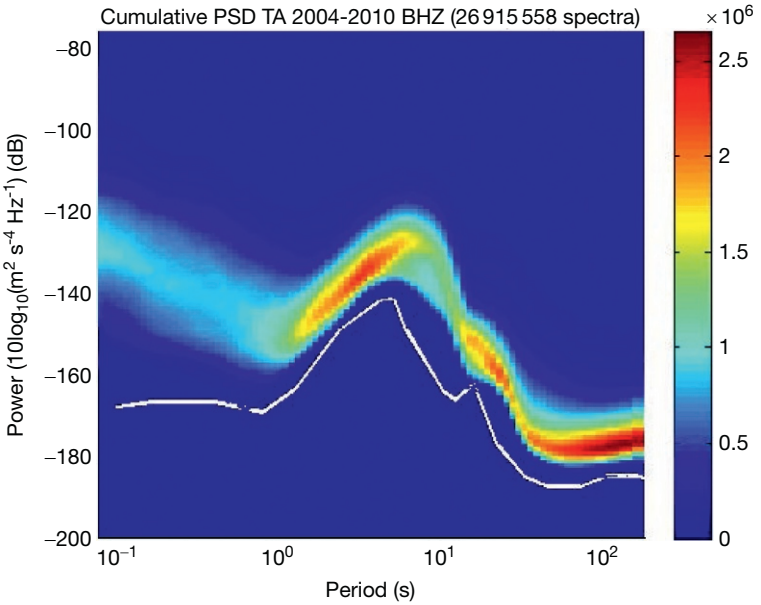

Figure 52 Showing the cumulative vertical acceleration PSD from 6 years (~27 million spectra) representing all installations of the EarthScope Transportable Array spanning the period 2004–10. At frequencies ~5–50 mHz, levels within ~10 dB of the NLNM are consistently resolved. Noise above 1 Hz shows greater variance, with levels typical of non-urban surface sites. Adapted from Busby R, Hafner K, and Woodward B (2013) Transportable array: experience in station design and new prospects. In: *IRIS Seismic Instrumentation Technology Symposium*; Busby R, et al. (2013) Sensor emplacement techniques and seismic noise analysis for USArray transportable array seismic stations. In: *EGU General Assembly Conference Abstracts*, p. 13298.

can self-level in the borehole. Installation methods and siting criteria for the best low-frequency noise, however, are not necessarily mature or standardized and are areas of active research.

1.02.3.7.2 Lower gain and greater bandwidth

New borehole sensors are within reach achieving GSN-goal performance with a response extending to higher frequencies. Future sensors may also be able to increase operating range using lower gain. Lower gain potentially improves signal handling in the presence of strong high-frequency signals.

1.02.3.7.3 Downhole digitization: integrated with a sensor

Digitizing equipment has been incorporated in borehole sensors for decades (Rodgers et al., 1987), but this technique has not been used on a wide scale in present major research broadband networks because no integrated borehole system meeting global network design goals has yet been demonstrated. Potential advantages include the following:

- No analog cabling carrying very low-level signals susceptible to corrosion, noise, or electromagnetic interference.
- Simpler connectors and small flexible cables.
- Tight integration of metadata, since the digital system is coupled to a known sensor.
- Possible digital orientation compensation.
- Thermal stability of both digitizer and sensor in the borehole environment.
- Minimal surface expression.
- Sensor 'fusion.' For example, accelerometer and velocity output data can be digitally merged.
- Possible output in physical units, such as 'nanometer per second.'
- Many fewer and less sensitive lines exposed to lightning.
- Simpler and faster deployment.

The approach also carries some disadvantages compared to current practice:

- Loss of modularity for sensor and system fault isolation.
- Forces affinity of a sensor with a particular manufacturer's acquisition methods, formats, protocols, and 'eccentricities' – especially disparate concepts of time. Current networks achieve uniformity at the level of data acquisition using sensors with a voltage output and network-wide usage of a common A/D system. Diverse digital operating environments can be difficult and time consuming to merge.
- More buried equipment to fail.
- Dynamic power variation creates thermal transients.
- More rapid system obsolescence. Few data loggers installed in 1990 are still operating, while many very good sensors continue to produce high-quality data when well maintained.

1.02.3.7.4 Complementary technologies

Incorporation of additional SG into seismic data sets may improve low-frequency data (Rosat and Hinderer, 2011; Van Camp et al., 2008; Widmer-Schnidrig, 2003). Optically sensed systems (Zumberge et al., 2010, 2012) may improve the ability to deploy instrumentation in unusual environments, such as extreme cold or heat, although such systems will need to overcome dependence on variation of mechanical parameters. MEMS technology will require significant improvement to compete with the performance of sensitive broadband electromechanical sensors. MEMS sensors reporting the lowest noise (Milligan, 2013; Standley and Pike, 2008) achieve −140 dB acceleration PSD at 0.1 Hz and show a $1/f$ noise characteristic. Use as a general-purpose broadband sensor will require noise reduction of several orders of magnitude. MEMS sensors will continue, however, to replace conventional electromechanical sensors in high-signal/high-noise applications (Wu et al., 2013). GPS will continue to be integrated in stations complementing inertial measurements not only in near-source applications (Bock et al., 2011; Guo et al., 2013; Houlié et al., 2011; Zheng et al., 2012).

Acknowledgments

The author would like to thank Charles R. Hutt, Adam Ringler, Tom VanZandt, and the editors for helpful reviews and discussions.

1.03.1 Introduction

Earth's normal modes, or free oscillations, are standing waves along the surface and radius of the Earth. These standing waves only exist at discrete frequencies and are similar to the different 'tones' of musical instruments. The study of the Earth's free oscillations is fundamental to seismology, as it is a key part of the theory of the Earth's dynamic response to external or internal forces. Essentially, the same theory is applicable to phenomena as diverse as post-seismic relaxation, analysis of seismic surface waves and body waves. The study of free oscillations *per se* is concerned with analyzing and extracting information at very long periods (~3000–100 s period) since in this range of periods the intrinsic standing wave modes of oscillation are evident in seismic spectra. Normal mode peaks can be observed in the frequency spectrum of large earthquakes with magnitudes of, say, $M_w > 7.5$, though the best observations are made for large and deep earthquakes such as the $M_w = 8.5$ Bolivia earthquake of 1994. Such spectra contain important information about the large-scale structure of the Earth. For example, the strongest evidence that the inner core is solid (Dziewonski and Gilbert, 1971) and anisotropic (Romanowicz and Breger, 2000; Tromp, 1993; Woodhouse et al., 1986) comes from the study of free oscillations.

Free oscillations provide essential constraints on both the spherically symmetric 'average' Earth, and also on lateral variations in Earth structure due to heterogeneity in temperature, composition, and anisotropy. Modal data are particularly valuable in this regard because, unlike other kinds of seismic data, modal observables depend upon broad averages of the Earth's

structural parameters, and are not nearly so affected by limitations of data coverage due to the uneven distribution of seismic events and stations. There is an enormous wealth of information yet to be extracted from long-period spectra; one has only to examine almost any portion of a seismic spectrum in detail to realize that current models often do not come close to providing adequate predictions. It is only from such very long-period data that it may be possible to obtain direct information on the three-dimensional distribution of density (Ishii and Tromp, 1999; Romanowicz, 2001; Trampert et al., 2004). Even very large scale, information on lateral variations in density has the potential to bring unique information to the study of convection and thermal and compositional evolution.

Very long-period spectra are also an essential element in the study of earthquakes, as it is only by using data at the longest periods that it is possible to determine the overall moment of very large events. For example, estimates of the moment of the great Sumatra earthquake based on mantle waves, even at periods of several hundred seconds, significantly underestimate the true moment, as the length and duration of the rupture make it possible to gauge the true, integrated moment only by using data at the longest seismic periods (e.g., Park et al., 2005).

Figure 1(a) shows an example of data and theoretical amplitude spectra computed for the spherically symmetric nonrotating PREM model (Dziewonski and Anderson, 1981). Modes appear as distinct peaks in the frequency domain. For higher frequencies, the modes are more closely spaced and begin to overlap. The theoretical peaks appear at frequencies very close to the observed peaks. However, the observed peaks are distorted in shape and amplitude due to three-dimensional effects. For example, mode ${}_1S_4$ is split into two peaks in the data spectrum, which is not seen in the theoretical spectrum. When adding the effects of Earth rotation and ellipticity of figure (**Figure 1(b)**), the peaks in the synthetic spectrum start looking more similar to the data; mode ${}_1S_4$ has become broader in the synthetic spectrum. Even better agreement is obtained for a fully three-dimensional Earth model (**Figure 1(c)**), for example, the pair of modes ${}_0S_7$–${}_2S_3$ now looks very similar in the data and synthetic spectra. However, there are also still significant differences demonstrating that a lot can still be learnt from studying long-period normal mode spectra. Not shown here, but equally important in studying both Earth structure and earthquakes, is the *phase spectrum*. Examples illustrating this are shown in later sections.

Normal mode studies represent the quest to reveal and to understand the Earth's intrinsic vibrational spectrum. However, this is a difficult quest, because it is only at the very longest periods ($\geq$100 s, say) that there is the possibility of obtaining data of sufficient duration to make it possible to achieve the necessary spectral resolution. Essentially the modes attenuate before the many cycles necessary to establish a standing wave pattern have elapsed. Thus, in many observational studies, over a wide range of frequencies, the normal mode representation has the role, primarily, of providing a method for the calculation of theoretical seismograms. Although observed spectra contain spectral peaks, the peaks are broadened by the effects of attenuation in a path-dependent way. Thus, rather than making direct measurements

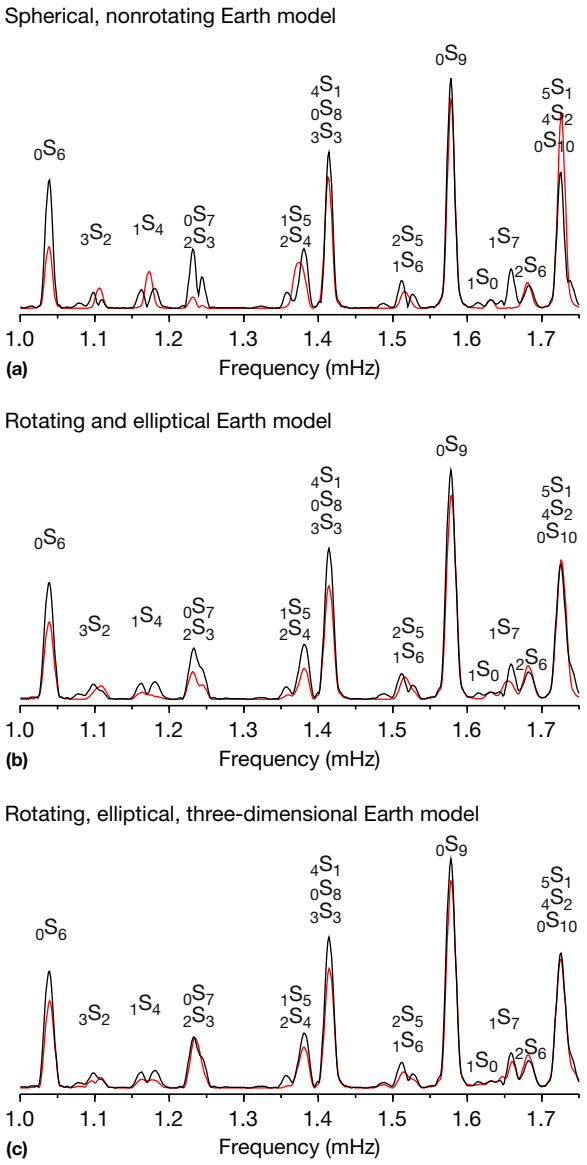

Figure 1 Data (black line) and synthetic spectrum (red line) computed using normal mode summation, for the vertical component recording at station ANMO following the great Sumatra event of 26 December 2004, using three different Earth models: (a) spherical, nonrotating, (b) rotating and elliptical, and (c) rotating, elliptical, three-dimensional structure Earth models. The calculations for rotation, ellipticity, and three-dimensional structure are fully coupled for all 140 modes below 3 mHz.

on observed spectra, the analysis needs to be based on comparisons between data and synthetic spectra, in order to derive models able to give improved agreement between data and synthetics.

The use of normal mode theory as a method of synthesis extends well beyond the realm normally thought of as normal mode studies. For example, it has become commonplace to calculate global body wave theoretical seismograms by mode summation in a spherical model, to frequencies higher than 100 mHz (10 s period). Typically such calculations can be

done in seconds on an ordinary workstation; the time, of course, depending strongly upon the upper limit in frequency and on the number of samples in the time series. The advantage of the method is that all seismic phases are automatically included, with realistic time and amplitude relationships. Although the technique is limited (probably for the foreseeable future) to spherically symmetric models, the comparison of such synthetics with data provides a valuable tool for understanding the nature and potential of the observations and for making measurements such as differences in timing between data and synthetics, for use in tomography. Thus, the period range of applications of the normal mode representation extends from several thousand seconds to ~5 s. In between these ends of the spectrum is an enormous range of applications: studies of modes *per se*, surface wave studies, analysis of overtones and long-period body waves, each having relevance to areas such as source parameter estimation and tomography. **Figure 2** shows an example of synthetic and data traces to illustrate this. The normal mode synthetic is calculated by summing all modes with period ≥6 s. The body waves P, PP, S, and SS are visible in the early part of the synthetic and data seismograms, and the surface waves arrive in the later part. It is important to note that S diffracted waves can also be obtained using normal mode summation, as normal modes form a complete basis set and thus all waves existing in a spherical Earth model are automatically included when all modes are summed up to a certain period. Differences between the synthetic and observed data seismograms can be attributed to unmodeled three-dimensional heterogeneity.

There are a number of excellent sources of information on normal modes theory and applications. The comprehensive monograph by Dahlen and Tromp (1998) provides in-depth coverage of the material and an extensive bibliography. An earlier monograph by Lapwood and Usami (1981) contains much interesting and useful information, treated from a fundamental point of view, as well as historical material about early theoretical work and early observations. A review by Takeuchi and Saito (1972) is a good source for the ordinary differential equations for spherical Earth models and methods of solution. Other reviews are by Gilbert (1980), Dziewonski and Woodhouse (1983b), and Woodhouse (1996). A review of normal mode observations can be found in **Chapter 1.04**. Because of this extensive literature, we tend in this article to expand on some topics that have not found their way into earlier reviews but are nevertheless of fundamental interest and utility. We will first derive the equations of motion using Hamilton's principle, and introduce the concept of generalized spherical harmonics. We will then show how to obtain the

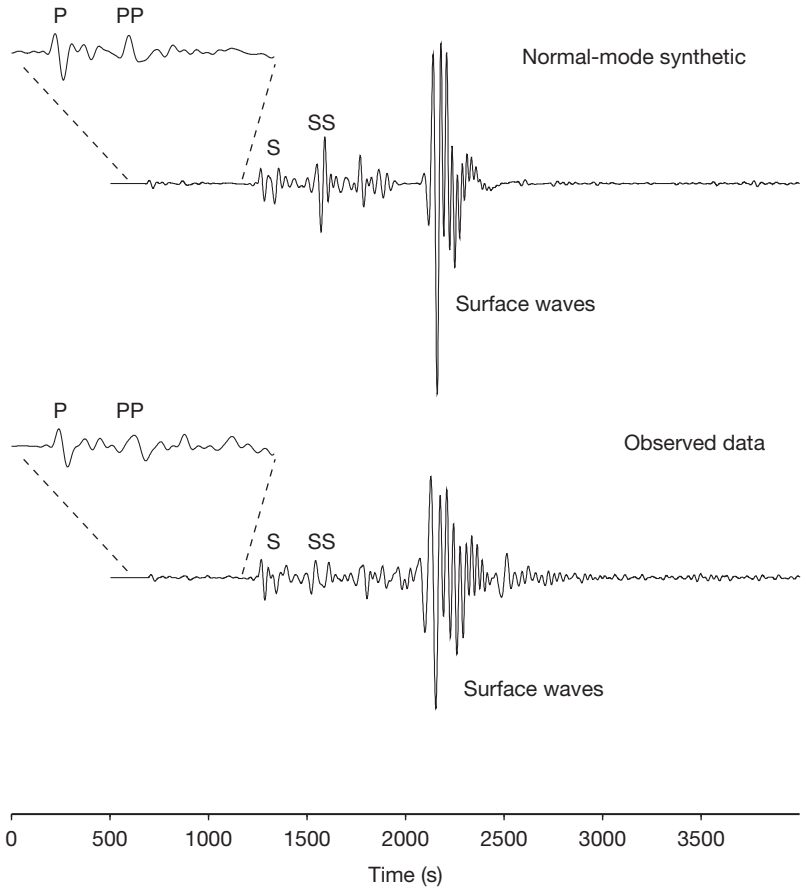

Figure 2 Data and *normal mode* synthetic for a vertical component record at station HRV following an event in Hawaii on 15 October 2006. The epicentral *distance* is 73°. For the calculation of the synthetic seismogram, the Harvard/Lamont quick-CMT centroid location and moment tensor parameters were used (G. Ekström, www.globalcmt.org).

solution for a spherically symmetric Earth and the numerical method used for calculating the modes. Finally, we will explain the calculation of synthetic seismograms in spherical and three-dimensional Earth models and discuss the characteristics of the normal mode spectrum.

1.03.2 Equations of Motion and Hamilton's Principle

To a good approximation, except in the vicinity of an earthquake or explosion, seismic displacements are governed by the equations of elasticity. At long periods self-gravitation also plays an important role. The equations of motion can be derived using conservation laws (e.g., Woodhouse, 1996). Alternatively, they can be derived from a variational principle, which significantly lessens the algebra involved. First, the Lagrangian, which is the total kinetic energy minus the total potential energy, is defined. Then the equations of motion and boundary conditions are obtained by requiring that the Lagrangian be stationary with respect to small variations in displacement and gravitation. There are two alternative ways to use a variational principle, depending on the domain in which the displacement and gravitation are varied. In the frequency domain, Rayleigh's principle has been used (Woodhouse and Dahlen, 1978), and in the time domain Hamilton's principle can be used. Here, we show how the equations of motion arise from Hamilton's principle by first defining the Lagrangian and then varying the Lagrangian with respect to displacement and gravity to get the equations of motion and corresponding boundary conditions.

1.03.2.1 Definition of the Earth Model and Lagrangian

Consider a material which is initially in equilibrium under self-gravitation. Each particle of the material is labeled by Cartesian coordinates x_i ($i=1, 2, 3$), representing its initial position. The material undergoes time-dependent deformation in which the particle initially at x_i moves to $r_i=r_i(\mathbf{x}, t)$ where t is time (Figure 3). A *hyperelastic* material is defined as one in which there exists an internal energy density function which is a function of the Green strain tensor

$$e_{ij}=\frac{1}{2}(r_{k,i}r_{k,j}-\delta_{ij}) \qquad [1]$$

where $r_{k,i}\equiv\partial r_k/\partial x_i$, δ_{ij} is the Krönecker-delta; summation over repeated indices is assumed. Thus, we introduce the internal elastic energy function, per unit mass, $E(\mathbf{x}, \mathbf{e}, s)$, where s is specific entropy. We shall be concerned only with isentropic deformations, and can henceforth omit the dependence on s. Note that E is represented as a function of the coordinates x_i which label a specific material particle. $E(\mathbf{x}, \mathbf{e})$ is regarded as a given function characterizing the elastic properties of the material. This form of the internal energy function, which forms the basis of finite theories of elasticity, as well as the theory of linear elasticity which we need here, arises from the very general consideration that elastic internal energy should not change as a result of rigid rotations of the material.

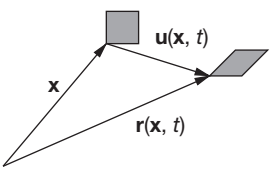

Figure 3 Schematic depiction of the particle at location **x** moving and deforming to location **r**(**x**, t).

The gravitational field is characterized by a potential field $\phi(\mathbf{r})$, which satisfies Poisson's equation

$$\frac{\partial^2\phi}{\partial r_k\partial r_k}=4\pi G\rho(\mathbf{r}) \qquad [2]$$

where ρ is the density. We state this equation in terms of the coordinates r_k, as it represents an equation valid in the current configuration of the material.

The Lagrangian governing motion of the elastic-gravitational system (total kinetic energy minus total potential energy) is

$$L=\int\int\left(\frac{1}{2}\rho\dot{r}_k\dot{r}_k-\rho E(\mathbf{x}, \mathbf{e})-\frac{1}{2}\rho\phi\right)\mathrm{d}^3r\,\mathrm{d}t \qquad [3]$$

where '˙' represents the material time derivative (i.e., the derivative with respect to t at constant $\mathbf{x}$). The three terms of the integrand represent the kinetic energy, (minus) the elastic energy, and (minus) the gravitational energy, respectively, making use of the fact that the gravitational energy released by assembling a body from material dispersed at infinity is $-\int\frac{1}{2}\rho\phi\,\mathrm{d}^3r$. The integral in eqn [3] is over the volume occupied by the Earth, which is taken to consist of a number of subregions with internal interfaces and an external free surface. Hamilton's principle requires that the Lagrangian L be stationary with respect to variations in displacement $\delta r_i(\mathbf{x}, t)$, subject to the constraint that ϕ is determined by eqn [2], and also to the requirement of mass conservation:

$$\rho\mathrm{d}^3r=\rho^0\mathrm{d}^3x \qquad [4]$$

where $\rho^0=\rho^0(\mathbf{x})$ is the initial density. That is

$$\rho=\rho^0/J \qquad [5]$$

where J is the Jacobian

$$J=\frac{\partial(r_1, r_2, r_3)}{\partial(x_1, x_2, x_3)} \qquad [6]$$

The gravitational constraint [2] can be incorporated into the variational principle by introducing a field η which acts as a Lagrange multiplier (e.g., Seliger and Whitham, 1968):

$$L'=\int\int\left\{\frac{1}{2}\rho\dot{r}_k\dot{r}_k-\rho E(\mathbf{x}, \mathbf{e})-\frac{1}{2}\rho\phi+\eta\left(\frac{\partial^2\phi}{\partial r_k\partial r_k}-4\pi G\rho\right)\right\}\mathrm{d}^3r\,\mathrm{d}t \qquad [7]$$

the term involving η vanishes by eqn [2], and therefore, L' is stationary with respect to variations in η. If we also require that L' be stationary under variations in gravitational field $\delta\phi$ we obtain the Euler–Lagrange equation for η:

$$\frac{\partial^2\eta}{\partial r_k\partial r_k}=\frac{1}{2}\rho \qquad [8]$$

which can be satisfied by setting $\eta=\phi/8\pi G$. Thus, we obtain

$$L' = \int\int\left\{\frac{1}{2}\rho\dot{r}_k\dot{r}_k - \rho E(\mathbf{x},\mathbf{e}) - \rho\phi - \frac{1}{8\pi G}\frac{\partial\phi}{\partial r_k}\frac{\partial\phi}{\partial r_k}\right\}\mathrm{d}^3 r\,\mathrm{d}t \qquad [9]$$

Changing the spatial integration variables, making use of eqn [4], we may also write:

$$L' = \int\int\left\{\frac{1}{2}\rho^0\dot{r}_k\dot{r}_k - \rho^0 E(\mathbf{x},\mathbf{e}) - \rho^0\phi - \frac{1}{8\pi G}\phi'_{,k}\phi'_{,k}\right\}\mathrm{d}^3 x\,\mathrm{d}t \quad [10]$$

where ϕ' represents the gravitational potential at the fixed coordinate point $\mathbf{x}$. Notice that the first three terms of the integrand have been transformed by regarding $\mathbf{r}$ to be a function of $\mathbf{x}$ (at each fixed t) through the function $\mathbf{r}(\mathbf{x}, t)$ which defines the deformation. However, the fourth term (which *could* be treated in the same way) has been transformed by renaming the dummy integration variables r_i to x_i. Hence the need to introduce ϕ' since ϕ represents $\phi(\mathbf{r}(\mathrm{x}, \mathrm{t}))$, which is different from $\phi(\mathbf{x}, t)$. The requirement that L' be stationary with respect to variations $\delta\mathbf{r}(\mathbf{x}, t)$, $\delta\phi(\mathbf{r}, t)$ provides a very succinct, complete statement of the elasto-gravitational dynamical equations. In other words, L' will be stationary under variations in $\delta\mathbf{r}(\mathbf{x}, t)$, $\delta\phi(\mathbf{r}, t)$ if and only if $\mathbf{r}$, ϕ are eigenfunctions of the associated Earth model.

1.03.2.2 Equations of Motion and Boundary Conditions

To obtain the partial differential equations for infinitesimal deformations, we approximate L' in the case that $r_k = x_k + \epsilon u_k(\mathbf{x}, t)$ (Figure 3) and $\phi' = \phi^0 + \epsilon\phi^1(\mathbf{x}, t)$ where ϵ is a small parameter. We seek to express the Lagrangian L' in terms of the fields u_i, ϕ^1, to second order in ϵ. We have, to second order in ϵ:

$$\phi = \phi^0 + \epsilon u_i\phi^0_{,i} + \frac{1}{2}\epsilon^2 u_i u_j\phi^0_{,ij} + \epsilon\phi^1 + \epsilon^2 u_i\phi^1_{,i} \qquad [11]$$

We expand $\rho^0 E[\mathbf{x}, \mathbf{e}]$ to second order in strain:

$$\rho^0(\mathbf{x})E(\mathbf{x},\mathbf{e}) = a + t^0_{ij}e_{ij} + \frac{1}{2}c_{ijkl}e_{ij}e_{kl} \qquad [12]$$

As a result of their definitions, as first and second derivatives of $\rho^0(\mathbf{x})E(\mathbf{x}, \mathbf{e})$ with respect to strain, at zero strain, t^0_{ij} and c_{ijkl} possess the symmetries:

$$t^0_{ij} = t^0_{ji} \qquad [13]$$

$$c_{ijkl} = c_{jikl} = c_{ijlk} = c_{klij} \qquad [14]$$

We use the notation t^0_{ij} since these expansion coefficients represent the initial stress field. The strain tensor [1] is

$$e_{ij} = \frac{1}{2}\epsilon\left(u_{i,j} + u_{j,i}\right) + \frac{1}{2}\epsilon^2 u_{k,i}u_{k,j} \qquad [15]$$

Thus, the second order expansion of L' becomes:

$$\begin{aligned} L' = \int\int\Big\{&-a - \rho_0\phi^0 - \frac{1}{8\pi G}\phi^0_{,i}\phi^0_{,i} \\ &-\epsilon\left(t^0_{ij}u_{i,j} + \rho_0 u_i\phi^0_{,i} + \rho_0\phi^1 + \frac{1}{4\pi G}\phi^0_{,i}\phi^1_{,i}\right) \\ &\frac{1}{2}\epsilon^2\Big[\rho^0\dot{u}_k\dot{u}_k - \Lambda_{jilk}u_{i,j}u_{k,l} - \rho^0 u_i u_j\phi^0_{,ij} \\ &-2\rho^0 u_j\phi^1_{,j} - \frac{1}{4\pi G}\phi^1_{,i}\phi^1_{,i}\Big]\Big\}\mathrm{d}^3 x\,\mathrm{d}t \end{aligned} \qquad [16]$$

where we have introduced

$$\Lambda_{jilk} \equiv \delta_{ik}t^0_{jl} + c_{ijkl} \qquad [17]$$

and where the $\Lambda_{jilk}u_{k,l}$ term in eqn [16] is the incremental Piola–Kirchhoff stress tensor. The Euler–Lagrange equations which require that L' be stationary with respect to variations $\delta\mathbf{u}$, $\delta\phi^1$, are given by

$$\frac{\partial L'}{\partial u_i} = \left(\frac{\partial L'}{\partial u_{i,j}}\right)_{,j} \quad \text{and} \quad \frac{\partial L'}{\partial\phi^1} = \left(\frac{\partial L'}{\partial\phi^1_{,i}}\right)_{,i} \qquad [18]$$

They must hold for each power of ϵ. Thus, the first order terms in eqn [16] give the two following equations, which represent the requirement that the initial configuration be (i) in equilibrium and (ii) under self-gravitation:

$$t^0_{ij,j} = \rho^0\phi^0_{,i} \qquad [19]$$

$$\phi^0_{,ii} = 4\pi G\rho^0 \qquad [20]$$

The terms in L' that are independent of ϵ do not contribute to the variation, and thus can be omitted. When eqns [19] and [20] are satisfied, there remain only the second order terms:

$$\begin{aligned} L'' = \int\int\frac{1}{2}\Big[&\rho^0\dot{u}_k\dot{u}_k - \Lambda_{jilk}u_{i,j}u_{k,l} - \rho^0 u_i u_j\phi^0_{,ij} - 2\rho^0 u_i\phi^1_{,i} \\ &-\frac{1}{4\pi G}\phi^1_{,i}\phi^1_{,i}\Big]\mathrm{d}^3 x\,\mathrm{d}t \end{aligned} \qquad [21]$$

In eqn [21] we omit the factor ϵ^2, absorbing the small parameter into the definitions of the fields $\mathbf{u}$, ϕ^1. The Euler–Lagrange equations for L'' (similar to eqn [18]) corresponding to variations $\delta\mathbf{u}$, $\delta\phi^1$ give the equations of motion:

$$\rho^0\left(\ddot{u}_i + \phi^1_{,i} + \phi^0_{,ij}u_j\right) = \left(\Lambda_{jilk}u_{k,l}\right)_{,j} \qquad [22]$$

$$\phi^1_{,jj} = -4\pi G\left(\rho^0 u_i\right)_{,i} \qquad [23]$$

The same equations can alternatively be derived using conservation laws, see for example Woodhouse (1996).

The variational principle also leads to certain natural boundary conditions at the *free* surface (i.e., the ocean surface or the outer surface of the solid Earth in the absence of an ocean) and at internal boundaries in the case that $\mathbf{r}(\mathbf{x}, t)$ is required to be continuous at such boundaries. These internal boundaries are so-called *welded* boundaries, such as the Mohorovicic discontinuity between the crust and mantle and the 660 km discontinuity between the upper and lower mantle. These are as given below. We also wish to include the case that the model contains fluid regions, having free-slip, boundary conditions at their interfaces with solid regions – the so-called *frictionless* boundaries, which exist at the ocean floor, the inner core boundary, and the outer core boundary. The correct treatment of such boundaries introduces complications that, in the interests of giving a concise account, we do not analyze in detail here. Woodhouse and Dahlen (1978) show that it is necessary to include additional terms in the Lagrangian to account for the additional degrees of freedom corresponding to slip (i.e., discontinuous u_i) at such boundaries. The stress boundary conditions are most conveniently stated in terms of the vector t_i defined on the boundary by

$$t_i = \Lambda_{jilk}u_{k,l}n_j - n_i\left(\pi^0 u_k\right)_{;k} + \pi^0 u_{k;i}n_k \quad \text{with } \pi^0 = t^0_{jk}n_j n_k \qquad [24]$$

where n_i is the unit normal to the boundary, and where the semicolon notation, for example, $u_{k;i}$, is used to indicate differentiation *in* the surface: $u_{k;i} = u_{k,i} - n_i n_j u_{k,j}$. We also require the gravitational potential to vanish at *infinity*. The complete set of boundary conditions is

$$\begin{array}{lllll}
\text{Welded}: & \left[t^0_{ij}n_j\right]^+_- = 0, & \overset{-}{[u_i]}^+ = 0, & [t_i]^+_- = 0, & \\
\text{Frictionless}: & \left[t^0_{ij}n_j\right]^+_- = 0, & t^0_{ij}n_j = n_i\pi^0, & [u_k n_k]^+_- = 0, & [t_i]^+_- = 0, \qquad t_i = n_i t_k n_k, \\
\text{Free}: & t^0_{ij}n_j = 0, & & t_i = 0, & \\
\text{All}: & \left[\phi^0\right]^+_- = 0, & \left[\phi^0_{,i}\right]^+_- = 0, & \left[\phi^1\right]^+_- = 0, & \left[\phi^1_i + 4\pi G\rho^0 u_i\right]^+_- = 0, \\
\text{Infinity}: & \phi^0 \to 0, & & \phi^1 \to 0, &
\end{array} \qquad [25]$$

where $[\,]^+_-$ represents the discontinuity of the enclosed quantity across the boundary. Equations [22]–[25] govern the unknown displacement field $u_i(\boldsymbol{x}, t)$ and gravity field $\phi^1(\boldsymbol{x}, t)$ which represent the possible free oscillations of the Earth. All other quantities ρ^0, t^0_{ij}, ϕ^0, Λ_{ijkl} are regarded as given parameters of the Earth model subject to the equilibrium conditions [19] and [20].

1.03.2.3 The Seismic Source

In order to excite the normal modes, we need to apply a force, or seismic source. In the presence of an applied force distribution $f_i = f_i(\mathbf{x}, t)$, per unit volume, the equation of motion [22] becomes

$$\rho^0\left(\ddot{u}_i + \phi^1_{,i} + \phi^0_{,ij}u_j\right) - \left(\Lambda_{jilk}u_{k,l}\right)_{,j} = f_i \qquad [26]$$

Taking the Fourier transform in time, we shall also write

$$\rho^0\left(-\omega^2 u_i + \phi^1_{,i} + \phi^0_{,ij}u_j\right) - \left(\Lambda_{jilk}u_{k,l}\right)_{,j} = f_i \qquad [27]$$

where ω is the frequency. We shall employ the Fourier transform pair:

$$u_i(\mathbf{x}, \omega) = \int_{-\infty}^{\infty} u_i(\mathbf{x}, t)e^{-i\omega t}dt, \quad u_i(\mathbf{x}, t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} u_i(\mathbf{x}, \omega)e^{i\omega t}dt \qquad [28]$$

Here, and in subsequent equations, we rely on the context to distinguish between time-domain and frequency-domain quantities, adopting the convention that if ω appears in an equation then all functions appearing are the Fourier transforms of the original, time-dependent functions.

Earthquake sources can be modeled by choosing particular force distributions f_i. The problem of determining the *equivalent body force distribution* to represent (prescribed) slip on an earthquake fault was originally solved by Burridge and Knopoff (1964) using the elastodynamic representation theorem. A very general and, at the same time, simple approach to the problem of determining body force equivalents is that of Backus and Mulcahy (1976). They argue that an earthquake occurs as a result of the failure of the assumed constitutive law, in the linear case *Hooke's law*, relating stress and strain. This leads them to introduce a symmetric tensor quantity $\Gamma_{ij} = \Gamma_{ij}(\mathbf{x}, t)$, called the *stress glut*, which represents the failure of Hooke's law to be satisfied. Importantly, Γ_{ij} (i) will be zero outside the fault zone, (ii) will be zero at times before the earthquake, and (iii) will have vanishing time derivative at times after slip has ceased. Thus, the *glut rate*, $\dot{\Gamma}_{ij}$, is compact in space and time. The earlier concept of *stress-free strain*, due to Eshelby (1957), is a closely related one. The strain, for slip on a fault, contains δ-function terms at the fault, because the displacement is discontinuous. The stress, on the other hand, is finite on the fault. Thus, there exists a stress glut – a failure of the stress to satisfy Hooke's law, and a stress-free strain, that is, a component of the strain field that is not reflected in the stress. The existence of a nonvanishing stress glut, Γ_{ij}, leads us to replace eqn [22] by

$$\rho^0\left(\ddot{u}_i + \phi^1_{,i} + \phi^0_{,ij}u_j\right) = \left(\Lambda_{jilk}u_{k,l} - \Gamma_{ij}\right)_{,j} \qquad [29]$$

that is

$$\rho^0\left(\ddot{u}_i + \phi^1_{,i} + \phi^0_{,ij}u_j\right) - \left(\Lambda_{jilk}u_{k,l}\right)_{,j} = -\Gamma_{ij,j} \qquad [30]$$

and thus comparing [26] with [30], the equivalent body force distribution is found to be $f_i = -\Gamma_{ij,j}$. Because $\dot{\Gamma}_{ij}(\mathbf{x}, t)$ is compact in space and time, it is appropriate for calculations at long period and long wavelength to replace it by a δ-function in space and time. Defining the *moment tensor*

$$M_{ij} = \int_V \Gamma_{ij}(\mathbf{x}, \infty)d^3x = \int_{-\infty}^{\infty}\int_V \dot{\Gamma}_{ij}(\mathbf{x}, t)d^3x dt \qquad [31]$$

where V is the source volume – the region over which Γ_{ij} is nonzero – a suitable form for Γ_{ij} is $\Gamma(\mathbf{x}, t) \approx M_{ij}\delta^3(\mathbf{x} - \mathbf{x}_s)H(t - t_s)$, where $H(t)$ is the Heaviside step function, and where $\mathbf{x}_s$, t_s are the source coordinates. Thus $f_i \approx -M_{ij}\partial_j\delta^3(\mathbf{x} - \mathbf{x}_s)H(t - t_s)$. In what follows we shall consider the more general point source

$$f_i = \left(F_i - M_{ij}\partial_j\right)\delta^3(\mathbf{x} - \mathbf{x}_s)H(t - t_s) \qquad [32]$$

in which M_{ij} is not necessarily symmetric, recognizing that for sources not involving the action of forces external to the Earth, so-called indigenous sources such as earthquakes, must be symmetric and M_{ij} must be zero. The solution for a point force F_i is of fundamental theoretical interest since the solution in this case is the Green's function for the problem, which can be used to construct solutions for any force distribution f_i. Nonsymmetric M_{ij} corresponds to a source which exerts a net torque or couple on the Earth, such as meteorite impacts.

1.03.2.4 Viscoelasticity and Intrinsic Attenuation

The hyperelastic constitutive law based on the internal energy function $E(\mathbf{x}, \mathbf{e})$ needs to be modified to include the effects of energy loss due to such effects as grain boundary sliding and creep. Such *anelastic* effects lead to dissipation of energy (i.e., conversion of elastic stored energy into heat) and thus to the decay, or *attenuation* of seismic waves. In addition, they are responsible for such effects as post-seismic relaxation, and the theory developed here is in large part applicable to this problem also. A generalization of the constitutive law which retains linearity is the viscoelastic law, which supposes that stress

depends not only on the strain at a given instant, but also on the strain history. This can be written as

$$t_{ij}(t) = \int_{-\infty}^{\infty} c_{ijkl}(t-t')u_{k,l}(t')\mathrm{d}t' \qquad [33]$$

where t_{ij} is incremental stress. (In fact it can be shown that the true increment in stress, at a material particle, includes terms in the initial stress: $t^1_{ij} = c_{ijkl}u_{k,l} + t^0_{ik}u_{j,k} + t^0_{jk}u_{i,k} - t^0_{ij}u_{k,k}$, but this makes no difference to the discussion here.) Thus, the elastic constants become functions of time, relative to a given time t at which the stress is evaluated. Importantly, since stress can depend only upon *past* times, $c_{ijkl}(t)$ must vanish for negative values of t; that is, it must be a *causal* function of time. In order to recover the strict Hooke's law, $t_{ij} = c_{ijkl}u_{k,l}$ we need $c_{ijkl}(t) = c_{ijkl}\delta(t)$ (we are distinguishing here between c_{ijkl} unadorned, which has the units of stress, and $c_{ijkl}(t)$, which has the units of stress/time). In the frequency domain, using the convolution theorem,

$$t_{ij}(\omega) = c_{ijkl}(\omega)u_{i,j}(\omega) \qquad [34]$$

Because $c_{ijkl}(t)$ is a causal function, its Fourier transform

$$c_{ijkl}(\omega) = \int_0^{\infty} c_{ijkl}(t)\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t \qquad [35]$$

will be analytic, that is, will have no singularities, in the lower half of the complex ω-plane, as the integral [35] will converge unconditionally in the case that ω possesses a negative imaginary part. From eqn [35] $c_{ijkl}(\omega)^* = c_{ijkl}(-\omega^*)$. For our purposes here, the key conclusion is that *in the frequency domain*, it makes virtually no difference to the theory whether the material is hyperelastic, or viscoelastic, as we have simply everywhere to substitute $c_{ijkl}(\omega)$ for c_{ijkl}. In fact there is even no need to introduce a new notation, but only to remember that now c_{ijkl} can represent a complex quantity depending on ω and analytic in the lower half of the complex ω-plane. When writing equations in the time domain, we have to remember that c_{ijkl} can be a convolution *operator*, acting on the strain. (It may be remarked that the above derivation of the equations of motion, based on Hamilton's principle, is in need of modification if $E(\mathbf{x}, \boldsymbol{\epsilon})$ does not exist. We do not quite know how to do this, but a monograph by Biot (1965) discusses the use of variational principles in the presence of anelastic effects.) Kanamori and Anderson (1977), and references cited therein, is a good source for further information on this topic.

1.03.2.5 Final Equation of Motion

It is often useful to summarize the equations and the boundary conditions by a single simple equation:

$$(\mathcal{H} + \rho^0\partial_t^2)\mathbf{u} = \mathbf{f} \qquad [36]$$

where $\mathcal{H}$ represents the integro-differential operator corresponding to the left side of eqn [26], omitting the term in $\rho^0\ddot{\mathbf{u}}$. Here, ϕ^1 is thought of as a functional of $\mathbf{u}$, that is, as the solution of Poisson's equation [23], corresponding to a given $\mathbf{u}(\mathbf{x}, t)$, together with the boundary conditions relating to ϕ^1 in eqn [25]. Thus, $\mathcal{H}\mathbf{u}$ incorporates the solution of eqn [23]. In the attenuating case, $\mathcal{H}$ also includes the time-domain convolutions arising from the viscoelastic rheology.

1.03.3 Spherical Harmonics and Generalized Spherical Harmonics

Free oscillations involve the motion of the whole Earth, so we need to solve the equations of motion in spherical coordinates. The reduction of these equations in spherical coordinates is most easily accomplished through the use of the generalized spherical harmonic formalism (Phinney and Burridge, 1973). These enable any tensor field to be readily expanded in spherical harmonics, facilitating the derivation of all modal equations in spherical harmonics. Here, we describe how this formalism is used, giving some key results without derivation. We shall use a standard set of Cartesian coordinates (x, y, z) and spherical coordinates (r, θ, ϕ) related by

$$\begin{aligned} x_1 &= x = r\sin\theta\cos\phi, \\ x_2 &= y = r\sin\theta\sin\phi, \\ x_3 &= z = r\cos\theta \end{aligned} \qquad [37]$$

Unit vectors in the coordinate directions are given by

$$\begin{aligned} \hat{\mathbf{r}} &= [\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta], \\ \hat{\boldsymbol{\theta}} &= [\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta], \\ \hat{\boldsymbol{\phi}} &= [-\sin\phi, \cos\phi, 0] \end{aligned} \qquad [38]$$

Spherical components of vectors and tensors will be written, for example, $u_\theta = u_k\hat{\theta}_k, t^0_{r\phi} = t^0_{ij}\hat{r}_i\hat{\phi}_j$.

1.03.3.1 Spherical Harmonics

We define the complex spherical harmonics following Edmonds (1960)

$$Y_l^m(\theta,\phi) = (-1)^m\left[\frac{(l-m)!}{(l+m)!}\right]^{(1/2)} P_l^m(\cos\theta)\mathrm{e}^{\mathrm{i}m\phi} \qquad [39]$$

where angular order $l = 0, 1, 2, \cdots$, azimuthal order $m = -l, -l+1, \cdots, l$ and $P_l^m(x)$ are the associated Legendre functions

$$P_l^m(x) = \frac{(1-x^2)^{m/2}}{2^l l!}\frac{\mathrm{d}^{l+m}}{\mathrm{d}x^{l+m}}(x^2-1)^l \qquad [40]$$

The spherical harmonics Y_l^m satisfy the orthogonality relation:

$$\int_{-\pi}^{\pi}\int_0^{\pi} Y_{l'}^{m'}(\theta,\phi)^* Y_l^m(\theta,\phi)\sin\theta\,\mathrm{d}\theta\mathrm{d}\phi = \delta_{l'l}\delta_{m'm} \qquad [41]$$

Figure 4 shows examples of the surface expression of the first few spherical harmonics $Y_l^m(\theta,\phi)$. The number of nodal lines in the θ-direction is given by $l-m$, so for $m=0$ there will be l nodal lines in the θ-direction. The number of nodal lines in the ϕ-direction is given by $2m$, that is, for $m=0$ there are no nodal lines in the ϕ-direction.

1.03.3.2 Generalized Spherical Harmonics

The prescription provided by the generalized spherical harmonic formalism is first to define the *spherical contravariant components* of the vectors and tensors that appear, and then to expand their dependence on (θ,ϕ) in terms of complete sets of functions appropriate to the particular component. For a tensor of rank p, having spherical components $s_{i_1 i_2 \cdots i_p}$, spherical contravariant components are defined by

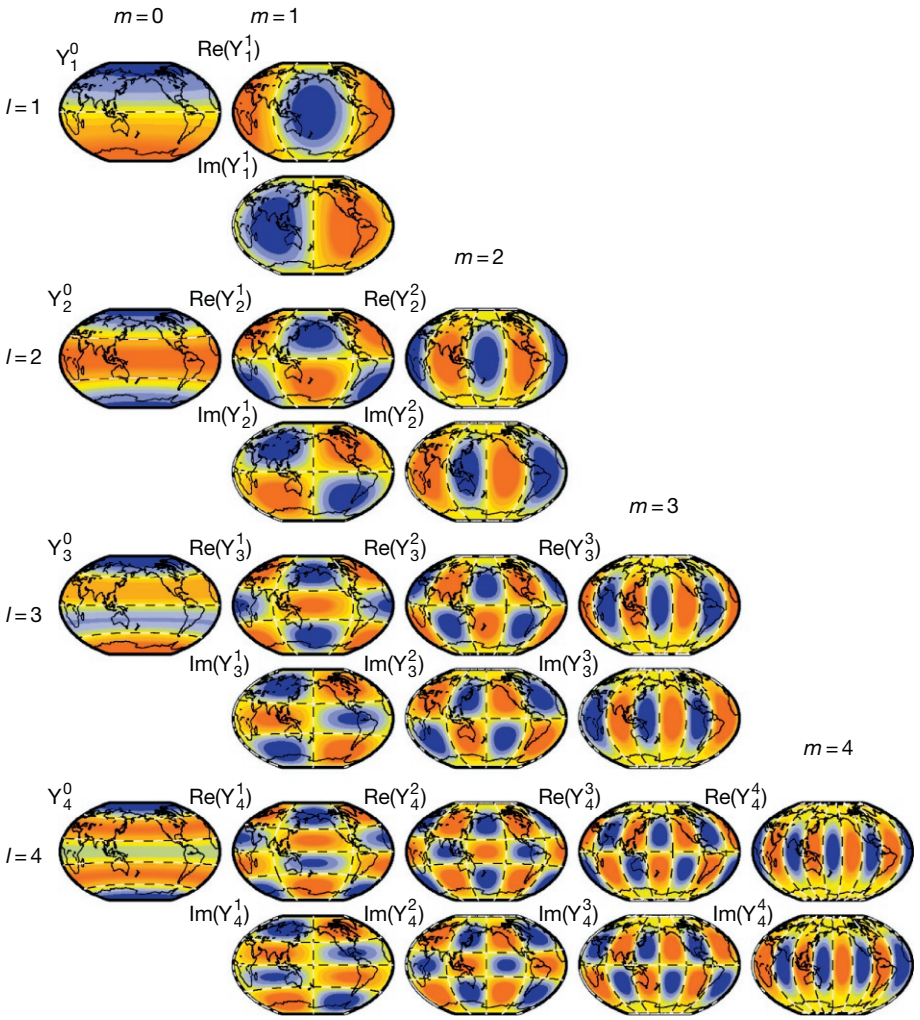

Figure 4 Spherical harmonics Y_l^m, showing real and imaginary parts for $m \geq 1$, for angular order $l = 1 - 4$. Dashed lines indicate the zero value contour, that is, the 'nodal lines' of the spherical harmonic. Blue is positive and red is negative.

$$s^{\alpha_1\alpha_2\cdots\alpha_p} = C^{\dagger\alpha_1 i_1} C^{\dagger\alpha_2 i_2} \times \cdots \times C^{\dagger\alpha_p i_p} s_{i_1 i_2 \cdots i_p} \qquad [42]$$

where indices i_k label the spherical components $i_k \in \{r, \theta, \phi\}$ and where indices α_k take values $\alpha_k \in \{-1, 0, +1\}$; the non-vanishing coefficients $C^{\dagger\alpha i}$ are $C^{\dagger 0r} = 1$, $C^{\dagger\pm 1\theta} = \mp 2^{-1/2}$, $C^{\dagger\pm 1\phi} = 2^{-1/2} i$. The inverse transformation, from spherical contravariant components to spherical components is

$$s_{i_1 i_2 \cdots i_p} = C_{i_1\alpha_1} C_{i_2\alpha_2} \times \cdots \times C_{i_p\alpha_p} s^{\alpha_1\alpha_1\cdots\alpha_p} \qquad [43]$$

with $C_{i\alpha} = (C^{\dagger\alpha i})^*$. The spherical harmonic basis, $Y_l^{Nm}(\theta, \phi)$ appropriate for each contravariant component is determined by the sum $N = \alpha_1 + \alpha_2 \cdots \alpha_p$ of its indices. Thus, we expand

$$s^{\alpha_1\alpha_1\cdots\alpha_p} = \sum_{lm} s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p}(r) Y_l^{Nm}(\theta, \phi) \quad \text{with } N = \alpha_1 + \alpha_1 + \cdots + \alpha_p \qquad [44]$$

where summations over l and m are for integers $l = 0, 1, \ldots, \infty$, $m = -l, -l+1, \ldots, l$. $Y_l^{Nm}(\theta, \phi)$ are the generalized spherical harmonics:

$$Y_l^{Nm}(\theta, \phi) = P_l^{Nm}(\cos\theta) e^{im\phi} = d_{Nm}^{(l)}(\theta) e^{im\phi} \qquad [45]$$

The *real* quantities $d_{Nm}^{(l)}(\theta) = P_l^{Nm}(\cos\theta)$ are rotation matrix elements employed in the quantum mechanical theory of angular momentum (Edmonds, 1960); thus Y_l^{Nm} vanish for N or m outside the range $-l$ to l. The spherical harmonic degree l characterizes a group representation of the rotation group; as a consequence, tensor fields that are spherically symmetric have only the term with $l = 0$, $N = 0$, $m = 0$. The property of the rotation matrix elements

$$d_{Nm}^{(l)}(0) = \begin{cases} 1 & \text{if } m = N \text{ and } l \geq |N| \\ 0 & \text{otherwise} \end{cases} \qquad [46]$$

is a very useful one, for example, for calculations of source excitation coefficients, when it is required to evaluate spherical harmonic expressions for $\theta = 0$ (see the succeeding text). Equation [46] says that regarded as $(2l+1) \times (2l+1)$ matrix, having row index N and column index m, $d_{Nm}^{(l)}(0)$ is the unit matrix. Matrices $d_{Nm}^{(l)}(\theta)$ have symmetries $d_{-N-m}^{(l)}(\theta) = d_{mN}^{(l)}(\theta) = (-1)^{m-N} d_{Nm}^{(l)}(\theta)$, from which follows the relation $Y_l^{Nm}(\theta, \phi)^* = (-1)^{m-N} Y_l^{-N-m}(\theta, \phi)$, where * denotes the complex conjugate.

Y_l^{Nm} satisfy the orthogonality relation

$$\int_{-\pi}^{\pi}\int_{0}^{\pi} Y_{l'}^{Nm'}(\theta,\phi)^* Y_l^{Nm}(\theta,\phi)\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi = \frac{4\pi}{2l+1}\delta_{l'l}\delta_{m'm} \quad [47]$$

Other normalizations for the spherical harmonics have frequently been used in the literature. The generalized spherical harmonics can be reduced to completely normalized spherical harmonics using $N=0$ (see eqn [41]), resulting in $Y_l^m(\theta,\phi) = v_l Y_l^{0m}$ where $v_l \equiv \sqrt{(2l+1)/4\pi}$. In this chapter, we shall adopt the same conventions as in the paper by Phinney and Burridge (1973) for the generalized spherical harmonics, using the explicit form $v_l Y_l^{0m}$ when completely normalized spherical harmonics are needed. Thus, the expansion coefficients in eqn [44] can be written

$$s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p}(r) = \frac{2l+1}{4\pi}\int_{-\pi}^{\pi}\int_{0}^{\pi} Y_l^{Nm}(\theta,\phi)^* s^{\alpha_1\alpha_1\cdots\alpha_p}\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \quad \text{with } N=\alpha_1+\alpha_1+\cdots+\alpha_p \quad [48]$$

The following is the key property of the generalized spherical harmonics under differentiation:

$$\left(\pm\partial_\theta + i\csc\theta\,\partial_\phi\right) Y_l^{Nm} = \sqrt{2}\,\Omega_{\pm N}^{l} Y_l^{N\mp 1 m} - N\cot\theta\, Y_l^{Nm} \quad [49]$$

which leads to the following rule for the expansion coefficients of the gradient of a tensor:

$$\left.\begin{aligned} s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p|0} &= \frac{\mathrm{d}}{\mathrm{d}r} s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p} \\ s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p|\pm} &= r^{-1}\Omega_{\mp N}^{l} s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p} - r^{-1}\begin{pmatrix}\text{the sum of the terms}\\ \text{obtained from } s_{lm}^{\alpha_1\alpha_1\cdots\alpha_p}\\ \text{by adding } \pm 1 \text{ to each}\\ \text{of } \alpha_1\alpha_1\cdots\alpha_p \text{ in turn,}\\ \text{omitting any terms for}\\ \text{which the resulting}\\ \text{index } \alpha_k \pm 1 \notin \{-1,0,1\}\end{pmatrix} \end{aligned}\right\} \quad [50]$$

where $\Omega_N^l \equiv [(l+N)(l-N+1)/2]^{1/2}$ and $N \equiv \alpha_1+\alpha_2+\cdots+\alpha_p$. The notation $s_{lm}^{\alpha_1\alpha_2\ldots\alpha_p|\alpha_{p+1}}$ is used to denote the expansion coefficients of the spherical contravariant components of the tensor having Cartesian components $s_{i_1 i_2\cdots i_p, i_{p+1}}$. Contraction over contravariant indices is carried out using the metric tensor $g_{\alpha_1\alpha_2} = C_{i\alpha_1}C_{i\alpha_2}$, which has nonvanishing entries $g_{00}=1$, $g_{-+}=g_{+-}=-1$. Thus, for example, the expansion coefficients of the divergence of a tensor $t_i = s_{ij,j}$, say, is given by

$$t_{lm}^{\alpha} = -s_{lm}^{\alpha+|-} + s_{lm}^{\alpha 0|0} - s_{lm}^{\alpha-|+} = \begin{cases} -s_{lm}^{-+|-} + s_{lm}^{-0|0} - s_{lm}^{--|+} & \alpha=-1 \\ -s_{lm}^{0+|-} + s_{lm}^{00|0} - s_{lm}^{0-|+} & \alpha=0 \\ -s_{lm}^{++|-} + s_{lm}^{+0|0} - s_{lm}^{+-|+} & \alpha=1 \end{cases}$$

$$= \begin{cases} -\frac{1}{r}\left(\Omega_0^l s_{lm}^{-+} - s_{lm}^{-0}\right) + \frac{\mathrm{d}}{\mathrm{d}r}s_{lm}^{-0} - \frac{1}{r}\left(\Omega_2^l s_{lm}^{--} - s_{lm}^{0-} - s_{lm}^{-0}\right) & \alpha=-1 \\ -\frac{1}{r}\left(\Omega_1^l s_{lm}^{0+} - s_{lm}^{-+} - s_{lm}^{00}\right) + \frac{\mathrm{d}}{\mathrm{d}r}s_{lm}^{00} - \frac{1}{r}\left(\Omega_1^l s_{lm}^{0-} - s_{lm}^{+-} - s_{lm}^{00}\right) & \alpha=0 \\ -\frac{1}{r}\left(\Omega_2^l s_{lm}^{++} - s_{lm}^{0+} - s_{lm}^{+0}\right) + \frac{\mathrm{d}}{\mathrm{d}r}s_{lm}^{+0} - \frac{1}{r}\left(\Omega_0^l s_{lm}^{+-} - s_{lm}^{+0}\right) & \alpha=1 \end{cases} \quad [51]$$

The major advantage of this formalism is that, in a spherically symmetric system, it enables vector and tensor relations to be transformed into relations for spherical harmonic coefficients, by the application of a straightforward set of rules. Importantly, the resulting relations (i) are true for each value of l and m separately and (ii) are the same for each spherical harmonic order m.

1.03.3.3 Wigner 3-j Symbols

The treatment of aspherical systems requires results for the products of spherical harmonic expansions. It can be shown that

$$Y_{l_1}^{N_1 m_1} Y_{l_2}^{N_2 m_2} = (-1)^{N_1+N_2-m_1-m_2}\sum_{l=|l_1-l_2|}^{l_1+l_2}(2l+1) \times \begin{pmatrix} l & l_1 & l_2 \\ -N_1-N_2 & N_1 & N_2 \end{pmatrix} \times \begin{pmatrix} l & l_1 & l_2 \\ -m_1-m_2 & m_1 & m_2 \end{pmatrix} Y_l^{N_1+N_2\, m_1+m_2} \quad [52]$$

Where the so-called *Wigner 3-j symbols* are the (real) quantities arising in the theory of the coupling of angular momentum in quantum mechanics (see Edmonds, 1960). These satisfy

$$\begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = 0 \quad \text{unless:}$$
$$|l_2-l_3| \le l_1,\ |l_3-l_1| \le l_2,\ |l_1-l_2| \le l_3,$$
any one of which implies the other two
$$|m_1| \le l_1,\ |m_2| \le l_2,\ |m_3| \le l_3,$$
$$m_1+m_2+m_3 = 0 \quad [53]$$

The *3-j* symbol is symmetric under even permutations of its columns, and either symmetric or antisymmetric under odd permutations, depending upon whether $l_1+l_2+l_3$ is even or odd. This has the consequence that if the sum of the l's is odd and if the m's are zero, the *3-j* symbol is 0. Equation [52] leads to the following result for the spherical harmonic coefficients of the product of two tensor fields; suppose that $c_{i_1 i_2\cdots i_p j_1 j_2\cdots j_q} = \alpha_{i_1 i_2\cdots i_p} b_{j_1 j_2\cdots j_q}$; then

$$c_{lm}^{\alpha_1\alpha_2\cdots\alpha_p\beta_1\beta_2\cdots\beta_q} = (-1)^{N_1+N_2-m} \times \sum_{l_1 l_2 m_1}\begin{pmatrix} l & l_1 & l_2 \\ -N_1-N_2 & N_1 & N_2 \end{pmatrix} \times \begin{pmatrix} l & l_1 & l_2 \\ -m & m_1 & m-m_1 \end{pmatrix} a_{l_1 m_1}^{\alpha_1\alpha_2\cdots\alpha_p} b_{l_2 m-m_1}^{\beta_1\beta_2\cdots\beta_q} \quad [54]$$

The summations here are over all values of l, l_1, m_1; however, it is a *finite* sum by virtue of the fact that the terms vanish for values outside the ranges specified in eqn [53].

1.03.3.4 Application: Point Force Distribution

As an application of the spherical harmonic formalism, here we consider the expansion of the point force distribution [32] in spherical harmonics. It will be sufficient to locate the source at time $t_s=0$ and at a point on the positive z-axis, that is, at $x=0$, $y=0, z=r_s$, where r_s is the source radius. Because $\theta=0$ is a singular point in the spherical coordinate system, we shall consider the limit as the source approaches the 'pole,' $\theta_s=0$, along the 'meridian,' $\phi_s=0$. In the frequency domain, eqn [32] becomes

$$f_i=\frac{1}{i\omega}\left(F_i-M_{ij}\partial_j\right)r^{-2}\csc\theta\,\delta(\theta-\theta_s)\,\delta(\phi)\delta(r-r_s) \qquad [55]$$

In the limiting process, $\theta_s\to 0$, we shall take F_i, M_{ij} to have constant spherical components F_ϕ, M_{rr}, $M_{r\theta}$, etc. As $\theta_s\to 0$, the $\hat{\boldsymbol{\theta}}$, $\hat{\phi}$, and $\hat{r}$ directions end up pointing along the x, y, z directions, respectively, of the global Cartesian coordinate system (e.g., see eqn [38]), and thus although $\hat{\boldsymbol{\theta}}, \hat{\phi}$ are undefined at $\theta=0$, we can nevertheless interpret the spherical components F_ϕ, $M_{r\theta}$, etc. as representing the components F_y, M_{zx}, etc. of the point force and moment tensor in the global Cartesian system. Let χ represent the expression $\chi=(i\omega)^{-1}r^{-2}\csc\theta\delta(\theta-\theta_s)\delta(\phi)\delta(r-r_s)$, so that [55] can be written: $f_i=F_i\chi-\partial_i M_{ij}\chi$. The spherical contravariant components of F_i and M_{ij}, using a matrix representation of eqn [43], are given by

$$\begin{bmatrix}F^-\\F^0\\F^+\end{bmatrix}=\begin{pmatrix}\frac{1}{\sqrt{2}}&\frac{i}{\sqrt{2}}&0\\0&0&1\\-\frac{1}{\sqrt{2}}&\frac{i}{\sqrt{2}}&0\end{pmatrix}\begin{bmatrix}F_\theta\\F_\phi\\F_r\end{bmatrix},$$

$$\begin{pmatrix}M^{--}&M^{-0}&M^{-+}\\M^{0-}&M^{00}&M^{0+}\\M^{+-}&M^{+0}&M^{++}\end{pmatrix}=\begin{pmatrix}\frac{1}{\sqrt{2}}&\frac{i}{\sqrt{2}}&0\\0&0&1\\-\frac{1}{\sqrt{2}}&\frac{i}{\sqrt{2}}&0\end{pmatrix}$$

$$\times\begin{pmatrix}M_{\theta\theta}&M_{\theta\phi}&M_{\theta r}\\M_{\phi\theta}&M_{\phi\phi}&M_{\phi r}\\M_{r\theta}&M_{r\phi}&M_{rr}\end{pmatrix}\begin{pmatrix}\frac{1}{\sqrt{2}}&0&-\frac{i}{\sqrt{2}}\\\frac{i}{\sqrt{2}}&0&\frac{i}{\sqrt{2}}\\0&1&0\end{pmatrix} \qquad [56]$$

The spherical harmonic expansion coefficients of $F^\alpha\chi$ and $M^{\alpha_1\alpha_2}\chi$, for which we use the notation $(F^\alpha\chi)_{lm}$, $(M^{\alpha_1\alpha_2}\chi)_{lm}$, are immediate using [48], integrating out the δ-functions contained in χ. We obtain

$$\begin{aligned}(F^\alpha\chi)_{lm}&=\frac{2l+1}{4\pi i\omega}\frac{\delta(r-r_s)}{r^2}Y_l^{\alpha m}(\theta_s,0)^*F^\alpha\\&=\frac{2l+1}{4\pi i\omega}\frac{\delta(r-r_s)}{r^2}d^{(l)}_{\alpha m}(\theta_s)F^\alpha\\&=\begin{cases}\dfrac{2l+1}{4\pi i\omega}\dfrac{\delta(r-r_s)}{r^2}F^\alpha & \text{if } m=\alpha \text{ and } l\ge|\alpha|\\0 & \text{otherwise}\end{cases}\end{aligned} \qquad [57]$$

where θ_s has been set to 0 in the second line, using [46]. Similarly,

$$\begin{aligned}(M^{\alpha_1\alpha_2}\chi)_{lm}&=\frac{2l+1}{4\pi i\omega}\frac{\delta(r-r_s)}{r^2}Y_l^{\alpha_1+\alpha 2m}(\theta_s,0)^*M^{\alpha_1\alpha_2}\\&=\frac{2l+1}{4\pi i\omega}\frac{\delta(r-r_s)}{r^2}d^{(l)}_{\alpha_1\alpha 2m}(\theta_s)M^{\alpha_1\alpha_2}\\&=\begin{cases}\dfrac{2l+1}{4\pi i\omega}\dfrac{\delta(r-r_s)}{r^2}M^{\alpha_1\alpha_2} & \text{if } m=\alpha_1+\alpha_2 \text{ and } l\ge|\alpha_1+\alpha_2|\\0 & \text{otherwise}\end{cases}\end{aligned} \qquad [58]$$

To complete the evaluation of the coefficients f^α_{lm} corresponding to eqn [55], we need to find the spherical harmonic coefficients of the divergence of the field represented in eqn [58], for which we can employ eqn [51]; we find

$$\begin{bmatrix}f^-_{lm}\\f^0_{lm}\\f^+_{lm}\end{bmatrix}=\begin{bmatrix}(F^-\chi)_{lm}+(M^{-+}\chi)^{|-}_{lm}-(M^{-0}\chi)^{|0}_{lm}+(M^{--}\chi)^{|+}_{lm}\\(F^0\chi)_{lm}+(M^{0+}\chi)^{|-}_{lm}-(M^{00}\chi)^{|0}_{lm}+(M^{0-}\chi)^{|+}_{lm}\\(F^+\chi)_{lm}+(M^{++}\chi)^{|-}_{lm}-(M^{+0}\chi)^{|0}_{lm}+(M^{+-}\chi)^{|+}_{lm}\end{bmatrix} \qquad [59]$$

$$=\frac{2l+1}{4\pi i\omega}\times\begin{cases}\begin{bmatrix}M^{--}\Omega_2^l r^{-1}\\0\\0\end{bmatrix}\dfrac{\delta(r-r_s)}{r^2} & m=-2, l\ge 2\\\begin{bmatrix}F^- - M^{-0}\partial_r-2M^{-0}r^{-1}-M^{0-}r^{-1}\\M^{0-}\Omega_1^l r^{-1}\\0\end{bmatrix}\dfrac{\delta(r-r_s)}{r^2} & m=-1, l\ge 1\\\begin{bmatrix}M^{-+}\Omega_0^l r^{-1}\\F_0-M^{00}\partial_r-2M^{00}r^{-1}-M^{-+}r^{-1}-M^{+-}r^{-1}\\M^{+-}\Omega_0^l r^{-1}\end{bmatrix}\dfrac{\delta(r-r_s)}{r^2} & m=0\\\begin{bmatrix}0\\M^{0+}\Omega_1^l r^{-1}\\F^+ - M^{+0}\partial_r-2M^{+0}r^{-1}-M^{0+}r^{-1}\end{bmatrix}\dfrac{\delta(r-r_s)}{r^2} & m=1, l\ge 1\\\begin{bmatrix}0\\0\\M^{++}\Omega_2^l r^{-1}\end{bmatrix}\dfrac{\delta(r-r_s)}{r^2} & m=2, l\ge 2\end{cases} \qquad [60]$$

These are the spherical harmonic coefficients of the force distribution [32] which will be needed in the following sections. The coefficients are zero for $|m|>2$.

1.03.4 The Green's Function for the Spherically Symmetric Earth

1.03.4.1 Reduction of the General Equations to the Spherically Symmetric Case

We consider here the case in which the Earth model is spherically symmetric. In this case the equations of motion are separable in spherical coordinates, and thus can be solved by reduction to ordinary differential equations. Since deviations from spherical symmetry are relatively small in the Earth, they can subsequently be treated by perturbation theory. We assume that in the initial equilibrium configuration the stress is hydrostatic, that is

$$t_{ij}^0 = -p^0\delta_{ij} \qquad [61]$$

Spherical symmetry requires that ρ^0, ϕ^0, p^0 are functions only of r. The gravitational acceleration is $g_i^0 = \phi_{,i}^0 = g^0(r)\hat{r}_i$, and the equilibrium equations [19], [20] and the boundary conditions in eqn [25] have the solutions:

$$\begin{aligned} g^0(r) &= \frac{4\pi G}{r^2}\int_0^r \rho^0(r)\mathrm{d}r,\\ \phi^0(r) &= -\int_r^\infty g^0(r)\mathrm{d}r = \frac{-GM}{a} - \int_r^a g^0(r)\mathrm{d}r,\\ p^0(r) &= \int_r^a \rho^0(r)g^0(r)\mathrm{d}r \end{aligned} \qquad [62]$$

where a is the radius of the Earth and M is the Earth's total mass $M = 4\pi\int_0^a r^2\rho^0(r)\mathrm{d}r$. The equations of motion [26] with [17] and [20] can be put into the form

$$\rho\left[-\omega^2 u_i - u_{k,k}g_i + \varphi_{,i} + (u_k g_k)_{,i}\right] - \left(C_{ijkl}u_{k,l}\right)_{,j} = f_i \qquad [63]$$

$$\left(\varphi_{,k} + 4\pi G\rho u_k\right)_{,k} = 0 \qquad [64]$$

Where we have introduced the effective stiffness tensor

$$C_{ijkl} = c_{ijkl} + p^0\left(\delta_{ij}\delta_{kl} - \delta_{il}\delta_{jk} - \delta_{ik}\delta_{jl}\right) \qquad [65]$$

which has the same symmetries (eqn [14]) as does c_{ijkl}. In eqns [63], [64], and in subsequent equations, we drop the superscripts in ρ^0, g^0, using simply ρ, g for these quantities. We also use the notation φ in place of ϕ^1. The applied force distribution f_i will be taken to be that given in eqns [32] and [55], having the spherical harmonic coefficients [60].

In a spherically symmetric model, the tensor field C_{ijkl} must be a spherically symmetric tensor field, and therefore its spherical harmonic expansion will have terms only of spherical harmonic degree $l=0$. Its spherical contravariant components $C^{\alpha_1\alpha_2\alpha_3\alpha_3} = C_{00}^{\alpha_1\alpha_2\alpha_3\alpha_3}$ must have indices that sum to zero, and must also satisfy the usual elastic tensor symmetries [14]. It is easily seen that there are only five independent components that satisfy these requirements: C^{0000}, C^{+-00}, C^{+0-0}, C^{++--}, C^{+-+-}, which must be real (in the nonattenuating case) in order that the spherical components C_{ijkl} are real. Conventionally, these are designated (Love, 1927; Takeuchi and Saito, 1972)

$$\begin{aligned} C^{0000} &= C(r),\\ C^{+-00} &= -F(r),\\ C^{+0-0} &= -L(r),\\ C^{++--} &= 2N(r),\\ C^{+-+-} &= A(r) - N(r) \end{aligned} \qquad [66]$$

the independent spherical components being (using eqn [43])

$$\begin{aligned} &C_{rrrr} = C(r), \quad C_{rr\theta\theta} = C_{rr\phi\phi} = F(r), \quad C_{r\theta r\theta} = C_{r\phi r\phi} = L(r),\\ &C_{\theta\phi\theta\phi} = N(r), \quad C_{\theta\theta\phi\phi} = A(r) - 2N(r), \quad C_{\theta\theta\theta\theta} = C_{\phi\phi\phi\phi} = A(r) \end{aligned} \qquad [67]$$

The mean *bulk modulus* κ and *shear modulus* μ can be defined by

$$\begin{aligned} \kappa &= \frac{1}{9}C_{iijj} = \frac{1}{9}(4A + C - 4N + 4F),\\ \mu &= \frac{1}{10}C_{ijij} - \frac{1}{30}C_{iijj} = \frac{1}{15}(A + C + 6L + 5N - 2F) \end{aligned} \qquad [68]$$

Other conventional notations are

$$\begin{aligned} \lambda &= \kappa - \frac{2}{3}\mu,\\ \upsilon_{\mathrm{PV}}^2 &= C/\rho,\\ \upsilon_{\mathrm{PH}}^2 &= A/\rho,\\ \upsilon_{\mathrm{SV}}^2 &= L/\rho,\\ \upsilon_{\mathrm{SH}}^2 &= N/\rho,\\ \eta &= F/(A - 2L) \end{aligned} \qquad [69]$$

where λ (and μ) are the Lame parameters, υ_{PV} and υ_{PH} are the vertical and horizontal polarized compressional wave velocities, and υ_{SV} and υ_{SH} are the vertical and horizontal polarized shear wave velocities. Thus, radial anisotropy (also called transverse isotropy) is allowed in a spherically symmetric model. In fact, the PREM model, which is commonly used in normal mode calculations, has radial anisotropy in the top 220 km. This feature is essential to explain the frequencies of Love and Rayleigh waves simultaneously. In the case that the material is *isotropic*, $A = C = \lambda + 2\mu = \kappa + \frac{4}{3}\mu$, $N = L = \mu$, and $\eta = 1$.

1.03.4.2 Derivation of the Radial Ordinary Differential Equations

Now we seek solutions u_i, φ of eqns [63] and [64] in terms of a spherical harmonic expansions. It is convenient to write

$$u_{lm}^- = \upsilon_l\Omega_0^l[V_{lm}(r) - iW_{lm}(r)] \qquad [70]$$

$$u_{lm}^0 = \upsilon_l U_{lm}(r) \qquad [71]$$

$$u_{lm}^+ = \upsilon_l\Omega_0^l[V_{lm}(r) + iW_{lm}(r)] \qquad [72]$$

where $\upsilon_l = \sqrt{(2l+1)/4\pi}$, as the '$U$, V, W' notation is almost universally used in the literature on long-period seismology. $U(r)$, $V(r)$, and $W(r)$ are the radial eigenfunctions which only depend on the radius. $U(r)$ is used to describe motion in the radial direction, while $V(r)$ and $W(r)$ are the tangential scalars. The expansion corresponding to eqn [44] is then equivalent to the vector spherical harmonic representation (e.g., Morse and Feshbach, 1953):

$$
\begin{aligned}
u_r &= \sum\nolimits_{lm} U_{lm}(r) v_1 Y_l^{0m}(\theta,\phi) \\
u_\theta &= \sum\nolimits_{lm} \left[V_{lm}(r)\partial_\theta + W_{lm}(r)\csc\theta\partial_\theta\right] v_1 Y_l^{0m}(\theta,\phi) \\
u_\phi &= \sum\nolimits_{lm} \left[V_{lm}(r)\csc\theta\partial_\phi - W_{lm}(r)\partial_\theta\right] v_1 Y_l^{0m}(\theta,\phi)
\end{aligned}
\qquad [73]
$$

where Y_l^{0m} are the spherical harmonics Y_l^m as defined in eqn [41]. We shall abbreviate such vector spherical armonic expansions using the shorthand

$$
u_i :\rightarrow \begin{bmatrix} U_{lm}(r) \\ V_{lm}(r) \\ W_{lm}(r) \end{bmatrix}
\qquad [74]
$$

meaning that the vector field having Cartesian components u_i is expressible in vector spherical harmonics as in eqn [73]. We shall also suppress the suffices l, m and the explicit dependence upon r, writing simply U, V, W.

The spherical harmonic expansion of f_i can also be converted into this vector spherical harmonic notation. Using eqn [60] with eqn [56] we obtain:

$$
f_i :\rightarrow \frac{v_l}{i\omega}
\begin{cases}
\begin{bmatrix} \left(rF_r + M_{\theta\theta} + M_{\phi\phi}\right)\delta^{(0)}(r) - M_{rr}\delta^{(1)}(r) \\ \frac{1}{2}\left(-M_{\theta\theta} - M_{\phi\phi}\right)\delta^{(0)}(r) \\ \frac{1}{2}\left(-M_{\theta\phi} + M_{\phi\theta}\right)\delta^{(0)}(r) \end{bmatrix} & m = 0 \\
\begin{bmatrix} \frac{\zeta}{2}\left(\mp M_{r\theta} + iM_{r\phi}\right)\delta^{(0)}(r) \\ \frac{1}{2\zeta}\left(\mp rF_\theta + irF_\phi \pm M_{r\theta} - iM_{r\phi}\right)\delta^{(0)}(r) + \left(\mp M_{\theta r} - iM_{\phi r}\right)\delta^{(1)}(r) \\ \mp\frac{i}{2\zeta}\left(\mp rF_\theta + irF_\phi \pm M_{r\theta} - iM_{r\phi}\right)\delta^{(0)}(r) + \left(\mp M_{\theta r} - iM_{\phi r}\right)\delta^{(1)}(r) \end{bmatrix} & m = \pm 1 \\
\begin{bmatrix} 0 \\ \frac{1}{4\zeta}\sqrt{\zeta^2 - 2}\left(M_{\theta\theta} - M_{\phi\phi} \mp iM_{\theta\phi} \mp iM_{\phi\theta}\right)\delta^{(0)}(r) \\ \mp\frac{i}{4\zeta}\sqrt{\zeta^2 - 2}\left(M_{\theta\theta} - M_{\phi\phi} \mp iM_{\theta\phi} \mp iM_{\phi\theta}\right)\delta^{(0)}(r) \end{bmatrix} & m = \pm 2
\end{cases}
\qquad [75]
$$

where $\delta^{(0)}(r) = r^{-3}\delta(r - r_s)$ and $\delta^{(1)}(r) = r^{-2}\delta'(r - r_s)$, and where $\zeta = \sqrt{l(l+1)}$.

Using the spherical harmonic formalism, the vector spherical harmonic representation of the *radial tractions* is given by

$$
C_{ijkl}u_{k,l}\hat{r}_j \rightarrow \begin{cases} P = Fr^{-1}\left(2U - \zeta^2 V\right) + C\partial_r U \\ S = L(\partial_r V - r^{-1}V + r^{-1}U) \\ T = L(\partial_r W - r^{-1}W) \end{cases}
\qquad [76]
$$

where we have introduced traction scalars $P = P_{lm}(r)$, $S = S_{lm}(r)$, and $T = T_{lm}(r)$. Because the radial tractions are required to be continuous at interfaces between different regions of the model (from eqn [25]), it is usual to treat them as a new dependent variables, and to express the derivatives $\partial_r U$, $\partial_r V$, $\partial_r W$ in terms of them:

$$
\begin{aligned}
\partial_r U &= -r^{-1}FC^{-1}\left(2U - \zeta^2 V\right) + C^{-1}P \\
\partial_r V &= r^{-1}(V - U) + L^{-1}S \\
\partial_r W &= r^{-1}W + L^{-1}T
\end{aligned}
\qquad [77]
$$

The vector spherical harmonic expansion of the left side of eqn [63] becomes:

$$
f_i :\rightarrow \begin{cases} -\rho\omega^2 U + 2r^{-2}(A - N)\left(2U - \zeta^2 V\right) + \rho(\partial_r g - 2r^{-1}g)U + \zeta^2 r^{-1}\rho g V - \partial_r P + 2r^{-1}F\partial_r U - 2r^{-1}P + r^{-1}\zeta^2 S + \rho\partial_r\varphi \\ -\rho\omega^2 V - r^{-2}A\left(2U - \zeta^2 V + 2r^{-2}N(U - V)\right) + r^{-1}\rho(gU + \varphi) - \partial_r S - 3r^{-1}S - r^{-1}\partial_r U \\ -\rho\omega^2 W + r^{-2}N\left(\zeta^2 - 2\right)W - \partial_r T - 3r^{-1}T \end{cases}
\qquad [78]
$$

Thus, ordinary differential equations in r for U, V, W, P, S, T are obtained by equating these to the forcing terms in eqn [75]. In addition, the expansion coefficients of the perturbation in gravitational potential, $\varphi = \varphi_{lm}(r)$, are subject to equations derived from eqn [64]. The boundary conditions [25] require that φ and $\partial_r\varphi + 4\pi G\rho U$ are continuous throughout the model, and that φ vanishes at infinity. For a given spherical harmonic degree l the solutions of Laplace's equation tending to zero at infinity are proportional to $r^{-l-1}$and for this reason it is useful to define the new dependent variable $\psi = \partial_r\varphi + (l+1)r^{-1}\varphi + 4\pi G\rho U$, so that ψ is continuous throughout the model and vanishes at the surface. This leads to the following coupled equations for $\varphi_{lm}(r)$, $\psi_{lm}(r)$:

$$
\begin{aligned}
\partial_r\varphi &= \psi - (l+1)r^{-1}\varphi - 4\pi G\rho U \\
\partial_r\psi &= 4\pi G\rho r^{-1}\left(\zeta^2 V - (l+1)U\right) + r^{-1}(l-1)\psi
\end{aligned}
\qquad [79]
$$

Thus, the complete boundary value problem for $\mathbf{u}(\mathbf{x}, \omega)$ is to find, for each l, m, solutions $U_{lm}(r), V_{lm}(r), W_{lm}(r), \phi_{lm}(r)$, $P_{lm}(r)$, $S_{lm}(r)$, $T_{lm}(r)$, $\psi_{lm}(r)$, satisfying (i) equality of the

expressions in eqns [75] and [78], (ii) eqns [77] – in essence definitions of P, S, T, and (iii) eqns [79] governing the self-gravitation.

The equations governing W and T are independent of the others, and so the problem naturally separates into the problems for the six functions U, V, ϕ, P, S, ψ, relating to *spheroidal* motion, and for the two functions W, T, relating to *toroidal* motion. These are related to spheroidal and toroidal modes (see **Figure 5**). Spheroidal modes involve both radial and tangential motion, just like P–SV body waves. Toroidal modes only involve tangential motion. Examples of U, V, W for fundamental spheroidal and toroidal modes are given in **Figure 6**. In a fluid region, shear stresses are required to vanish, resulting in $S=0$ and $L=N=0$, $A=C=F$; the second equation in [76] drops out and the equation arising from the second of eqn [78] can be solved for V, $V=(gU-P/\rho+\varphi)/r\omega^2$, and thus S and V can be eliminated from the equations, resulting in equations for the four remaining variables U, ϕ, P, ψ. The case $l=0$ leads to purely radial motion, $V=0$ with $\psi=\varphi/r$, $\mathrm{d}\varphi/\mathrm{d}r=-4\pi G\rho U$, and the effective equations involve only U, P. Examples of U for radial modes are given in **Figure 7**.

The equations are most conveniently stated as matrix differential equations, by rearranging them to give the radial derivatives of either the six (for spheroidal modes in a solid), four (for spheroidal modes in a fluid), or two functions (for radial and toroidal modes) to be determined in terms of the functions themselves. Here, we define *stress-displacement vectors* as follows:

$$\text{Spheroidal solid}: \ \mathbf{y}^{\mathrm{Ss}}=\begin{bmatrix} rU \\ r\zeta V \\ r\phi \\ rP \\ r\zeta S \\ r\psi/4\pi G \end{bmatrix},$$

$$\text{Spheroidal fluid}: \ \mathbf{y}^{\mathrm{Sf}}=\begin{bmatrix} rU \\ r\phi \\ rp \\ r\psi/4\pi G \end{bmatrix},$$

$$\text{Radial}: \ \mathbf{y}^{\mathrm{R}}=\begin{bmatrix} rU \\ rP \end{bmatrix},$$

$$\text{Toroidal solid}: \ \mathbf{y}^{\mathrm{Ts}}=\begin{bmatrix} r\zeta W \\ r\zeta T \end{bmatrix} \qquad [80]$$

In each case, the resulting equations take the form:

$$\frac{\mathrm{d}\mathbf{y}}{\mathrm{d}r}=\mathbf{A}\mathbf{y}+\mathbf{a}\delta(r-r_s)+\mathbf{b}\delta'(r-r_s) \qquad [81]$$

where the vectors $\mathbf{a}=\mathbf{a}(r, \omega, l, m)$, $\mathbf{b}=\mathbf{b}(r, \omega, l, m)$ represent the forcing or earthquake source and can be readily derived from eqn [75]. The matrices $\mathbf{A}=\mathbf{A}(r, \omega, l)$ can be written in terms of submatrices in the form

$$\mathbf{A}=\begin{pmatrix} \mathbf{T} & \mathbf{K} \\ \mathbf{S} & -\mathbf{T}' \end{pmatrix} \qquad [82]$$

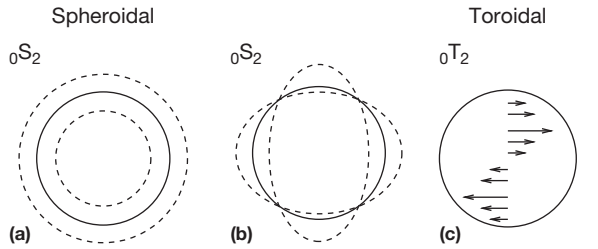

Figure 5 Oscillation patterns for (a) fundamental radial mode $_0S_0$, also called the 'breathing' mode, (b) fundamental spheroidal mode $_0S_2$ ($m=0$), also called the 'football' mode, and (c) fundamental toroidal mode $_0T_2$ ($m=0$).

where $\mathbf{K}$ and $\mathbf{S}$ are symmetric and where $\mathbf{T}'$ is the transpose of $\mathbf{T}$. The fact that the equations have this special form stems from the fact that they arise from a variational principle, and in fact are a case of Hamilton's canonical equations (Chapman and Woodhouse, 1981; Woodhouse, 1974). However, the usual variational derivations of the equations of motion neglect attenuation, and so it is interesting that this symmetry of the equations remains valid in the attenuating case. It plays an important part in methods of calculation normal modes (see the succeeding text), and also enables a complex version of the theory in attenuating media to be developed along the same lines. The specific forms of matrices $\mathbf{T}$, $\mathbf{K}$, $\mathbf{S}$ for spheroidal modes in solid regions are

$$\mathbf{T}^{\mathrm{Ss}}=\begin{pmatrix} (1-2F/C)/r & \zeta F/Cr & 0 \\ -\zeta/r & 2/r & 0 \\ -4\pi G\rho & 0 & -l/r \end{pmatrix}, \quad \mathbf{K}^{\mathrm{Ss}}=\begin{pmatrix} 1/C & 0 & 0 \\ 0 & 1/L & 0 \\ 0 & 0 & 4\pi G \end{pmatrix},$$

$$\mathbf{S}^{\mathrm{Ss}}=\begin{pmatrix} -\rho\omega^2+4(\gamma-\rho gr)/r^2 & \zeta(\rho gr-2\gamma)/r^2 & -\rho(l+1)/r \\ \zeta(\rho gr-2\gamma)/r^2 & -\rho\omega^2+\left[\zeta^2(\gamma+N)-2N\right]/r^2 & \rho\zeta/r \\ -\rho(l+1)/r & \rho\zeta/r & 0 \end{pmatrix} \qquad [83]$$

where $\gamma=A-N-F^2/C$. For spheroidal modes in fluid regions, $V=0$ and $S=0$ and so we have

$$\mathbf{T}^{\mathrm{Sf}}=\begin{pmatrix} \left(g\zeta^2/\omega^2r-1\right)/r & \zeta^2/\omega^2r^2 \\ -4\pi G\rho & -l/r \end{pmatrix}, \quad \mathbf{K}^{\mathrm{Sf}}=\begin{pmatrix} 1/C-\zeta^2/\rho\omega^2r^2 & 0 \\ 0 & 4\pi G \end{pmatrix},$$

$$\mathbf{S}^{\mathrm{Sf}}=\begin{pmatrix} -\rho\omega^2+\rho g\left(g\zeta^2/r\omega^2-4\right)/r & \rho\left(g\zeta^2/r\omega^2-l-1\right)/r \\ \rho\left(g\zeta^2/r\omega^2-l-1\right)/r & \rho\zeta^2/r^2\omega^2 \end{pmatrix} \qquad [84]$$

In the case of radial modes, we also have $\phi=0$ and $\psi=0$, reducing the equations to

$$\mathbf{T}^{\mathrm{R}}=((1-2F/C)/r), \quad \mathbf{K}^{\mathrm{R}}=(1/C), \quad \mathbf{S}^{\mathrm{R}}=\left(-\rho\omega^2+4(\gamma-\rho gr)/r^2\right) \qquad [85]$$

Finally, in the case of toroidal modes, we are only solving for W and T, leading to equations

$$\mathbf{T}^{\mathrm{Ts}}=(2/r), \quad \mathbf{K}^{\mathrm{Ts}}=(1/L), \quad \mathbf{S}^{\mathrm{Ts}}=\left(-\rho\omega^2+\left(\zeta^2-2\right)N/r^2\right) \qquad [86]$$

In the case that there is no forcing f_i, the equations reduce to the homogeneous system $\mathrm{d}\mathbf{y}/\mathrm{d}r=\mathbf{A}\mathbf{y}$, together with the usual

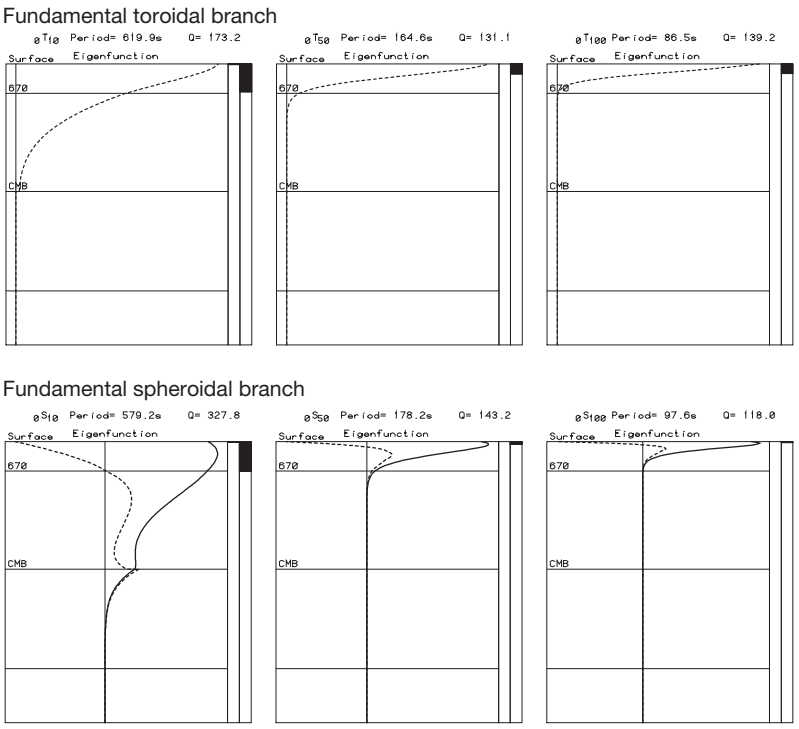

Figure 6 Eigenfunctions of selected toroidal and spheroidal fundamental modes ($n=0$). For the toroidal modes, the dashed lines show $W(r)$, and for spheroidal modes the dashed lines denote $V(r)$ and the solid lines $U(r)$. At high angular order l, the toroidal modes correspond to Love waves and the spheroidal modes to Rayleigh waves.

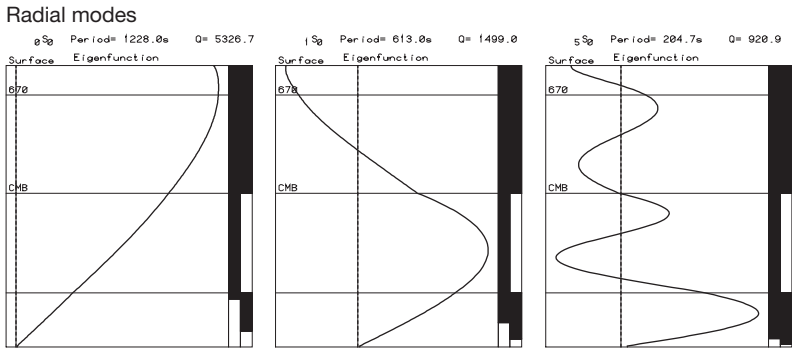

Figure 7 Eigenfunctions of selected radial modes ($l=0$). The solid lines show $U(r)$.

boundary conditions at the center of the Earth and at the surface. This is an eigenvalue problem for ω having solutions corresponding to the modes of *free oscillation*. The eigenvalues will be denoted by ω_k, where k is an index that incorporates the angular order l, the *overtone number* n and the mode type: spheroidal or toroidal. The modal multiplets are conventionally given the names ${}_nS_l$ for spheroidals and ${}_nT_l$ for toroidals. Overtone number is an index labeling the eigenfrequencies for a given l and for a given mode type, in increasing order. For radial modes, the overtone number equals the number of nodal lines along the radius (see Figure 7). Since the spherical harmonic order m does not enter into the equations, the modes are *degenerate*, meaning that there are $2l+1$ different eigenfunctions, $m=-l, -l+1, \ldots, l$ corresponding to the same given eigenvalue ω_k. The eigenfunctions will be denoted by $\mathbf{s}^{(km)}(\mathbf{x})$. These are the solutions $\mathbf{u}(\mathbf{x})$ given by eqn [73], for different values of m, but with the *same* scalar eigenfunctions $U(r)$, $V(r)$, $W(r)$, $\varphi(r)$. The set of $2l+1$ eigenfunctions, $\mathbf{s}^{(km)}(\mathbf{x})$, for a given eigenfrequency ω_k is said to constitute a *multiplet*. The eigenfunctions represent the spatial shape of a mode of free oscillation at frequency ω_k, because $\mathbf{s}^{(km)}(\mathbf{x})e^{i\omega_k t}$ is a solution of the complete dynamical equations in the absence of any forcing. Of course the eigenfunction is defined only up to an overall factor.

If the medium is attenuating, the eigenfrequencies will be complex, their (positive) imaginary parts determining the rate of decay of the mode with time. It is conventional to quantify this decay rate in terms of the 'Q' of the multiplet, Q_k, which is defined in such a way that the mode decays in amplitude by a factor $e^{-\pi/Q_k}$ per cycle. Therefore, $Q_k = \mathrm{Re}\,\omega_k / 2\mathrm{Im}\,\omega_k$, typically

a large number, indicating that the modes decay by a relatively small fraction in each cycle. Q has also been called the *quality factor*.

In the case of forcing, eqn [81] leads to solutions $\mathbf{y}(l, m, r)$ which are discontinuous at the source radius r_s. It can be shown that the discontinuity at r_s is given by (Hudson, 1969; Ward, 1980):

$$[\mathbf{y}]_{r=r_s-}^{r=r_s+} = \mathbf{s} = \mathbf{a} + \mathbf{A}\mathbf{b} - \frac{\mathrm{d}\mathbf{b}}{\mathrm{d}r} \qquad [87]$$

and thus the boundary value problem for $\mathbf{y}$ requires the solution of the homogeneous equation $\mathrm{d}\mathbf{y}/\mathrm{d}r = \mathbf{A}\mathbf{y}$ above and below the source, subject the conditions that the solution (i) is nonsingular at the center of the Earth, (ii) has vanishing traction components at the surface, and (iii) has the prescribed discontinuity $\mathbf{s}$ at the source radius r_s. The specific forms for the discontinuity vector $\mathbf{s}$, using [75] and [87], are (As described earlier, we are here considering the source to be located at $(\theta = \epsilon, \phi = 0)$, for some infinitesimal, positive ϵ; thus (F_θ, F_ϕ, F_r) coincide with (F_x, F_y, F_z) in the global Cartesian frame defined in eqn [37]. Similarly, $(M_{\theta\theta}, M_{\theta\phi}, \text{etc.})$ coincide with $(M_{xx}, M_{xy}, \text{etc.})$. If the source is located at a general colatitude θ_s and longitude ϕ_s, the results can be applied in a rotated frame in which the (θ, ϕ, r) components map into (South, East, Up), coordinate θ is epicentral distance and coordinate ϕ is azimuth of the receiver at the source, measured anticlockwise from South.)

$$\mathbf{s}^{\mathrm{Ss}} = \frac{v_l}{i\omega r_s^2} \times \begin{cases} \begin{bmatrix} r_s M_{rr}/C \\ 0 \\ 0 \\ -r_s F_r - M_{\theta\theta} - M_{\phi\phi} + 2M_{rr}F/C \\ \zeta\left(M_{\theta\theta} + M_{\phi\phi}\right)/2 - \zeta M_{rr}F/C \\ 0 \end{bmatrix} & l \geq 1, m = 0 \\ \begin{bmatrix} 0 \\ r_s\left(\mp M_{\theta r} + iM_{\phi r}\right)/2L \\ 0 \\ \zeta\left(\mp M_{\theta r} + iM_{\phi r} \pm M_{r\theta} - iM_{r\phi}\right)/2 \\ r_s\left(\pm F_\theta - iF_\phi\right)/2 - \left(\mp M_{\theta r} + iM_{\phi r} \pm M_{r\theta} - iM_{r\phi}\right)/2 \\ 0 \end{bmatrix} & l \geq 1, m = \pm 1 \\ \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \sqrt{\zeta^2 - 2}\left(-M_{\theta\theta} + M_{\phi\phi} \pm iM_{\theta\phi} \pm iM_{\phi\theta}\right)/4 \\ 0 \end{bmatrix} & l \geq 2, m = \pm 2 \end{cases} \qquad [88]$$

$$\mathbf{s}^{\mathrm{R}} = \frac{v_0}{i\omega r_s^2} \times \begin{bmatrix} r_s M_{rr}/C \\ -r_s F_r - M_{\theta\theta} - M_{\phi\phi} + 2M_{rr}F/C \end{bmatrix} \quad l = m = 0 \qquad [89]$$

$$\mathbf{s}^{\mathrm{Ts}} = \frac{v_l}{i\omega r_s^2} \times \begin{cases} \begin{bmatrix} 0 \\ \zeta\left(M_{\theta\phi} - M_{\phi\theta}\right)/2 \end{bmatrix} & l \geq 1, m = 0 \\ \begin{bmatrix} r_s\left(\pm M_{\phi r} + iM_{\theta r}\right)/2L \\ r_s\left(\mp F_\phi + iF_\theta\right)/2 + \left(\mp M_{\phi r} - iM_{\theta r} \pm M_{r\phi} + iM_{r\theta}\right)/2 \end{bmatrix} & l \geq 1, m = \pm 1 \\ \begin{bmatrix} 0 \\ \sqrt{\zeta^2 - 2}\left(\pm iM_{\theta\theta} \mp iM_{\phi\phi} + M_{\theta\phi} + M_{\phi\theta}\right)/4 \end{bmatrix} & l \geq 2, m = \pm 2 \end{cases} \qquad [90]$$

where the elastic parameters are those evaluated at the source radius r_s. We consider here only the case that the source is located in a continuous, solid region of the model. Equivalent results (in the case that the moment tensor is symmetric and the material is isotropic) are given by Ward (1980).

1.03.5 Numerical Solution of the Radial Equations*

1.03.5.1 Methods of Solution*

The inhomogeneous (i.e., with forcing term f_i) boundary value problem as formulated above gives a unique solution for each value of ω. The solution in the time domain can then be obtained in the form of an integral in ω, using the inverse Fourier transform [28]. This, in essence, is the basis of several practical methods for calculating theoretical seismograms, for example, the *reflectivity method* (Fuchs and Muller, 1971) and the direct solution method of Friederich and Dalkolmo (1995). Alternatively, the inverse transform can be evaluated by completing the integration contour in the upper half of the complex ω plane. Then it is found that the solution can be reduced to a sum over residues, each pole of the integrand corresponding to a particular mode *of free oscillation* of the model. A more usual approach to the normal mode problem is to consider first the free (i.e., unforced) modal solutions of the equations, and then to make use of the orthogonality and completeness properties of the eigenfunctions to obtain solutions of the inhomogeneous (i.e., forced) problem. Here, we have examined first the inhomogenous problem because the demonstration of orthogonality and completeness in the general (attenuating) case is a nontrivial issue, and it is only by virtue of the analysis of the inhomogeneous problem, and the resulting analytic structure of the integrand in the complex ω plane, that orthogonality and completeness can be demonstrated. It is necessary to show (in the nonattenuating case) that the only singularities of the integrand are simple poles on the real ω-axis. Then the modal sum emerges and completeness is demonstrated by the solution itself. In the attenuating case the situation is more complex, and there are other singularities located on the positive imaginary ω axis – let us call them the relaxation singularities, as they are associated with decaying exponential functions in the time domain. Thus, while the solution developed here for the inhomogeneous problem remains valid in this case, arguments based on orthogonality and completeness cannot be made. The solution can nevertheless be derived in the form of a sum over residues, and other singularities. While the contribution from relaxation singularities is the main focus of attention in the analysis of post-seismic relaxation, they are expected to make negligible contributions for the typical seismic application. However, even in the seismic domain it is necessary to know modal excitations in the attenuating case, and these are difficult to determine, other than by a rather complex application of mode-coupling theory (Lognonne, 1991; Tromp and Dahlen, 1990), which will be difficult to carry out to high frequencies. Using the inhomogenous solution, on the other hand, the 'seismic' modes and their excitations emerge naturally as the contributions from the residues of poles near the real axis, and can be calculated exactly and economically.

In both the attenuating and nonattenuating cases and for both the homogenous and inhomogeneous problems, the integration of the ordinary differential equation presents severe numerical difficulties. One problem is that the equations are such that evanescent – exponentially increasing and decreasing – solutions exist on more than one spatial scale. At moderately high frequencies, when the equations are integrated numerically, the solutions are effectively projected onto the solution having the most rapid exponential increase, and thus even though a linearly independent set of solutions is guaranteed, theoretically, to remain a linearly independent set, it becomes, numerically, a one-dimensional projection. The general solution of this difficulty is to reformulate the equations in terms of minors (i.e., subdeterminants) of sets of solutions (Gilbert and Backus, 1966). The standard method for normal mode calculations (Woodhouse, 1988) is based on the minor formulation of the equations, and uses a novel generalization of Sturm–Liouville theory to bracket modal frequencies, itself a nontrivial issue for the spheroidal modes, as the modes are irregularly and sometimes very closely spaced in frequency, making an exhaustive search difficult and computationally expensive. The program MINOS of Guy Masters, developed from earlier programs of Gilbert, and of Woodhouse (also a development of Gilbert's earlier programs), implements this method, and has been generously made available to the community. The direct solution method for the inhomogeneous problem, of Friederich and Dalkolmo (1995) is based on the minor formulation in the non-self-gravitating case, developed for the flat-earth problem by Woodhouse (1980b). Here, we outline some of the key features of the minor approach.

1.03.5.2 Numerical Integration*

Let us be specific by assuming that the model has a solid inner core, a fluid outer core, and a solid mantle. It may or may not have an ocean. Let us also consider the case of spheroidal oscillations, for which the solution vector is six dimensional in solid regions ($\mathbf{y}^{Ss}$) and four dimensional in fluid regions ($\mathbf{y}^{Sf}$). Toroidal and radial modes are much simpler.

The basic method of solution is to start at the center of the Earth, and to specify that the solution should be nonsingular there. By assuming that the medium is homogeneous and isotropic within a small sphere at the center, it is possible to make use of known analytical solutions in terms of the spherical Bessel functions (Love, 1911; Pekeris and Jarosch, 1958; Takeuchi and Saito, 1972). Thus (in the spheroidal case that we are considering), there is a three-dimensional set of solutions to be regarded as candidates for components of the solution at the center. Using these three solutions as starting solutions, the equations can be integrated toward the surface, for example, using Runge–Kutta techniques. We introduce a 6×3 matrix $\mathbf{Y} = \mathbf{Y}^{Ss}(r)$ having colums equal to these three solutions, and which has 3×3 subpartitions $\mathbf{Q} = \mathbf{Q}^{Ss}(r)$ and $\mathbf{P} = \mathbf{P}^{Ss}(r)$, that is, $\mathbf{Y} = \begin{bmatrix} \mathbf{Q} \\ \mathbf{P} \end{bmatrix}$. What is important about $\mathbf{Y}$ is the subspace of six-dimensional space that is spanned by its three columns, a property that is left unchanged if $\mathbf{Y}$ is post-multiplied by any nonsingular 3×3 matrix. Assuming, for the moment, that $\mathbf{Q}$ and $\mathbf{P}$ are nonsingular, and post-multiplying by $\mathbf{Q}^{-1}$ and by $\mathbf{P}^{-1}$ we conclude that both $\begin{bmatrix} \mathbf{1} \\ \mathbf{U} \end{bmatrix}$ and $\begin{bmatrix} \mathbf{V} \\ \mathbf{1} \end{bmatrix}$, where $\mathbf{V}$ and $\mathbf{U}$ are the mutually inverse matrices $\mathbf{V} = \mathbf{Q}\mathbf{P}^{-1}$, $\mathbf{U} = \mathbf{P}\mathbf{Q}^{-1}$ and where $\mathbf{1}$ is the unit matrix, have columns spanning the same three-dimensional space as is spanned by the columns of $\mathbf{Y}$. An unexpected property of $\mathbf{U}$, $\mathbf{V}$, stemming from the self-adjointness property of the equations and boundary conditions, is that

*Starred sections are intended for the more specialist reader, and the chapter can be understood without reading these extra sections.

they are *symmetric*. It is not difficult to show that by virtue of the particular structure of the differential equations noted in eqn [82] that if **U**, and (therefore) **V** are symmetric at a given radius, then they remain symmetric as the equations are integrated to other radii. To demonstrate this, consider:

$$\frac{\mathrm{d}}{\mathrm{d}r}(\mathbf{Q}'\mathbf{P}-\mathbf{P}'\mathbf{Q})=\frac{\mathrm{d}}{\mathrm{d}r}(\mathbf{Y}'\boldsymbol{\Sigma}\mathbf{Y})=\mathbf{Y}'\mathbf{A}'\boldsymbol{\Sigma}\mathbf{Y}+\mathbf{Y}'\boldsymbol{\Sigma}\mathbf{A}\mathbf{Y}=0 \qquad [91]$$

where we have introduced the partitioned matrix

$$\boldsymbol{\Sigma}=\begin{pmatrix}\mathbf{0} & \mathbf{1}\\ -\mathbf{1} & \mathbf{0}\end{pmatrix}$$

where **1** is the unit matrix of appropriate dimension, so that the matrix

$$\boldsymbol{\Sigma}\mathbf{A}=\begin{pmatrix}\mathbf{S} & -\mathbf{T}'\\ -\mathbf{T} & -\mathbf{K}\end{pmatrix}$$

is symmetric. We shall also make use of the fact (Woodhouse, 1988) that in the nonattenuating case, $-\boldsymbol{\Sigma}\mathbf{A}_\lambda$, by which we shall mean the partial derivative of **A** with respect to $\lambda=\omega^2$, is positive semidefinite, that is, that $\gamma'(-\boldsymbol{\Sigma}\mathbf{A}_\lambda)\gamma\geq 0$ for any real column γ, as can be verified using the forms for the submatrices of **A** [83]–[86]. Thus, if $\mathbf{Q}'\mathbf{P}-\mathbf{P}'\mathbf{Q}$ vanishes at a given radius, it vanishes everywhere in the interval over which the equations are being integrated. But we can write $\mathbf{Q}'\mathbf{P}-\mathbf{P}'\mathbf{Q}=\mathbf{Q}'(\mathbf{P}\mathbf{Q}^{-1}-\mathbf{Q}'^{-1}\mathbf{P}')\mathbf{Q}$, which shows that $\mathbf{P}\mathbf{Q}^{-1}$ is symmetric if $\mathbf{Q}'\mathbf{P}-\mathbf{P}'\mathbf{Q}$ vanishes. It is interesting to note that this argument does not rely on **Q** and **P** being nonsingular throughout the interval of integration, since $\mathbf{Q}'\mathbf{P}-\mathbf{P}'\mathbf{Q}$ remains finite and continuous. It is a lengthy algebraic exercise to show that **U** and **V** are symmetric at the center of the Earth (i.e., when the analytic solutions are used), but nevertheless this can be verified (it can be easily checked numerically).

To continue the narrative, the equations for $\mathbf{Y}^{\mathrm{IC}}$ are being integrated in the inner core, and we arrive at the inner core boundary. Here, the component of the solution corresponding to the shear traction on the boundary (the fifth element in our notation) is required to vanish. Thus, at the boundary we need to select from the three-dimensional space spanned by the columns of **Y** the (in general) two-dimensional subspace stress-displacement vectors having vanishing fifth elements. This subspace is most easily identified by considering the basis constituted by $\begin{bmatrix}\mathbf{V}\\ \mathbf{1}\end{bmatrix}$, since its first and third columns have vanishing fifth elements, and thus by deleting the middle column, together with the second and fifth rows, as they correspond to variables not needed on the fluid side, we obtain the following rule for transmitting the basis of allowable solutions from the solid to the fluid side of the boundary:

$$\begin{pmatrix}v_{11} & v_{12} & v_{13}\\ v_{12} & v_{22} & v_{23}\\ v_{13} & v_{23} & v_{33}\\ 1 & 0 & 0\\ 0 & 1 & 0\\ 0 & 0 & 1\end{pmatrix}\rightarrow\begin{pmatrix}v_{11} & v_{13}\\ v_{13} & v_{33}\\ 1 & 0\\ 0 & 1\end{pmatrix} \qquad [92]$$

We can now continue the integration, using the 4×2 matrix $\mathbf{Y}^{\mathrm{OC}}$ in the fluid outer core. We can define **Q**, **P**, **V**, **U** similarly, now 2×2, rather than 3×3 matrices, and again **V**, **U** are symmetric. Continuing the integration, we arrive at the outer core boundary, and again need to consider how to transmit the solution space across the boundary. Elements in rows 1, 2, 3, 4 on the fluid side need to be continuous with elements in rows 1, 3, 4, 6 on the solid side. The fifth element on the solid side, the shear traction component $r\zeta S$, has to vanish. Since the horizontal displacement can be anything on the solid side we have to add to the basis to represent solutions having nonvanishing horizontal displacements on the solid side. The easiest way to satisfy these requirements is to consider the basis represented by $\begin{bmatrix}\mathbf{1}\\ \mathbf{U}\end{bmatrix}$. It can be easily verified that the follwing rule satisfies the requirements:

$$\begin{pmatrix}1 & 0\\ 0 & 1\\ u_{11} & u_{12}\\ u_{12} & u_{22}\end{pmatrix}\rightarrow\begin{pmatrix}1 & 0 & 0\\ 0 & 1 & 0\\ 0 & 0 & 1\\ u_{11} & 0 & u_{12}\\ 0 & 0 & 0\\ u_{12} & 0 & u_{22}\end{pmatrix} \qquad [93]$$

The middle column has been inserted to represent the fact that the solution space has to contain vectors with nonvanishing horizontal displacement scalar $(r\zeta V)$ at the base of the mantle.

We can now continue the integration through the mantle. In the inhomogenous problem, the next interesting event is when we arrive at the source radius r_s. In the homogeneous problem, on the other hand, we can continue the integrations to the ocean floor, applying the same rule as at the inner core boundary to transmit the solution space into the ocean, and then continue to the surface, where the free surface condition needs to be satisfied. The requirement, of course, is that there be a linear combination of the columns of the 4×2 matrix $\mathbf{Y}^{\mathrm{O}}=\begin{bmatrix}\mathbf{Q}^{\mathrm{O}}\\ \mathbf{P}^{\mathrm{O}}\end{bmatrix}$ (where superscript 'O' is for ocean) that have vanishing surface traction scalar rP and vanishing gravity scalar $r\psi/4\pi G$, that is, vanishing elements 3 and 4. This requires $\det(\mathbf{P}^{\mathrm{O}})=0$ at the free surface. In the absence of an ocean, we similarly need $\det(\mathbf{P}^{\mathrm{C}})=0$ where $\mathbf{P}^{\mathrm{C}}$ is the 3×3 matrix in the crust.

In the inhomogeneous case, we need to arrange for there to be a prescribed discontinuity $\mathbf{s}^{\mathrm{Ss}}$ at the source depth. Thus, we need to characterize the solution space above, as well as below the source. At the surface of the ocean the solution must have vanishing elements 3 and 4, and thus we choose $\mathbf{Y}^{\mathrm{O}}$ at the free surface to be, simply $\mathbf{Y}^{\mathrm{O}}=\begin{bmatrix}\mathbf{1}\\ \mathbf{0}\end{bmatrix}$. Now we can integrate the solution downwards, using the same fluid–solid rule at the ocean floor as was employed at the core–mantle boundary, until we reach the source radius r_s from above. If $\begin{bmatrix}\mathbf{1}\\ \mathbf{U}_1^{\mathrm{s}}\end{bmatrix}$ spans the solution space below the source and $\begin{bmatrix}\mathbf{1}\\ \mathbf{U}_2^{\mathrm{s}}\end{bmatrix}$ spans the solution space above the source, we need to solve

$$\begin{bmatrix}\mathbf{1}\\ \mathbf{U}_2^{\mathrm{s}}\end{bmatrix}\mathbf{x}_2-\begin{bmatrix}\mathbf{1}\\ \mathbf{U}_1^{\mathrm{s}}\end{bmatrix}\mathbf{x}_1=\mathbf{s}^{\mathrm{Ss}} \qquad [94]$$

for the two 3-vectors $\mathbf{x}_1$, $\mathbf{x}_2$ which represent the multipliers for the columns of each matrix that are needed to satisfy the

condition that the solution have the prescribed discontinuity. The solution is easily found to be

$$\mathbf{x}_1 = (\mathbf{U}_2 - \mathbf{U}_1)^{-1}\left(\mathbf{s}_{\mathrm{P}}^{\mathrm{Ss}} - \mathbf{U}_2\mathbf{s}_{\mathrm{Q}}^{\mathrm{Ss}}\right),$$
$$\mathbf{x}_2 = (\mathbf{U}_2 - \mathbf{U}_1)^{-1}\left(\mathbf{s}_{\mathrm{P}}^{\mathrm{Ss}} - \mathbf{U}_1\mathbf{s}_{\mathrm{Q}}^{\mathrm{Ss}}\right) \qquad [95]$$

where $\mathbf{s}_{\mathrm{Q}}^{\mathrm{Ss}}$, $\mathbf{s}_{\mathrm{P}}^{\mathrm{Ss}}$ are the upper and lower halves of $\mathbf{s}^{\mathrm{Ss}}$, and the solution vectors below and above the source are given by

$$\mathbf{y}_1^{\mathrm{Ss}} = \begin{bmatrix}\mathbf{x}_1\\ \mathbf{U}_1\mathbf{x}_1\end{bmatrix},\quad \mathbf{y}_2^{\mathrm{Ss}} = \begin{bmatrix}\mathbf{x}_2\\ \mathbf{U}_2\mathbf{x}_2\end{bmatrix} \qquad [96]$$

This determines the linear combination of the basis vectors that are needed to satisfy the source discontinuity condition, and hence to determine the solution at any point of the medium and, in particular, at the surface, where it may be required to calculate some seismograms.

1.03.5.3 Eigenfunctions and Eigenfrequencies*

There will be singularities in the integrand of the inverse Fourier transform when $\mathbf{U}_2 - \mathbf{U}_1$ is singular. This will occur for frequencies ω for which a solution exists to the homogenous (i.e., unforced) problem, that is, at the frequencies of free oscillation. If $\mathbf{U}_2 - \mathbf{U}_1$ is singular at a particular source radius it is, therefore, necessarily singular at all radii. To evaluate the inverse transform as a sum over residues, we can write,

$$\frac{1}{2\pi}\int_{-\infty}^{\infty} I(\omega)\mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}\omega \to \sum_k i\frac{\lim_{\omega\to\omega_k}\Delta(\omega)I(\omega)}{\Delta'(\omega_k)} \qquad [97]$$

where ω_k is a mode frequency and where $\Delta(\omega)$ is that factor in the denominator of the integrand $I(\omega)$ that vanishes at ω_k, assuming that it has a simple zero at ω_k. Thus, we can replace the inverse transform by a sum over residues provided that the singular part of the integrand is replaced by the expression corresponding to it on the right side of eqn [97]. From eqn [95], we find that the necessary replacement is

$$(\mathbf{U}_2 - \mathbf{U}_1)^{-1} \to i\frac{\mathrm{adj}(\mathbf{U}_2 - \mathbf{U}_1)}{\partial_\omega \det(\mathbf{U}_2 - \mathbf{U}_1)}\bigg|_{\omega=\omega_k} = \frac{1}{2i\omega_k}\mathbf{z}_k\mathbf{z}_k' \qquad [98]$$

where adj represents matrix adjoint – the matrix of cofactors. The second equality defines the column $\mathbf{z}_k$ and its transpose $\mathbf{z}_k'$, and arises from the fact that the adjoint of a singular matrix, assuming that the rank defect is 1, is expressible as a dyad; the factor $-1/2\omega_k$ is included in the definition for convenience, as with this definition of $\mathbf{z}_k$, it can be shown that the column $\mathbf{y}_k = \begin{bmatrix}\mathbf{z}_k\\ \mathbf{U}_1\mathbf{z}_k\end{bmatrix} = \begin{bmatrix}\mathbf{z}_k\\ \mathbf{U}_2\mathbf{z}_k\end{bmatrix}$ is an eigenfunction (i.e., a solution of $\mathrm{d}\mathbf{y}/\mathrm{d}r = \mathbf{A}\mathbf{y}$) and has normalization

$$\int_0^a \mathbf{y}_k'(-\Sigma\mathbf{A}_\lambda)\mathbf{y}_k\,\mathrm{d}r = 1 \qquad [99]$$

where the notation $-\Sigma\mathrm{A}_\lambda$ is that introduced in the discussion following eqn [82]. The eigenfunctions can be found without needing to calculate the derivatives of solutions with respect to ω, as it can be shown that $\det\mathbf{Q}_1 \det\mathbf{Q}_2\partial_\omega\det(\mathbf{U}_2 - \mathbf{U}_1)$ is independent of r. This is the basis for the construction of the eigenfunctions from solutions of the minor equations, although it was arrived at differently in Woodhouse (1988). We see that it is necessary to integrate both upwards and downwards in order to obtain $\mathbf{U}_1$ and $\mathbf{U}_2$ (or, rather, the minors from which they can be constructed, see below) at all radii r.

In the nonattenuating case, the eigenfunctions $\mathbf{y}_k$ are real, and eqn [99] reduces to the standard normalization conditions for the scalar eigenfunctions U_k, V_k, W_k (defined in terms of $\mathbf{y}_k$ as in eqn [80]),

$$\text{spheroidal}: \int_0^a \rho\left(U_k^2 + \zeta^2 V_k^2\right)r^2\,\mathrm{d}r = 1,$$
$$\text{toroidal}: \int_0^a \rho\zeta^2 W_k^2 r^2\,\mathrm{d}r \qquad [100]$$

In the attenuating case, on the other hand, the eigenfunctions are complex and the normalization condition [99] includes terms arising from the derivatives of the elastic parameters with respect to ω. In this case, eqn [99] determines both the phase and the amplitude of the eigenfunction. Using the replacement [98] in [95], and making use of the definitions of $\mathbf{s}^{\mathrm{Ss}}$, and similarly $\mathbf{s}^{\mathrm{Ts}}$, from eqns [88] to [90] it can be shown that the inhomogeneous solution, now in the time domain, can be written as a sum over residues:

$$\mathbf{y}_{lm}(r,t) = \sum_k -\frac{1}{2\omega_k^2}E_{km}\mathbf{y}_k(r)\mathrm{e}^{\mathrm{i}\omega_k t} \qquad [101]$$

where *modal excitations* E_{km} are given by

$$E_{km} = \begin{cases}\mathbf{y}_k'\boldsymbol{\Sigma}\mathbf{s}^{\mathrm{Ss}} & \text{spheroidal}\\ \mathbf{y}_k'\boldsymbol{\Sigma}\mathbf{s}^{\mathrm{Ts}} & \text{toroidal}\end{cases}$$
$$= \frac{v_l}{r_s}\begin{cases} -r_s U_k F_r - r_s\partial_r U_k M_{rr} - U_k\left(M_{\theta\theta} + M_{\phi\phi}\right) + \frac{1}{2}\zeta^2 V_k\left(M_{\theta\theta} + M_{\phi\phi}\right) + \frac{1}{2}\zeta^2 W_k\left(M_{\theta\phi} - M_{\phi\theta}\right) & m = 0\\ \frac{1}{2}\zeta r_s(V_k \mp iW_k)\left(\pm F_\theta - iF_\phi\right) + \frac{1}{2}\zeta r_s(\partial_r V_k \mp i\partial_r W_k)\left(\mp M_{\theta r} - iM_{\phi r}\right) + \frac{1}{2}\zeta(U_k - V_k \pm iW_k)\left(\pm M_{r\theta} - iM_{r\phi}\right) & l \geq 1, m = \pm 1\\ \frac{1}{4}\zeta\sqrt{\zeta^2 - 2}(V_k \mp iW_k)\left(M_{\phi\phi} - M_{\theta\theta} \pm iM_{\theta\phi} \pm iM_{\phi\theta}\right) & l \geq 2, m = \pm 2\end{cases} \qquad [102]$$

where eqn [76] has been used to express the radial traction components P_k, S_k, T_k in $\mathbf{y}_k$ in terms of U_k, V_k, W_k, and their derivatives. The eigenfunctions are those evaluated at the source radius r_s. In eqn [102], we have combined the results for toroidal and spheroidal modes; of course, for spheroidal modes $W_k = 0$ and for toroidal modes $U_k = V_k = 0$. This result for the modal excitations is equivalent, in the case of a symmetric moment tensor to the forms given in Table 1 of Woodhouse and Girnius (1982).

The sum over residues [101] needs to be carried out over all simple poles in the upper half of the complex ω-plane. It will include the oscillatory 'seismic modes' having $\mathrm{Re}\,\omega_k \neq 0$, and

also, possibly, 'relaxation modes' having Re $\omega_k = 0$, Im $\omega_k > 0$. The seismic modes will occur in pairs, $\omega_k, -\omega_k^*$ because the equations are symmetric under replacement of ω_k by $-\omega_k^*$ followed by complex conjugation (see discussion following eqn [35]). Thus, each seismic mode having Re $\omega_k > 0$ will have a partner, obtained by reflection in the imaginary axis, at $-\omega_k^*$. It is not necessary to consider the modes for which Re $\omega_k < 0$ explicitly, as when the final result for the displacement in the time domain is calculated, it is possible to include them automatically by adding the complex conjugate, in order that the final result should be real. In the attenuating case, the solution is still not necessarily complete, as the constitutive law may introduce a branch cut along the positive imaginary axis, corresponding to a continuous distribution of relaxation mechanisms. In this case the sum over residues needs to be augmented by an integral around any branch-cut singularities on the positive imaginary axis. In order to include the 'static' response of the medium it is necessary to analyze the behavior of the integrand at $\omega = 0$. We do not pursue this in detail here but make some general observations. Because the source that is being considered has, in general, nonvanishing net force and net moment we would obtain secular terms corresponding to translational and rotational rigid motions (degree $l = 1$ spheroidal and toroidal modes having zero frequency). If the force is set to zero and the moment tensor is taken to be symmetric, these modes would not be excited. In this case, the final displacement field, after all seismic modes and relaxation modes have died away can be found from the residue at zero frequency, and will correspond to the static ($\omega = 0$) solution of the equations in which the elastic parameters are replaced by their values at zero frequency – their so-called *relaxed* values. Alternatively, the final displacement can be found by considering the fact that if the static terms are omitted the final displacement is zero, because all modes attenuate with time, whereas, in fact, it is the *initial* displacement that should be zero. Thus, the static terms must be such as to cancel the dynamic terms at zero time. It is not obvious that these two different ways of evaluating the static response will agree (i.e., using the static solution for relaxed values of the moduli, or using the fact that the initial displacement must be zero). We conjecture, but do not claim to prove, that these two methods will give the same result. If this is so, it means that, provided that *all* modes are included in the sum, we can include the static response by substituting $e^{i\omega_k t} - 1$ for $e^{i\omega_k t}$ in eqn [101] – that is, by subtracting the value at zero time.

1.03.5.4 Minors*

A central role is played in the foregoing theory by the symmetric matrices $\mathbf{U}$ and $\mathbf{V}$, notwithstanding that they possess singularities within the domain of integration. From their definitions $\mathbf{V} = \mathbf{Q}\mathbf{P}^{-1}$, $\mathbf{U} = \mathbf{P}\mathbf{Q}^{-1}$, using the following standard formula for the inverse of a matrix in terms of its cofactors and its determinant, they can be expressed in terms of the various 3×3 or (in the fluid case) or 2×2 subdeterminants of $\mathbf{Y}$. Explicitly we have:

$$\mathbf{U} = \frac{m_2}{m_1}, \quad \mathbf{V} = \frac{m_1}{m_2} \quad (n = 1) \qquad [103]$$

$$\mathbf{U} = \frac{1}{m_1}\begin{pmatrix} -m_4 & m_2 \\ m_2 & m_3 \end{pmatrix}, \quad \mathbf{V} = \frac{1}{m_6}\begin{pmatrix} m_3 & -m_2 \\ -m_2 & -m_4 \end{pmatrix},$$

$$m_1 = \det \mathbf{Q}, \qquad m_6 = \det \mathbf{P} \quad (n = 2) \qquad [104]$$

$$\mathbf{U} = \frac{1}{m_1}\begin{pmatrix} m_{11} & -m_5 & m_2 \\ -m_5 & -m_6 & m_3 \\ m_2 & m_3 & m_4 \end{pmatrix}, \quad \mathbf{V} = \frac{1}{m_{20}}\begin{pmatrix} m_{10} & -m_9 & m_8 \\ -m_9 & -m_{15} & m_{14} \\ m_8 & m_{14} & m_{17} \end{pmatrix},$$

$$m_1 = \det \mathbf{Q}, \; m_{20} = \det \mathbf{P} \quad (n = 3) \qquad [105]$$

where m_k are the minors of the relevant 2×1, 4×2, 3×6 ($n = 1$, 2, or 3) solution matrices $\mathbf{Y}$. We are using a standard way of enumerating these (see Gilbert and Backus, 1966; Woodhouse, 1988). We include the $n = 1$ case here, which is relevant to the case of toroidal and radial oscillations, for the sake of completeness. The results still hold in this case, although the matrices $\mathbf{Q}$, $\mathbf{P}$, $\mathbf{V}$, $\mathbf{U}$ reduce in this case to simple numbers, and the minors reduce to the elements of the solution vector itself (the 1×1 subdeterminants of a 2×1 matrix $\mathbf{Y}$). It is well known (Gilbert and Backus, 1966) that differential equations can be derived that are satisfied by the minors, and thus that they can be calculated directly, without the need to integrate the equations for particular solution sets $\mathbf{Y}$. Thus, formulae and results involving $\mathbf{V}$, $\mathbf{U}$ can be readily transcribed into formulae involving the minors. Essentially, any one of $\mathbf{U}$, $\mathbf{V}$, $\mathbf{m}$ provides a way of characterizing a subspace of the $2n$ dimensional space of interest ($n = 1$, 2, or 3), in a way that is independent of any specific basis. However, the minors have the practical advantage that they do not become infinite in the domain of integration.

The matrices $\mathbf{U}$ and $\mathbf{V}$ possess another remarkable property which results from the positive semi-definiteness of $-\boldsymbol{\Sigma}\mathbf{A}_\lambda$ in the nonattenuating case. Using this property, it is possible to show that the derivatives $\mathbf{U}_\lambda$ and $\mathbf{V}_\lambda$ also have definiteness properties. For upward integration $\mathbf{U}_\lambda \leq 0$ and $\mathbf{V}_\lambda \geq 0$ where ≥ 0 and ≤ 0 is used as a shorthand for the relevant semi-definiteness property. To prove this, consider the matrix $\mathbf{P}'\mathbf{Q}_\lambda - \mathbf{Q}'\mathbf{P}_\lambda = -\mathbf{U}'\boldsymbol{\Sigma}\mathbf{U}_\lambda$. The radial derivative of this matrix is given by

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}r}(\mathbf{P}'\mathbf{Q}_\lambda - \mathbf{Q}'\mathbf{P}_\lambda) &= -\frac{\mathrm{d}}{\mathrm{d}r}(\mathbf{Y}'\boldsymbol{\Sigma}\mathbf{Y}_\lambda) \\ &= -(\mathbf{Y}'\mathbf{A}'\boldsymbol{\Sigma}\mathbf{Y}_\lambda) - \mathbf{Y}'\boldsymbol{\Sigma}(\mathbf{A}_\lambda\mathbf{Y} + \mathbf{A}\mathbf{Y}_\lambda) \\ &= -\mathbf{Y}'\boldsymbol{\Sigma}\mathbf{A}_\lambda\mathbf{Y} \geq 0 \end{aligned} \qquad [106]$$

where we have used $\mathrm{d}\mathbf{Y}/\mathrm{d}r = \mathbf{A}\mathbf{Y}$, together with its transpose and its derivative with respect to λ. The cancelation of the terms not involving A_λ is due to the symmetry of $\boldsymbol{\Sigma}\mathbf{A}$ and the antisymmetry of $\boldsymbol{\Sigma}$. We also have

$$\begin{aligned} \mathbf{V}_\lambda &= \left(\mathbf{Q}\mathbf{P}^{-1}\right)_\lambda = \mathbf{Q}_\lambda\mathbf{P}^{-1} - \mathbf{Q}\mathbf{P}^{-1}\mathbf{P}_\lambda\mathbf{P}^{-1} = \mathbf{Q}_\lambda\mathbf{P}^{-1} - \mathbf{P}'^{-1}\mathbf{Q}'\mathbf{P}_\lambda\mathbf{P}^{-1} \\ &= \mathbf{P}'^{-1}(\mathbf{P}'\mathbf{Q}_\lambda - \mathbf{Q}'\mathbf{P}_\lambda)\mathbf{P}^{-1} \end{aligned} \qquad [107]$$

Thus, eqn [106] shows that if $\mathbf{P}'\mathbf{Q}_\lambda - \mathbf{Q}'\mathbf{P}_\lambda \geq 0$ at some initial point, then it remains positive semi-definite during upward integration. Then, from [107], $V_\lambda \geq 0$, as we wished to show. Using the analytic solutions at the center of the Earth, it can be shown that $\mathbf{V}_\lambda$ does have the required properties at the starting point of integration, being independent of frequency at the

center of the Earth. Also, its semidefiniteness property is preserved on passing from solid to fluid and vice versa. Similarly, it can be shown that for upward integration $\mathbf{U}_\lambda \leq 0$.

The diagonal elements of $\mathbf{V}_\lambda$ and $\mathbf{U}_\lambda$, which necessarily share the semi-definiteness properties of the matrices themselves, require, for upward integration, that the diagonal elements of $\mathbf{V}$ and $\mathbf{U}$ are nondecreasing and nonincreasing functions of frequency, respectively. As a function of frequency these diagonal elements behave like the familiar tangent and cotangent function, having monotonic increase or decrease between their singularities. The singularities in $\mathbf{V}$ at the surface are of particular interest, since the frequencies for which $\mathbf{V}$ is singular (i.e., infinite) at the surface are precisely the frequencies of the normal modes. One particular diagonal element, namely υ_{11} in the notation used here, has the additional property, using [92], [93], that it is continuous at solid–fluid and fluid–solid boundaries. In the case of fluid–solid boundaries this is not so obvious, as both m_{10} and m_{20} vanish on the solid side ($\upsilon_{11} = m_{10}/m_{20}$, eqn [105]), but but it can be shown that the limit as the boundary is approached from the solid side is, in fact, equal to υ_{11} on the fluid side.

1.03.5.5 Mode Bracketing and Counting*

The function $\theta_R(r, \lambda) = -\frac{1}{\pi}\cot^{-1}(\upsilon_{11})$, which can be made continuous (as a function of r and as a function of λ) through singularities of υ_{11}, has the properties that (i) it is independent of frequency at the center of the Earth, (ii) it is nondecreasing as a function of λ, and (iii) it takes on integer values at the surface at the frequencies $\omega^2 = \lambda$ corresponding to the normal modes. This makes it an ideal mode counter, since two integrations of the equations, at frequencies ω_1, ω_2, say, can determine the values $\theta_R(a, \omega_1^2)$, $\theta_R(a, \omega_2^2)$ at the Earth's surface and it is necessary only to find how many integers lie between these values to determine how many modal frequencies lie between ω_1 and ω_2. There is a complication associated with fluid–solid boundaries. As discussed above, both m_{10} and m_{20} vanish on the solid side, even though υ_{11} remains continuous. This circumstance leads to singular behavior of θ_R as a function of λ, and we find that it is necessary to increment θ_R by 1 at a fluid–solid boundary when the (2,2) element of $\mathbf{S}^{Ss}$ (eqn [83]) is negative on the solid side, that is, for $\omega^2 > [\zeta^2(A - F^2/C) - 2N]/\rho r^2$, in which the elastic constants are those evaluated at the boundary, on the solid side and r is the radius of the boundary. For upward integration (the usual case), this occurs at the core–mantle boundary.

Figure 8 shows an example of the behavior of $\theta_R(x, \lambda)$ for spheroidal oscillations of degree $l = 10$. The θ_R mode counter can be used to bracket the modal frequencies by a bisection method that seeks values of frequency such that $\theta_R(a, \omega^2)$ takes on values lying between any pair of successive integers in an interval $[\theta_R(a, \omega^2_{\min}), \theta_R(a, \omega^2_{\max})]$.

Having bracketed the modal frequencies (for a given l) it is necessary to converge on the zeros of $\det[\mathbf{P}]|_{r=a}$. This can be done in a variety of standard ways, bisection being the ultimately safe method if all else fails. Figure 9 shows the resulting *dispersion diagram* for spheroidal modes up to 30 mHz. The crowding and irregularity of the distribution in the left side of the diagram demonstrate the need for the mode-counting scheme. For the toroidal modes, the dispersion diagram is much simpler (Figure 10), and so the mode-counting scheme is less critical.

1.03.6 Elastic Displacement as a Sum Over Modes

We shall here assume that a catalog of normal mode eigenfrequencies and scalar eigenfunctions has been calculated, including spheroidal modes (Figure 9) and toroidal modes

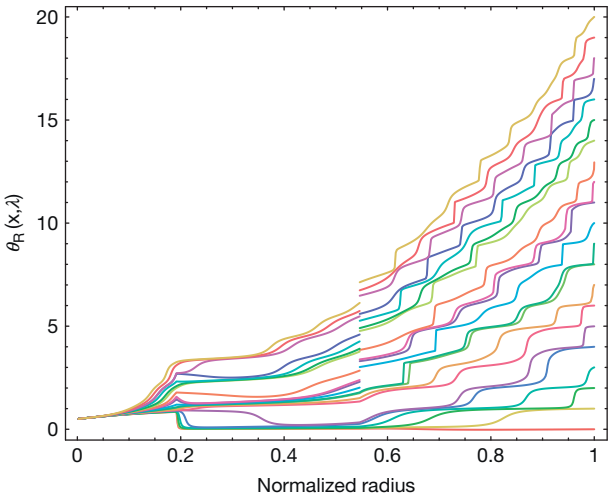

Figure 8 An example of the behavior of $\theta_R(x, \lambda)$ for the spheroidal oscillations of degree $l = 10$. It has been calculated for the true modal frequencies up to ${}_{20}S_{10}$, and thus the surface value of $\theta_R(x, \lambda)$, at normalized radius $x = 1$, takes on successive integer values equal to the overtone number. θ_R can be seen to be independent of frequency at the center of the Earth ($x = 0$) where θ_R $(0, \lambda) = 1/2$. The nondecreasing property of θ_R as a function of $\lambda = \omega^2$ means that successive curves never cross. Notice that θ_R is not a monotonic function of r. The discontinuity in θ_R at the core–mantle boundary, discussed in the text, affects the mode count for modes higher than ${}_9S_{10}$. In a sense, the values of $\theta_R(x, \lambda) = -(1/\pi)\cot^{-1}\upsilon_{11}$ are not of physical significance, since υ_{11} is a dimensional quantity, and thus the value of $\theta_R(x, \lambda)$ depends on the units employed. In any system of units, however, θ_R takes on integer values at the same values of its arguments. In other words, it is the *zero crossings* of υ_{11}, for which θ_R acts as a counter, that are of primary significance. The results shown here are for $\theta_R(x, \lambda) = -(1/\pi)\cot^{-1}\alpha\upsilon_{11}$, with $\alpha = 4 \times 10^4$ N m^{-3}.

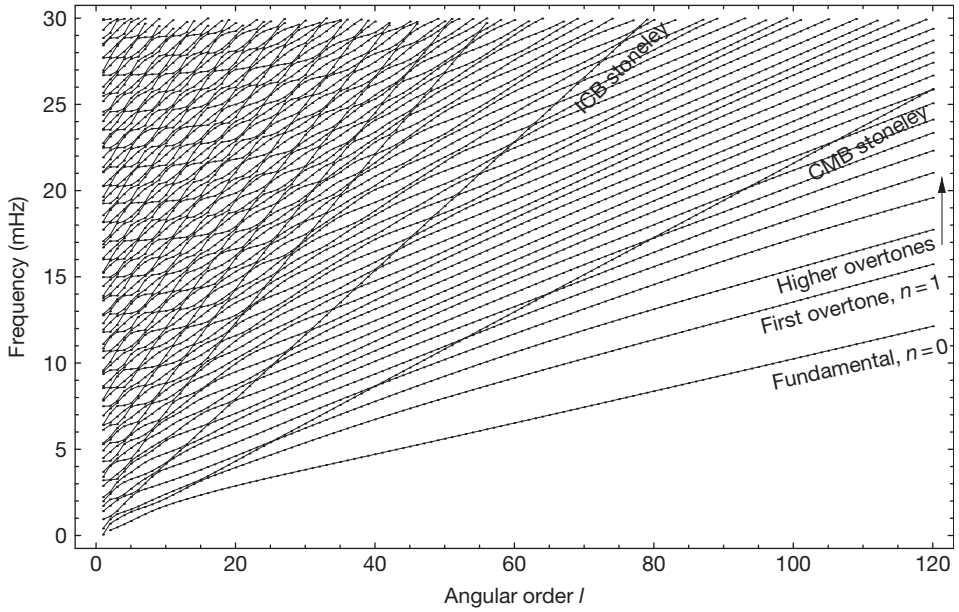

Figure 9 The dispersion diagram for spheroidal modes to 30 mHz. Modes with the same overtone number n are connected by lines, forming branch. The fundamental branch ($n=0$) and the first overtone branch ($n=1$) are indicated. Also shown are the Stoneley branches, which are modes that only exist at solid–fluid interfaces.

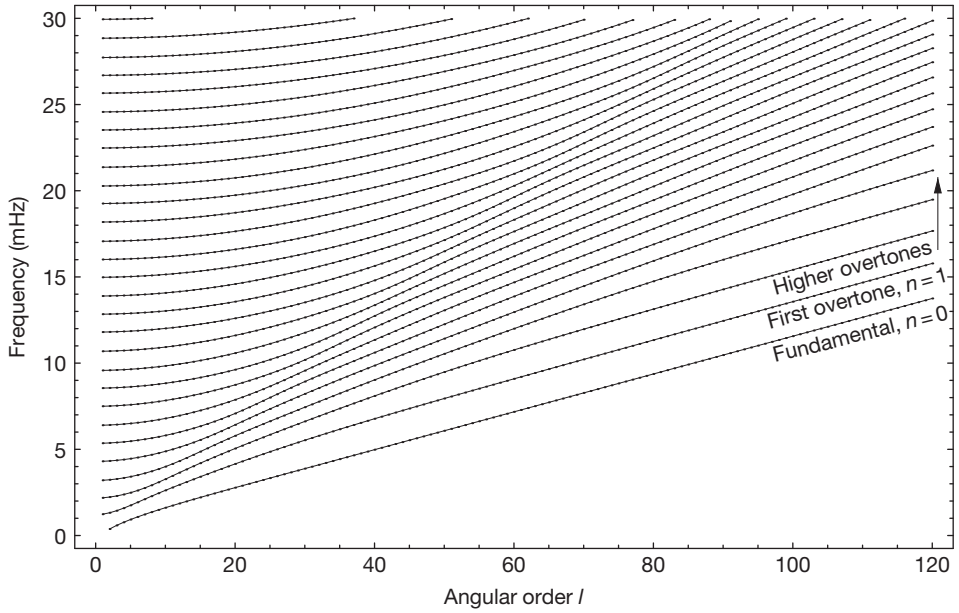

Figure 10 The dispersion diagram for toroidal modes to 30 mHz. Modes with the same overtone number n are connected by lines, forming branch. The fundamental branch ($n=0$) and the first overtone branch ($n=1$) are indicated.

(Figure 10). Rather than pursuing the in-homogenous problem outlined in earlier sections, we shall now adopt the more classical approach, making use of the orthogonality properties of the eigenfunctions to expand the applied force distribution and to find the modal excitations. The argument is strictly valid only in the nonattenuating case. Attenuation is subsequently included by introducing decay constants associated with each mode. Recall that the eigenfrequencies ω_k and the eigenfunctions $\mathbf{s}^{(km)}$ are solutions of the eigenvalue problem

$$\mathcal{H}\mathbf{s}^{(km)} = \rho\omega_k^2\mathbf{s}^{(km)} \qquad [108]$$

where each multiplet is labeled by $k=n, l, q$ with q denoting the modal type (either spheroidal or toroidal), l the angular order and n the overtone number. m is the azimuthal order. The problem is degenerate in the spherical nonrotating case, so for each normal mode multiplet there are $2l+1$ eigenfunctions $\mathbf{s}^{(km)}$ (labeled by m), all with the same eigenfrequency ω_k. It can be shown that the operator $\mathcal{H}$ is self adjoint in the sense

$$\int_V \mathbf{s}' \cdot \mathcal{H}\mathbf{s}\, \mathrm{d}^3x = \int_V \mathbf{s} \cdot \mathcal{H}\mathbf{s}'\, \mathrm{d}^3x \qquad [109]$$

for any differentiable $\mathbf{s}(\mathbf{x})$, $\mathbf{s}'(\mathbf{x})$ satisfying the boundary conditions for $\mathbf{u}$ in eqn [25], where the volume integration is over the entire Earth model. From this it follows that the eigenfunctions $\mathbf{s}^{(km)}(\mathbf{x})$ form a complete set and that the eigenvalues ω_k^2 are real. We can also assume that they are positive, on the grounds that the model should initially be in stable equilibrium. It is not difficult to show that eigenfunctions belonging to different eigenvalues are orthogonal or, in the case of degeneracy, can be orthogonalized, in the sense

$$\int_V \rho \mathbf{s}^{(k'm')*} \cdot \mathbf{s}^{(km)} \mathrm{d}^3x = 0 \quad \text{when } k \neq k' \text{ or } m \neq m' \qquad [110]$$

It is straightforward to obtain a formal solution of the equations of motion [36], that is, $\left(\mathcal{H} + \rho^0 \partial_t^2\right)\mathbf{u} = \mathbf{f}$, in terms of a sum of eigenfunctions $\mathbf{s}^{(km)}$. We expand the displacement field $\mathbf{u}(\mathbf{x}, t)$

$$\mathbf{u}(\mathbf{x}, t) = \sum_{km} a_{km}(t) \mathbf{s}^{(km)}(\mathbf{x}) \qquad [111]$$

where $a_{km}(t)$ are to be found. On substituting into eqn [36], multiplying by $\mathbf{s}^{(k'm')*}$ and integrating, making use of the orthogonality relation [110], we obtain

$$\ddot{a}_{km}(t) + \omega_k^2 a_{km}(t) = \omega_k^2 f_{km}(t) \qquad [112]$$

with

$$f_{km}(t) \equiv \frac{1}{\omega_k^2} \frac{\int_V \mathbf{s}^{(km)*}(\mathbf{x}) \cdot \mathbf{f}(\mathbf{x}, t)\, \mathrm{d}^3x}{\int_V \rho \mathbf{s}^{(km)*}(\mathbf{x}) \cdot \mathbf{s}^{(km)}(\mathbf{x})\, \mathrm{d}^3x} \qquad [113]$$

The ordinary differential equations [112] for each $a_{km}(t)$ may be solved (e.g., using the method of *variation of parameters* or Laplace transformation) to give

$$a_{km}(t) = \int_{-\infty}^{t} h_k(t - t') \dot{f}_{km}(t')\, \mathrm{d}t' \qquad [114]$$

with

$$h_k(t) = 1 - \cos \omega_k t \qquad [115]$$

a result due to Gilbert (1971). As pointed out by Gilbert, this result needs to be modified to account for attenuation by incorporating a decay factor $\exp(-\alpha_k t)$ into the cosine term, and thus in place of eqn [115] we write:

$$h_k(t) = 1 - \mathrm{e}^{-\alpha_k t} \cos \omega_k t \qquad [116]$$

where α_k is given in terms of the *quality factor* Q of the mode by $\alpha_k = \omega_k / 2Q_k$. Inserting the point source defined in eqn [32], we obtain:

$$a_{km}(t) = \frac{1}{\omega_k^2} \left(F_i s_i^{(km)}(\mathbf{x}_s)^* + M_{ij} s_{i,j}^{(km)}(\mathbf{x}_s)^* \right) h_k(t) \qquad [117]$$

assuming that eigenfunctions are normalized such that $\int_V \rho \mathbf{s}^{(km)*}(\mathbf{x}) \cdot \mathbf{s}^{(km)}(\mathbf{x}) \mathrm{d}^3x = 1$. The eigenfunctions are of the form [73], being functions of U, V, and W and the spherical harmonics $Y_l^m(\theta, \phi)$. Thus, it is a further exercise in spherical harmonic analysis to reduce the excitation coefficients, $E_{km} = \left(F_i s_i^{(km)}(\mathbf{x}_s)^* + M_{ij} s_{i,j}^{(km)}(\mathbf{x}_s)^* \right)$, to forms involving the scalar eigenfunctions U_k, V_k, W_k, and their derivatives. The result has already been derived in eqn [102] by a different route. Similar formulae are also to be found in Gilbert and Dziewonski (1975), Woodhouse and Girnius (1982), and Dziewonski and Woodhouse (1983b). Using eqn [117] in eqn [111], we obtain the following expression for a theoretical seismogram:

$$\mathbf{u}(\mathbf{x}, t) = \sum_{km} \frac{1}{\omega_k^2} E_{km} \mathbf{s}^{(km)}(\mathbf{x}) (1 - \mathrm{e}^{-\alpha_k t} \cos \omega_k t) \qquad [118]$$

The argument of the previous section shows that the correct form of this expression in the attenuating case is

$$\mathbf{u}(\mathbf{x}, t) = \sum_{\substack{km \\ \mathrm{Re}\,\omega_k > 0}} \mathrm{Re} \left\{ \frac{1}{\omega_k^2} E_{km} \mathbf{s}^{(km)}(\mathbf{x}) \left(1 - \mathrm{e}^{i\omega_k t}\right) \right\} \qquad [119]$$

where ω_k is now the complex frequency, and $\mathbf{s}^{km}$ is the complex eigenfunction, having normalization [99]. Additional terms need to be added to eqn [119] if it is desired to include relaxation effects. The actual seismogram is obtained by operating an 'instrument vector' in eqn [119].

This rather simple formula is the key ingredient of many seismological studies, as outlined in **Section 1.03.1**. Mode catalogs for PREM (Dziewonski and Anderson, 1981) exist up to 170 mHz (6 s period). **Figure 2** shows an example of such a synthetic seismogram, calculated by summing all modes up to 6 s period. For comparison, the observed seismogram for the same earthquake and station is also shown. The direct P and S and surface reflected PP and SS body waves are visible in both the synthetic and data seismograms. At later times, the surface waves can be observed. Differences between the synthetic and data seismogram can be attributed to 3D structure, which is not included in the calculation.

1.03.7 The Normal Mode Spectrum

1.03.7.1 Asymptotic Relations Relating Normal Modes, Body Waves, and Surface Waves

Here, we illustrate some of the properties of different multiplets in the normal mode spectrum. One way to gain insight into the physical character of modes is by relating them to traveling body waves and surface waves. The essential quantitative connection between modes and traveling waves is made by equating the horizontal wavelength (or wavenumber) of the mode with the corresponding horizontal wavelength (or wavenumber) of a traveling wave. For modes, this wavelength can be derived from the asymptotic properties of the spherical harmonics for large l. A point source at the pole $\theta = 0$ excites only the modes having low azimuthal order $|m| \leq 2$, as we have seen. For fixed m and large l we have (e.g., Abramowitz and Stegun, 1965):

$$Y_l^{0m}(\theta,\phi)\sim\frac{1}{\pi}\sqrt{\frac{2l+1}{4\pi}}(\sin\theta)^{-\frac{1}{2}}\cos\left[\left(l+\tfrac{1}{2}\right)\theta+\tfrac{1}{2}m\pi-\tfrac{1}{4}\pi\right]e^{im\phi} \quad [120]$$

where θ plays the role of epicentral distance. Thus, we can identify the horizontal wavenumber k ($=2\pi/$wavelength) to be

$$k=\left(l+\frac{1}{2}\right)/a \quad [121]$$

The angular order l, therefore, is a proxy for wavenumber k and dispersion diagrams such as those shown in Figures 9 and 10 can be interpreted, for large l, in the same way as are dispersion relations $\omega(k)$ for surface waves. In particular, we can define phase velocity

$$c(\omega)=\frac{\omega}{k} \quad [122]$$

and group velocity

$$U(\omega)=\frac{d\omega}{dk} \quad [123]$$

This defines the relationship between the $\omega-l$ plane and the dispersion properties of Love and Rayleigh waves and their overtones, Love waves corresponding to toroidal modes and Rayleigh waves to spheroidal modes.

In the case of body waves we may, similarly, identify the horizontal wavenumber in terms of frequency and *ray parameter* p (Brune, 1964, 1966). From classical ray theory in the spherical Earth, the horizontal wavenumber at the Earth's surface for a monochromatic signal traveling along a ray with given ray parameter $p=dT/d\Delta$ is

$$k=\frac{\omega p}{a} \quad [124]$$

Therefore, using eqn [121], we write

$$p=\frac{l+\frac{1}{2}}{\omega} \quad [125]$$

Thus, a mode of angular order l and angular frequency ω is associated with rays having the ray parameter given by eqn [125]. For toroidal modes these are S-rays, and for spheroidal modes they are both P- and S-rays. It is well known that rays exist only for ranges of depth for which

$$\frac{r}{v_P(r)}\geq p \quad \text{for P-waves} \quad [126]$$

$$\frac{r}{v_S(r)}\geq p \quad \text{for S-waves} \quad [127]$$

In the diagrams of Figures 6 **and** 11–13, the ranges of depth for which these inequalities are satisfied are indicated in two columns on the right side of each panel. The left column is for P-waves (relevant only for spheroidal multiplets) and the right column for S waves.

1.03.7.2 Differential Kernels for Spherically Symmetric Model Perturbations

Another way to gain understanding of the physical properties is through the use of *differential kernels* $K(r)$. These are, in essence, the derivatives of the eigenfrequency of a given mode with respect to a structural change at any radius. This takes the form of an integral (cf. the chain rule applied to an infinite number of independent variables). Differential kernels can be defined, for example, corresponding to perturbations in shear modulus and bulk modulus, at fixed density, and these are related to the distribution of elastic shear energy and compressional energy with radius. Similarly, kernels can be defined corresponding to anisotropic perturbations (see Chapter 1.19). Theoretical formulae for such kernels can be found in, for example, Backus and Gilbert (1967), and for anisotropic elastic parameters A, C, L, N, F in Dziewonski and Anderson (1981). Such kernels are a special case, in which the perturbation is spherically symmetric, of the kernels that arise when a general aspherical perturbation of the model is considered. This will be further discussed in Section 1.03.8.2. Here, we shall take relative perturbations in (isotropic) P-velocity, v_P, S-velocity, v_S and density ρ (at constant v_P and v_S) as the independent perturbations, and write

$$\delta\omega_k=\int_0^a\left(K_\rho(r)\frac{\delta\rho(r)}{\rho(r)}+K_P(r)\frac{\delta v_P(r)}{v_P(r)}+K_S(r)\frac{\delta v_S(r)}{v_S(r)}\right)dr \quad [128]$$

Our aim here is to use the kernels $K_P(r)$, $K_S(r)$ to give insight into the nature of the mode in terms of its traveling-wave content, and into how the P and S velocity distributions can be constrained by making observations of a given mode. The kernel $K_\rho(r)$ (for constant v_P and v_S) gives information about how the mode probes the density structure, adding to information about v_P and v_S available from modes but also from travel times.

1.03.7.3 Tour of Frequency-Wavenumber Space

Here, we will discuss the characteristics of the spheroidal and toroidal modes. Figure 9 shows the degenerate eigenfrequencies of spheroidal modes as a function of angular order l for the spherical reference model PREM. Lines connect modes of the same overtone number n, and define different *branches* of the dispersion curves. The *fundamental mode branch* ($n=0$) contains the modes with the lowest frequency for each l. Modes with $n>1$ are called *overtones*. The overtone branches cross-cut each other leading to a range of different normal mode classes, which will be discussed in the succeeding text. Figure 10 shows the same for the toroidal modes, which are much simpler and do not have cross-cutting branches. We will make a tour of $\omega-l$ space and use the eigenfunctions and differential kernels defined above to gain insight into the nature of the different types of mode.

Figures 6, 11–13 show eigenfunctions and differential kernels for a number of toroidal and spheroidal modes. By inspecting these diagrams, a few general observations can be made. Moving up along a mode branch (horizontal rows in Figures 11 and 12) will result in eigenfunctions and kernels which are more concentrated toward the surface. This reflects the fact that, for high l, the modes may be interpreted as surface waves as is most obvious for the fundamental branches of the toroidal modes (Figure 11) and spheroidal modes (Figure 12). Moving up in overtone number n, for constant l (vertical columns in Figures 11 and 12), leads to eigenfunctions that

Figure 11 Sensitivity kernels $K_S(r)$ (dashed lines) and $K_\rho(r)$ (dot-dashed lines) of selected toroidal modes.

are more oscillatory and to sensitivity kernels that penetrate more deeply.

The wave motion of toroidal modes is purely horizontal and only has one eigenfunction W (see Figure 6). Thus, for spherical, nonrotating Earth models, these modes can only be observed on the horizontal components of a theoretical seismogram and not on the vertical component. Toroidal modes are sensitive only to perturbations in S-velocity and density and have no sensitivity to the fluid core (Figure 11). The differential kernels tell us how the frequency of the mode will change if we increase the spherical velocity or density at a certain depth. When inspecting Figure 11, we find that increasing the shear wave velocity at any depth in the mantle will always lead to an increase in toroidal mode frequency as the $K_S(r)$ sensitivity kernel is always positive. For density, however, we find that it depends on the depth of the perturbation. For mode ${}_0T_2$, for example, an increase in density in the upper mantle will lead to a decrease in frequency, while an increase in the lower mantle will increase the frequency. When we move from the fundamentals to the overtones, we find that the density kernel $K_\rho(r)$ becomes oscillatory around zero (see, e.g., the $n=5$ overtones). These modes are almost insensitive to smooth variations in density, as the kernels will average to zero when integrated over depth. The sensitivity to density also becomes smaller for larger l along the same branch, which can clearly be seen when progressing from ${}_0T_2$ to ${}_0T_{10}$ along the fundamental mode branch. This agrees well with the interpretation of shorter period toroidal modes in terms of Love waves, which are also dominated by sensitivity to shear wave velocity and have much smaller sensitivity to density.

Figure 12 shows the examples of sensitivity kernels for the spheroidal modes. The spheroidal modes involve wave motion in both horizontal and vertical directions characterized by eigenfunctions $U(r)$ and $V(r)$ (Figure 6), and so are sensitive to perturbations in density and to both υ_P and υ_S. These modes are observed on both the horizontal and vertical components

of theoretical seismograms for a spherical, nonrotating Earth model. Again, moving to the right along the fundamental mode branch in Figure 12 shows that sensitivities become progressively concentrated closer to the surface. Spheroidal modes correspond to Rayleigh waves and at higher l the largest sensitivity is to shear wave velocity. This is similar to the toroidal modes, except that peak sensitivity is reached at subcrustal depths, making spheroidal modes less sensitive to large variations in shear velocity in the crust than is the case for toroidal modes.

The overtones sample different families of modes which relate to the branch crossings. Mode ${}_5S_{10}$ (Figure 12) corresponds to a Stoneley wave traveling along the inner core boundary. Stoneley waves are the analogue of a Rayleigh wave, but at a fluid–solid interface, rather than at a free surface. They exist both at the inner core boundary and at the core–mantle boundary. These modes follow lines of increasing frequency ω and angular order l in Figure 9, cross-cutting the branches with constant overtone number n. Mode ${}_1S_{10}$ (Figure 12) is a mixture of mantle mode and a Stoneley wave at the core–mantle boundary. The other modes in Figure 12 show a behavior similar to the toroidal modes. Notice that for ${}_5S_{50}$, the υ_P sensitivity decays below the P-wave ray-theoretic turning point (the point at which the shading terminates in the left vertical stripe at the right of the plot), and the υ_S sensitivity decays below the S-wave turning point. The fact that, for a given ray parameter, S-waves turn at greater depth than P-waves means that in modeling there is some potential for shallow P-velocity structure to trade off with deep S-velocity structure.

Figure 13 shows another family of spheroidal modes, which are characterized by low angular order l and high overtone number n. These modes are the PKIKP equivalent modes which

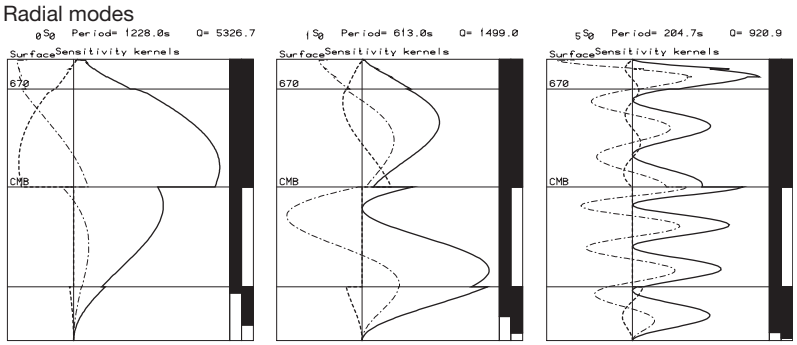

Figure 14 Sensitivity kernels of selected radial modes. $K_S(r)$ dashed, $K_P(r)$ solid, and $K_\rho(r)$ dot-dashed.

have strong sensitivity to core structure. Modes $_3S_2$ and $_{10}S_2$ have strong sensitivity to inner core υ_s, while $_{13}S_2$ is more strongly sensitive to υ_p. These modes display anomalous splitting which has been attributed to inner core anisotropy (Woodhouse et al., 1986) and its hemispherical variation (Deuss et al., 2010).

Finally, Figure 14 shows sensitivity kernels for radial modes, which are yet another subgroup of the spheroidal modes with angular order $l=0$. The radial modes are sensitive to both υ_s and υ_p and also to density. However, the sensitivities to υ_s and density oscillate around zero, while only for υ_p the sensitivity is always positive. This means that radial modes are very useful for obtaining constraints on the one-dimensional compressional structure of the Earth.

1.03.8 Normal Modes and Theoretical Seismograms in Three-Dimensional Earth Models

The previous two sections have dealt with the calculation of normal modes in a spherical symmetric, nonrotating Earth model and discussed the different modes that exist. In the spherical case, the modes are degenerate, that is, all $2l+1$ singlets in one multiplet have the same frequency. Also, toroidal modes will only be visible on the horizontal components of a seismogram, while spheroidal modes will be visible on both horizontal and vertical components. In the real Earth, the modes are split due to heterogeneous structure, rotation, and ellipticity, resulting in all singlets within one multiplet having different frequencies. Splitting effects the singlets within one normal mode multiplet, and is also called *self-coupling*. However, if two (or more) modes are close in frequency, then there will also be *cross-coupling* between the singlets of different modes causing further changes to the singlet frequencies. Cross-coupling also leads to mixing of the singlets of different modes, for example making the toroidal modes become visible on the vertical component of the seismogram. All these effects need to be taken into account when calculating synthetic spectra.

1.03.8.1 Theoretical Seismograms

The problem of calculating theoretical seismograms and spectra for three-dimensional models is a challenging one. A theoretically straightforward formalism exists for such calculations, based on expanding the wave field in terms of a complete set of (vector) functions. The equations that arise from requiring that the equations of motion be satisfied can be regarded as exact matrix equations. However, they are of infinite dimension, and even when truncated to give a practicable method of solution, the calculations require the manipulation and diagonalization of extremely large matrices. This is already problematic in the forward problem, but becomes even more so for the inverse problem, requiring calculations which are equivalent to thousands of forward problems. If the expansion is carried out in terms of the eigenfunctions of a spherical model (that is close to reality), the process is simplified, as the off-diagonal terms in the resulting matrices are small,

allowing some approximate schemes that are much less cumbersome to be developed.

Let us take the equation of motion in operator form (given in eqn [36]) as our starting point in considering the form that this theory takes. In the frequency domain:

$$(\mathcal{H}-\rho\omega^2)\mathbf{u}=\mathbf{f} \qquad [129]$$

The Earth will be considered to be in a state of steady rotation with angular velocity Ω about its center of mass, so that the expression for $\mathcal{H}$ acquires additional terms representing the Coriolis force and the centrifugal potential (Dahlen, 1968):

$$(\mathcal{H}\mathbf{u})_i=\rho\left(\phi^1_{,i}+\left[\phi^0-\tfrac{1}{2}(\Omega_k\Omega_k x_l x_l-\Omega_k\Omega_l x_k x_l)\right]_{,ij}u_j+2i\epsilon_{ijk}\Omega_j u_k\right)-\left(\Lambda_{jilk}u_{k,l}\right)_{,j} \qquad [130]$$

where, as previously, ϕ^1 is regarded as a functional of $\mathbf{u}$, by virtue of Poisson's equation [23]. The terms on the right-hand side of eqn [130] involving $\frac{1}{2}(\Omega_k\Omega_k x_l x_l-\Omega_k\Omega_l x_k x_l)$ relate to the centrifugal potential and the term involving $2i\epsilon_{ijk}\Omega_j u_k$ is the Coriolis force contribution. Let $\mathbf{s}^{(km)}$ represent the eigenfunctions of a spherical, nonrotating, nonattenuating reference model, with eigenfrequencies ω_k, so that

$$\mathcal{H}_0\mathbf{s}^{(km)}=\rho_0\omega_k^2\mathbf{s}^{(km)} \qquad [131]$$

satisfying the orthogonality relation

$$\int_V \rho_0\mathbf{s}^{(k'm')*}\cdot\mathbf{s}^{(km)}\,\mathrm{d}V=\delta_{k'k}\delta_{m'm} \qquad [132]$$

where $\mathcal{H}_0$ and ρ_0 are for the spherical, nonrotating, nonattenuating reference model. Now let us seek a solution of eqn [129] in terms of an expansion

$$\mathbf{u}(\mathbf{x},\omega)=\sum_{km}a_{km}\mathbf{s}^{(km)}(\mathbf{x}) \qquad [133]$$

with coefficients a_{km} to be found. Substituting the expansion for $\mathbf{u}(\mathbf{x},\omega)$ into eqn [129], and then taking the dot product with $\mathbf{s}^{(k'm')*}$ and integrating, we find

$$\sum_{km}\left[(k'm'|\mathcal{H}_1-\rho_1\omega^2|km)-(\omega^2-\omega_k^2)\delta_{k'k}\delta_{m'm}\right]a_{km}=(k'm'|f) \qquad [134]$$

where $\mathcal{H}_1=\mathcal{H}-\mathcal{H}_0,\rho_1=\rho-\rho_0$ and where we have introduced the notations $(k'm'|f)=\int_V \mathbf{s}^{(k'm')*}\cdot\mathbf{f}\,\mathrm{d}V$, $(k'm'|\mathcal{H}_1-\rho_1\omega^2|km)=\int_V \mathbf{s}^{(k'm')*}(\mathcal{H}_1-\rho_1\omega^2)\mathbf{s}^{(km)}\mathrm{d}V$. Equation [134] can be regarded as a matrix equation, albeit of infinite dimension, in which rows and columns of the matrix on the left side are labeled by $(k',\ m')$, $(k,\ m)$, respectively and in which the rows of the column on the right side are labeled by $(k',\ m')$. We can write

$$\mathbf{C}(\omega)\mathbf{a}=\frac{1}{i\omega}\mathbf{E} \qquad [135]$$

where $\mathbf{C}$ is the matrix having matrix elements $(k'm'|C(\omega)|km)=(k'm'|\mathcal{H}_1-\rho_1\omega^2|km)-(\omega^2-\omega_k^2)\delta_{k'k}\delta_{m'm}$ and where $\mathbf{E}/i\omega$ is the column vector having elements $(k'm'|f)$, the factor $1/i\omega$ being inserted to reflect the assumed step-function time dependence of the source, so that $\mathbf{E}$, which has elements E_{km} given in eqn [102], is independent of frequency. Hence, the formal solution is given by

$$\mathbf{a}=\frac{1}{i\omega}\mathbf{C}(\omega)^{-1}\mathbf{E} \qquad [136]$$

Recalling that we are thinking of the index k as incorporating angular order l, overtone number n, and the mode type (spheroidal or toroidal), the matrix $\mathbf{C}(\omega)$ consists of blocks of dimension $(2l'+1)\times(2l+1)$, as row index m' takes on values $-l'$ to l' and column index to takes on values $-l$ to l (**Figure 15**). Thus, each block within $\mathbf{C}(\omega)$ relates two particular multiplets k, k' of the spherical reference model. Because the deviation from the spherical reference model is regarded as small, the matrix elements in $\mathbf{C}$ are small, except for the elements on the diagonal proportional to $\omega^2-\omega_k^2$. These diagonal terms are small for values of ω close to ω_k, for a given multiplet k, but for other diagonal blocks, corresponding to multiplets not close in frequency to multiplet k, they are not small; thus the matrix is, mostly, diagonally dominant, except for diagonal blocks corresponding to multiplets close in frequency to ω. Of course the complete solution is to be obtained by substituting from eqn [136] into eqn [133] and then evaluating the inverse Fourier transform; thus we need to consider the behavior of the solution as a function of complex variable ω. In particular, we are interested in the singularities that occur in the complex ω plane, as these will correspond to the modes of the aspherical model, in much the same way as the modes of the spherical model correspond to singularities, in the frequency domain, of the solution of the inhomogenous problem (eqn [97] and the related discussion). The singularities in the solution [136] will be at the

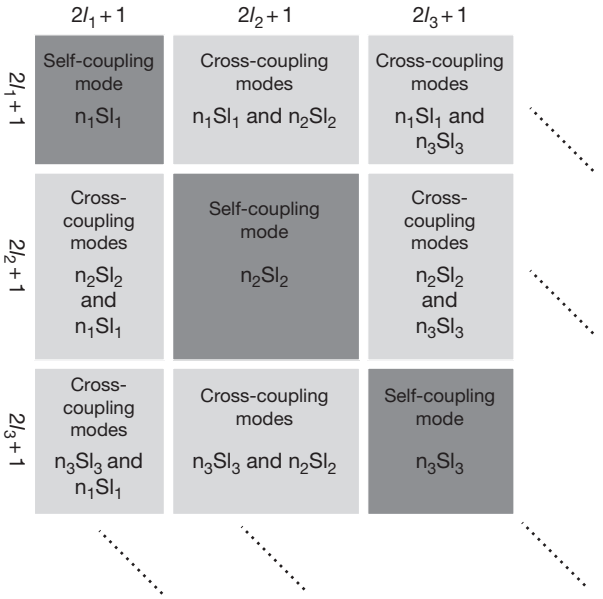

Figure 15 Schematic depiction of the different blocks in the matrix $\mathbf{C}(\omega)$ for the coupling of modes. Self-coupling blocks (dark gray) on the diagonal are of size $(2l_i+1)\times(2l_i+1)$ and one exists for each mode ${}_{ni}S_{li}$. Cross-coupling blocks (light gray) are of size $(2l_i+1)\times(2l_j+1)$ and exists for each pair of modes ${}_{ni}S_{li}$ and ${}_{nj}S_{lj}$.

frequencies $\omega = \omega_h$, say, for which there exists a nontrivial solution to the homogeneous problem

$$\mathbf{C}(\omega_h)\mathbf{r}_h = 0 \qquad [137]$$

This is an eigenvalue problem for ω_h and the corresponding right-eigenvector $\mathbf{r}_h$.

The eigenvalue problem is of a nonstandard form, since the dependence of $\mathbf{C}$ on the eigenvalue parameter $\lambda = \omega^2$, say, is not of the usual form $\mathbf{C}_0 - \lambda\mathbf{1}$. This is because, (i) perturbations in density ρ_1 introduce a more general dependence on ω^2, (ii) by virtue of attenuation, the perturbations in the elastic parameters entering into $\mathcal{H}_1$ are dependent upon ω, (iii) the terms arising from rotation depend upon ω, rather than on ω^2. Thus, the equation for $\mathbf{C}(\omega)$ is of the form

$$\mathbf{C}(\omega) = \mathbf{V}(\omega) + i\omega\mathbf{W} - \omega^2\mathbf{T} - (\omega^2 - \omega_k^2)\mathbf{I} \qquad [138]$$

where $\mathbf{V}(\omega)$ is the potential energy operator which incorporates the contributions from perturbations in the elastic parameters Λ_{ijkl} and the centrifugal potential, $\mathbf{W}$ is the Coriolis rotation operator, $\mathbf{T}$ is the kinetic energy operator which contains the perturbations to density ρ_1 and $\mathbf{I}$ is the identity matrix. (For a spherical, nonrotating model, $\mathbf{V} = \mathbf{W} = \mathbf{T} = 0$ and we find that the eigenvalues are given by $\omega_h = \omega_k$, i.e., the eigenvalues of the spherical, nonrotating reference model.)

The form of the solution as a sum over residues arising from singularities at $\omega = \omega_h$ can be obtained by replacing the inverse Fourier transform by a summation over singularities h, and within the integrand carrying out the replacement (Deuss and Woodhouse, 2004, cf. eqn [98]):

$$\mathbf{C}(\omega)^{-1} \to i\frac{\mathbf{r}_h\mathbf{l}_h}{\mathbf{l}_h\partial_\omega\mathbf{C}(\omega_h)\mathbf{r}_h} \qquad [139]$$

where $\mathbf{l}_h$ is the left-eigenvector (a *row* rather than a column), the solution of

$$\mathbf{l}_h\mathbf{C}(\omega_h) = 0 \qquad [140]$$

We are assuming here that eqns [137] and [140] determine the right and left eigenvectors $\mathbf{r}_h$, $\mathbf{l}_h$ uniquely, up to multiplying factors, such factors being immaterial for the evaluation of the residue contribution [139]. Thus, from eqn [133] the solution in the time domain can be written

$$\mathbf{u}(\mathbf{x}, t) = 2\mathrm{Re}\sum_{hkm}\frac{1}{\omega_h}\frac{\mathbf{l}_h\cdot\mathbf{E}}{\mathbf{l}_h\partial_\omega\mathbf{C}(\omega_h)\mathbf{r}_h}(km|\mathbf{r}_h)\mathbf{s}^{(km)}(\mathbf{x})e^{i\omega_h t} \qquad [141]$$

where the notation $(km/\mathbf{r}_h)$ represents individual elements of the column $\mathbf{r}_h$. As previously, the contribution from singularities in the left half of the complex ω-plane is incorporated by taking twice the real part, the summation in eqn [141] being taken only for ω_k in the right half-plane.

In order to make use of this theory it is necessary to obtain expressions for the matrix elements $(k'm'/\mathbf{C}(\omega)/km)$ in terms of the perturbations in elastic parameters, density, etc. and deviations of surfaces of discontinuity from the spherically symmetric reference model. Fairly complete forms for these are given by Woodhouse (1980a), omitting terms in anisotropic parameters and in initial stress. For anisotropic perturbations, see Chapter 1.19. The basic method is to expand the perturbations in spherical harmonics l'', m'', and then to evaluate the integrals of triples of spherical harmonics using the formula, derivable from eqns [47] and [52],

$$\frac{1}{4\pi}\int_{-\pi}^{\pi}\int_0^{\pi}\left(Y_{l'}^{N'm'}\right)^* Y_{l''}^{N''m''}Y_l^{Nm}\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi$$
$$= (-1)^{N'-m'}\begin{pmatrix} l' & l'' & l \\ -N' & N'' & N\end{pmatrix}\begin{pmatrix} l' & l'' & l \\ -m' & m'' & m\end{pmatrix}$$
$$(-N' = N'' + N) \qquad [142]$$

The resulting form for the matrix elements can then be written in the form

$$(k'm'|\mathbf{C}(\omega)|km) = \sum_{l''m''}(-1)^{-m'}\begin{pmatrix} l' & l'' & l \\ -m' & m'' & m\end{pmatrix}\left(k'||\mathbf{C}^{(l''m'')}\right)(\omega)||k) \qquad [143]$$

where the so-called *reduced matrix element* appearing in the right side, itself defined by this equation, is independent of m and m'. This particular form for the dependence of the matrix elements on m and m' is a consequence of the *Wigner–Eckart theorem* (see Edmonds, 1960). The expressions for the reduced matrix elements take the form of radial integrals involving pairs of scalar eigenfunctions, for multiplets k' and k, and on the $(l''m'')$ component of the spherical harmonic expansion of heterogeneity, together with terms evaluated at boundaries corresponding to the $(l''m'')$ components of the deflections of the boundaries.

1.03.8.2 Splitting of Isolated Modes: The Splitting Function

The theory above is fairly complete for the oscillations of a general Earth model. Apart from the treatment of aspherical boundary perturbations, which involves a linearization of the boundary conditions, it is in principal an exact theory (Woodhouse, 1983), provided that coupling between *all* multiplets is take into account – that is, provided that the eigenvalue problem for ω_h includes all the blocks (i.e., all modes) of the full matrix $\mathbf{C}(\omega)$. Of course the theory cannot be applied in its full form, owing to the need to manipulate infinite-dimensional matrices, and so a number of approximate schemes have been developed. The simplest, and up to now most widely applied method is to reduce the eigenvalue problem for ω_h to that for a single diagonal block or mode – the so-called *self-coupling* approximation. In this case, we focus on a single multiplet, k, and reduce $\mathbf{C}(\omega)$ to the $(2l+1)\times(2l+1)$ block matrix corresponding to multiplet k, see Figure 15. This is a justifiable approximation for the calculation of $\mathbf{u}(\mathbf{x}, \omega)$ for frequencies near ω_k if the mode can be considered *isolated*, which is to say that there are no other modes nearby having similar frequency and significant coupling terms. A precise statement of the conditions that need to be satisfied for a mode to be considered isolated has not, to our knowledge, been worked out but, roughly speaking, it is necessary for the ratio $(k'm'|\mathbf{C}(\omega)|km)/(\omega_k^2 - \omega_{k'}^2)$ for all other multiplets k' to be small, for ω near the frequency ω_k of the target multiplet.

In the self-coupling approximation the dependence of $\mathbf{C}(\omega)$ can be linearized for frequencies near ω_k: $\mathbf{C}(\omega) \approx \mathbf{C}(\omega_k) + \mathbf{C}'(\omega_k)\delta\omega$, and a $(2l+1)\times(2l+1)$ matrix eigenvalue problem is obtained for $\delta\omega$:

$$[\mathbf{C}(\omega_k) + \mathbf{C}'(\omega_k)\delta\omega]\mathbf{r} = 0 \qquad [144]$$

having eigenvalues $\delta\omega_h$, say. This can also be written, to zeroth order

$$\mathbf{H}^{(k)}\mathbf{r} = \delta\omega\mathbf{r} \qquad [145]$$

where the $(2l+1)\times(2l+1)$ matrix $\mathbf{H}^{(k)}$, called the *splitting matrix* of the target multiplet, k, has elements $(km'|\mathbf{H}^{(k)}|km) = (km'|\mathbf{C}(\omega_k)|km)/2\omega_k$. This has now become a standard eigenvalue problem, involving diagonalization of the matrix $\mathbf{H}^k = \mathrm{I}\delta\omega\mathrm{r}$, which can easily be performed. The matrix $\mathbf{H}^k$ is given by

$$\mathbf{H}^k = \frac{1}{2\omega_k}\mathbf{C}(\omega_k) = \frac{1}{2\omega_k}\left(\mathbf{V}(\omega_k) + \mathrm{i}\omega_k\mathbf{W} - \omega_k^2\mathbf{T}\right) \qquad [146]$$

The contribution to the right side of eqn [141] can be written (Woodhouse and Girnius, 1982)

$$\mathbf{u}_k(\mathbf{x}, t) = \mathrm{Re}\sum_{m'm} -\frac{1}{\omega_k^2}\left(\exp\left(\mathrm{i}\mathbf{H}^{(k)}t\right)\right)_{mm'} E_{km'}\mathbf{s}^{(km)}(\mathbf{x})\mathrm{e}^{\mathrm{i}\omega_k t} \qquad [147]$$

the matrix exponential arising from the identity

$$\sum_{h=1}^{2l+1}\frac{\mathbf{r}_h\mathbf{l}_h}{\mathbf{l}_h\cdot\mathbf{r}_h}\exp(\mathrm{i}\delta\omega_h t) = \exp(\mathrm{i}\mathbf{H}t) \qquad [148]$$

where $\delta\omega_h$ are the eigenvalues of $\mathbf{H}$ and $\mathbf{r}_h$ and $\mathbf{l}_h$ its right and left eigenvectors; the division by $\mathbf{l}_h\cdot\mathbf{r}_h$ ensures that the eigenvectors are properly normalized. Equation [147], which is directly comparable to the result for the spherical reference model in eqn [119] (The static, time-independent terms are not included, as we are considering an approximation valid only in the spectral neighborhood of ω_k, the frequency of the target multiplet.), has the simple interpretation that at time $t=0$ the modes are excited as they would be in the reference model, as the matrix exponential is initially equal to the unit matrix. With time, the effective excitation $\exp(\mathrm{i}\mathbf{H}^{(k)}t)\mathbf{E}_k$ evolves on a slow time scale characterized by the incremental eigenfrequencies $\delta\omega_h$, the eigenvalues of $\mathbf{H}^{(k)}$. In the frequency domain, this leads to *splitting* of the degenerate eigenfrequency ω_k into $2l+1$ *singlets* – hence the name *splitting matrix* for $\mathbf{H}^{(k)}$.

It is straightforward to set up the inverse problem of estimating the splitting matrix for isolated multiplets using data spectra for many events. This is simplified by recognizing that the $(2l+1)\times(2l+1)$ matrix $\mathbf{H}^{(k)}$ is equivalent to a certain function on the sphere, known as the *splitting function* (Woodhouse and Giardini, 1985). It can be shown that for scalar perturbations from the reference model, such as ρ_1, κ_1, μ_1, $\mathbf{H}^{(k)}$ is expressible in terms of coefficients $c_{l''m''}$ which represent the spherical harmonic expansion coefficients of even degree l'', and up to finite spherical harmonic degree $l'' \le 2l$ by the expression

$$\left(km'|\mathbf{H}^{(k)}|km\right) = \Omega\beta_k m\delta_{m'm} + \omega_k\sum_{\substack{l''=0\\ l'' \text{ even}}}^{2l}\sum_{m''=-l''}^{l''}(-1)m'\left(\frac{2l''+1}{4\pi}\right)^{1/2}$$
$$\times(2l+1)\begin{pmatrix} l & l'' & l\\ 0 & 0 & 0\end{pmatrix}\begin{pmatrix} l & l'' & l\\ -m' & m'' & m\end{pmatrix}c^{(k)}_{l''m''} \qquad [149]$$

where the first term is the effect of Coriolis forces (Dahlen, 1968), β_k being the (known) rotational splitting parameter for the multiplet. Thus, the inverse problem for $\mathbf{H}^{(k)}$ is equivalent to the estimation of $c_{l''m''}$. The function on the sphere

$$\eta(\theta,\phi) = \sum_{\substack{l''=0\\ l'' \text{ even}}}^{2l}\sum_{m''=-l''}^{l''} c^{(k)}_{l''m''}\nu_l Y^{0m''}_{l''}(\theta,\phi) \qquad [150]$$

can be interpreted, at least for high-l modes, as the even degree expansion of $\delta\omega_{\mathrm{local}}/\omega_k$, in which $\delta\omega_{\mathrm{local}}$ is the eigenfrequency that a spherically symmetric model would possess if its radial structure were the same as the structure beneath the point (θ,ϕ) (Jordan, 1978). Only even degrees are present by virtue of the fact that the first 3-j symbol in eqn [149] vanishes for odd values of l''. Thus, self-coupling is only sensitive to even degree structure, that is, the average between pairs of antipodal points. Clearly, this is not the case for traveling waves and represents a shortcoming of splitting theory.

The splitting function leads to a two-stage inversion for three-dimensional structure in which stage 1 is to find the structure coefficients $c^{(k)}_{l''m''}$ that bring data and theoretical spectra into agreement, using as many events and stations as are available. Stage 2 is to determine the structural perturbations to internal heterogeneity of the Earth of degree l'' and m'' needed to match the inferred values of $c^{(k)}_{l''m''}$. Stage 1 of the procedure is nonlinear, owing to the fact that the relation between the synthetics $\mathbf{u}(\mathbf{x}, t)$ and structure coefficients $c^{(k)}_{l''m''}$ involves the exponential $\exp i\mathbf{H}^{(k)}t$. Stage 2, on the other hand, is linear; $c^{(k)}_{l''m''}$ is related to three-dimensional structural perturbations by integrals involving known differential kernels, that is

$$c^{(k)}_{l''m''} = \int_0^a\left(K^{l''}_{\rho}(r)\frac{\delta\rho^{l''m''}(r)}{\rho(r)} + K^{l''}_{\mathrm{P}}(r)\frac{\delta\upsilon_{\mathrm{P}}(r)}{\upsilon_{\mathrm{P}}(r)} + K^{l''}_{\mathrm{S}}(r)\frac{\delta\upsilon^{l''m''}_{\mathrm{S}}(r)}{\upsilon_{\mathrm{S}}(r)}\right)\mathrm{d}r$$
$$+\sum_d \delta h_{l''m''}H^d_{l''} \qquad [151]$$

where $K^{l''}_{\rho}(r)$, $K^{l''}_{\mathrm{P}}(r)$, $K^{l''}_{\mathrm{S}}(r)$ are known kernels for density, compressional velocity, shear wave velocity perturbation and $H^d_{l''}$ for discontinuity perturbations such as crustal thickness and CMB topography. Practical formulas for calculating these kernels are given in Woodhouse (1980a). This is a similar procedure to that commonly employed in surface wave studies, in which one first determines two-dimensional maps of phase velocity, over a range of frequencies, and then uses these to infer the three-dimensional structure perturbations needed to explain the inferred phase velocity maps. The spectral fitting approach using splitting function coefficients $c^{(k)}_{l''m''}$ has been widely applied (e.g., Deuss et al., 2013; Giardini et al., 1987, 1988; He and Tromp, 1996; Masters et al., 2000; Resovsky and Ritzwoller, 1995, 1998; Ritzwoller et al., 1988; Romanowicz and Breger, 2000).

Figure 16 shows an example of data and theoretical spectra using the self-coupling approximation, and including splitting function coefficients estimated from a large collection of data. In the left panel only the splitting effects of rotation and ellipticity are taken into account, whereas in the right panel the estimated splitting function has been used to calculate the synthetic spectra. The effects of ellipticity and rotation can be calculated for the spherical reference model and do not require knowledge of the three-dimensional structure. While rotation and ellipticity lead to some splitting of the singlets (**Figure 16(a)**), further splitting is present which is attributed

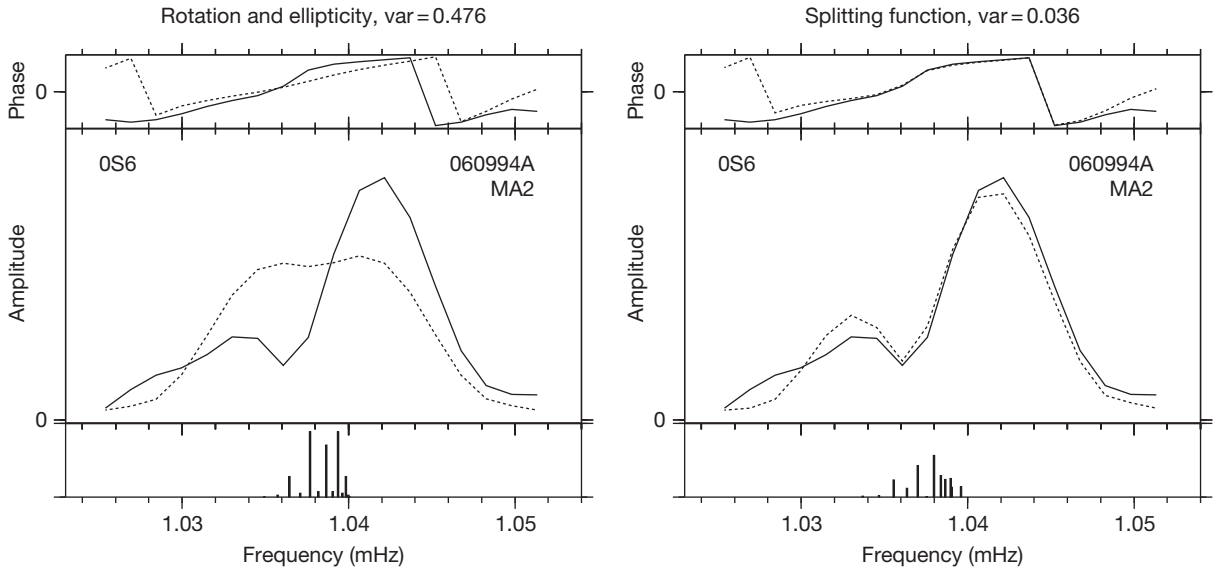

Figure 16 Data and synthetic spectra for ${}_0S_6$ for an earthquake in Bolivia. The time window is 5–70 h. The solid lines are the observed phase (top) and amplitude spectrum (middle), and dashed lines are for the synthetic spectra. In the left diagram, only splitting due to rotation and ellipticity is taken into account, in the right diagram the estimated splitting function is used, reducing the misfit variance ratio for this record from 0.476 to 0.036. The distribution of singlets contributing to the synthetic spectra and their relative excitation amplitudes are indicated at the bottom of each panel. Phase is in the interval $[-\pi, \pi]$. Reproduced from Deuss A, Ritsema J, and van Heijst HJ (2013) A new catalogue of normal-mode splitting function measurements up to 10 mHz. *Geophysical Journal International* 193: 920–937.

to three-dimensional structure and can be accounted for by using the splitting function coefficients in the calculation of the theoretical spectra (**Figure 16(b)**). The distribution of singlets and their excitations is known only by virtue of the inversion itself. There is no possibility here of resolving the singlets in individual spectra, but by modeling a large collection of spectra, for many events and stations, the underlying singlet distribution is unmasked. This example illustrates the fact that there are large differences between data and synthetics prior to estimating the splitting function coefficients, indicating that long-period spectra represent a rich source of information about the Earth's three-dimensional structure.

Figure 17 shows splitting function maps (i.e., using eqn [150]) which are measured by nonlinear inversion of large numbers of spectra such as shown in **Figure 16**. This is stage one of the inversion procedure. The top panel (**Figure 17(a)**) shows mode ${}_1S_{14}$ which is sensitive to shear wave velocity in most of the mantle and peaks in compressional velocity sensitive at the CMB; this mode is almost a Stoneley mode. The observed splitting function for ${}_1S_{14}$ shows higher frequencies in the 'ring around the Pacific,' which is also predicted for the mantle tomographic model S40RTS (Ritsema et al., 2011). These higher frequencies are due to higher velocity anomalies which are found in tomographic models in the regions of the subduction zones around the Pacific. Mode ${}_2S_{12}$ (**Figure 17(b)**) is mainly sensitive to upper mantle shear wave velocity, and is very well predicted by mantle shear wave velocity model S40RTS. Mode ${}_5S_4$ (**Figure 17(c)**) is predominantly sensitive to compressional velocity, and is less well predicted by shear wave velocity model S40RTS. Finally, mode ${}_{13}S_2$ (**Figure 17(d)**) is sensitive to the inner core, and displays strong zonal splitting (i.e., higher frequency anomalies near the poles and low frequency anomaly along the equator). This signature is not predicted by mantle models alone and requires inner core anisotropy (e.g., Woodhouse et al., 1986).

The splitting function approach has been used in inversions for tomographic velocity models (Ishii and Tromp, 1999; Li et al., 1991; Resovsky and Ritzwoller, 1999). Some recent tomographic shear wave velocity models, such as S20RTS and S40RTS (Ritsema et al., 1999, 2011), make use of splitting functions in addition to body wave, surface wave, and overtone data to provide improved constraints on the low degree structure. Splitting functions have also been used in the discovery of inner core anisotropy (Woodhouse et al., 1986), its hemispherical variation (Deuss et al., 2010) and have provided constraints on the possible rotation of the inner core (Laske and Masters, 1999; Sharrock and Woodhouse, 1998).

1.03.8.3 Normal Mode Coupling

The fact that in the self-coupling approximation seismic spectra depend only upon the *even* spherical harmonic degrees of heterogeneity points to a shortcoming of the theory. Since spherical harmonics of even degree are symmetric under point reflection in the center of the Earth, self-coupling theory predicts that the seismic spectra depend only upon the average structure between pairs of antipodal points. Thus, the interaction, or coupling, of modes must be a key effect for understanding wave phenomena that do not have this symmetry property. **Figure 18** shows the combined dispersion diagrams for spheroidal and toroidal modes at low frequencies ($f \leq 3$ MHz), an expanded version of the lower left corner of the dispersion diagrams in **Figures 9** and **10**. Many modes of different branches or even type (e.g., spheroidal or toroidal) have very similar frequencies, which leads to 'resonance' between the singlets of the different modal multiplets; we call

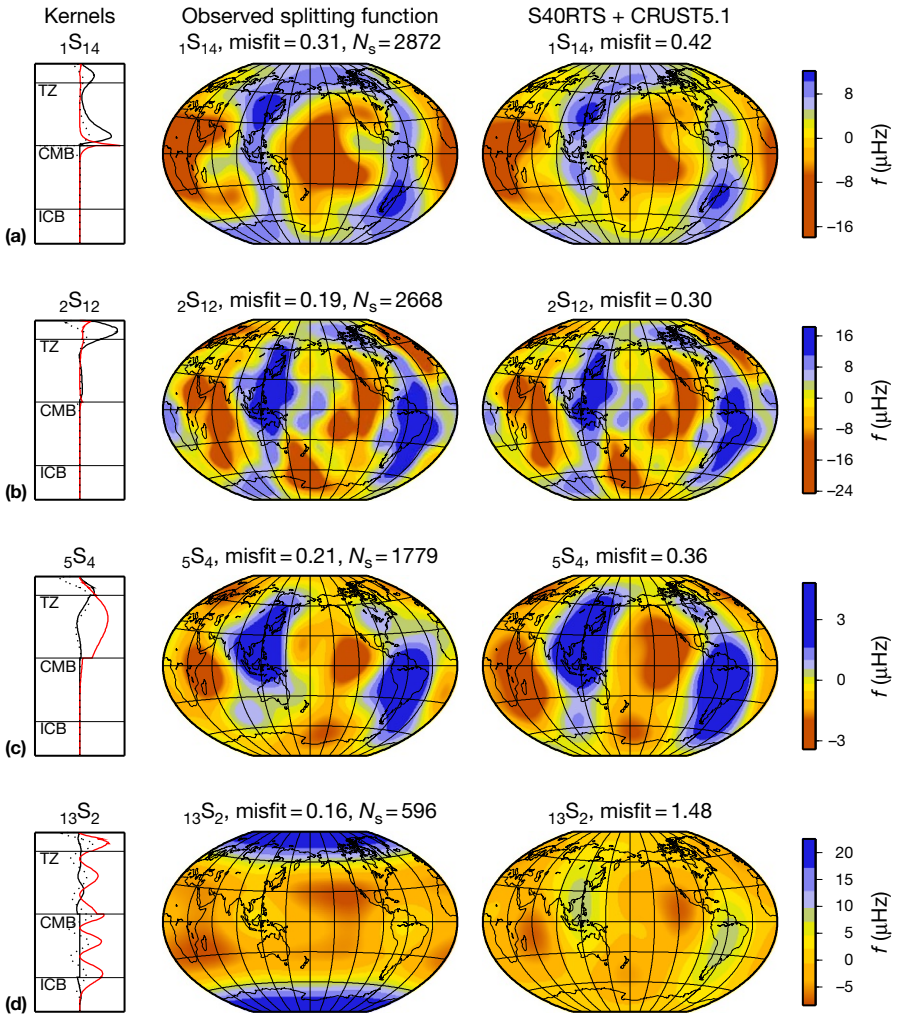

Figure 17 Observed splitting function maps and predictions for mantle model S20RTS. N_s gives the total number of spectra used for the splitting function measurement. The misfit is calculated between the observed spectra and theoretical spectra and is found to be much smaller using the observed splitting functions instead of the predictions for the S40RTS mantle shear wave velocity model (Ritsema et al., 2011) and crustal model CRUST5.1. The left panels show the sensitive kernels for each mode, where red is υ_p, solid black is υ_s, and dashed is density. Reproduced from Deuss A, Ritsema J, and van Heijst HJ (2013) A new catalogue of normal-mode splitting function measurements up to 10 mHz. *Geophysical Journal International* 193: 920–937.

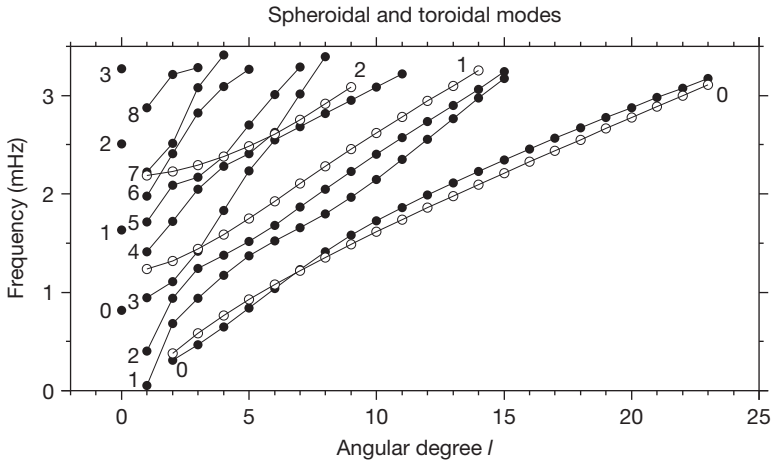

Figure 18 Eigenfrequencies of spheroidal (black circles) and toroidal multiplets (white circles) below 3 mHz for the preliminary reference model (PREM, Dziewonski and Anderson, 1981). A multiplet with angular order l consists of $2l+1$ singlets with azimuthal order $m = -l, -l+1, \cdots, l-1, l$. The branches are labeled by their overtone number n (left spheroidal, right toroidal), the fundamental mode branch is $n = 0$.

this effect *cross-coupling* in seismology. Coupling between modes allows for sensitivity to both even and odd degree structure. Two spheroidal modes ${}_nS_l$, ${}_{n'}S_{l'}$ will be sensitive to structure of degree $|l-l'| \le l'' \le |l+l'|$, and requiring that $l+l'+l''$ is even. So, if $l+l'$ is odd, there will be sensitivity to odd-degree structure. And if $l+l'$ is even (and the special case of self-coupling when $l+l'$), then there will only be sensitivity to even degree structure. The same holds for pairs of toroidal modes. Pairs of spheroidal and toroidal modes also couple due to heterogeneity of degree $|l-l'|+1 \le l'' \le |l+l'|-1$, and requiring that $l+l'+l''$ is odd. Additional coupling exists due to the Coriolis force and ellipticity, which both couple pairs of spheroidal and toroidal modes which differ by one in angular order, that is, ${}_nS_l - {}_{n'}T_{l'\pm1}$. Ellipticity also couples same type modes which differ in angular order by zero or two. Ellipticity coupling can also be seen as special case of $l''=2$ structure.

The theory can be straightforwardly extended to include the coupling of groups of modes. The resulting method is known as *quasi degenerate perturbation theory* (Dahlen, 1969; Luh, 1973, 1974; Woodhouse, 1980a), or *group coupling*. A small group of multiplets $\{k_1, k_2, k_3, \ldots\}$, close in frequency, is selected, and the eigenvalue problem is reduced to that for the matrix obtained from $\mathbf{C}(\omega)$ by selecting only the blocks corresponding to the chosen multiplets. This problem can then be linearized in $\delta\omega$, relative to a fiducial frequency in the chosen band, in much the same way as in the case of self-coupling, outlined above, the resulting matrix eigenvalue problem being of dimension $(2l_1+1)+(2l_2+1)+(2l_3+1)+\cdots$ (**Figure 15**). The selected group of modes is said to form a *super-multiplet*. Resovsky and Ritzwoller (1995) have generalized the notion of the splitting function and structure coefficients to include coupling between pairs of multiplets, so that $c^{(k)}_{l''m''}$ becomes $c^{(k_1k_2)}_{l''m''}$ and estimates have been made of such coefficients from seismic spectra (see, e.g., Deuss et al., 2013; Resovsky and Ritzwoller, 1998). While these have lead to odd-degree splitting function coefficients, they have not yet been included in tomographic inversions. Of particular interest, though, is the observation of hemispherical variations in inner core anisotropy (a type of odd-degree structure) which has been made using cross-coupling between pairs of inner core sensitive and inner core confined modes (Deuss et al., 2010).

The *self-coupling* and *group coupling* techniques depend upon the assumption that further cross-coupling is not needed to approximate the complete solution, which as we have shown, includes coupling between all multiplets. Of course full coupling calculations cannot be done for a truly infinite set of modes, but it is feasible at low frequencies to include coupling between all multiplets below a specified frequency. We shall call this *full coupling*. Deuss and Woodhouse (2001) have compared the different approximations used in computing normal mode spectra, and have found that *self-coupling* and *group coupling* can be a poor approximation to *full coupling*, indicating that a more complete version of the theory will need to be used in the future as it is desired to constrain the three-dimensional distribution of parameters, such as density, attenuation, and mantle anisotropy, on which the spectra depend more subtly.

Figure 19 shows a comparison between data and spectra calculated using *self-coupling* with those resulting from a *full coupling* calculation in which the coupling of all 140 modes up to 3 mHz has been included (see Deuss and Woodhouse, 2001, for details of the calculation). The spheroidal modes are clearly seen, and there is also signal for toroidal mode ${}_0T_{10}$ on the vertical component, which is due to Coriolis coupling. In the self-coupling calculation ${}_0T_{10}$ is not seen, but it appears in the full coupling calculation which includes Coriolis coupling between spheroidal mode ${}_0S_9$ and toroidal mode ${}_0T_{10}$. There is reasonable agreement between the data and full coupling synthetics, but the differences between data and synthetics are comparable to the difference between the *self-coupling* and *full coupling* synthetics. It may be expected that *group coupling* would be justified, and that coupling among wide bands of modes can be ignored. However, coupling on groups still shows significant differences compared to *full-coupling* (see **Figure 20**).

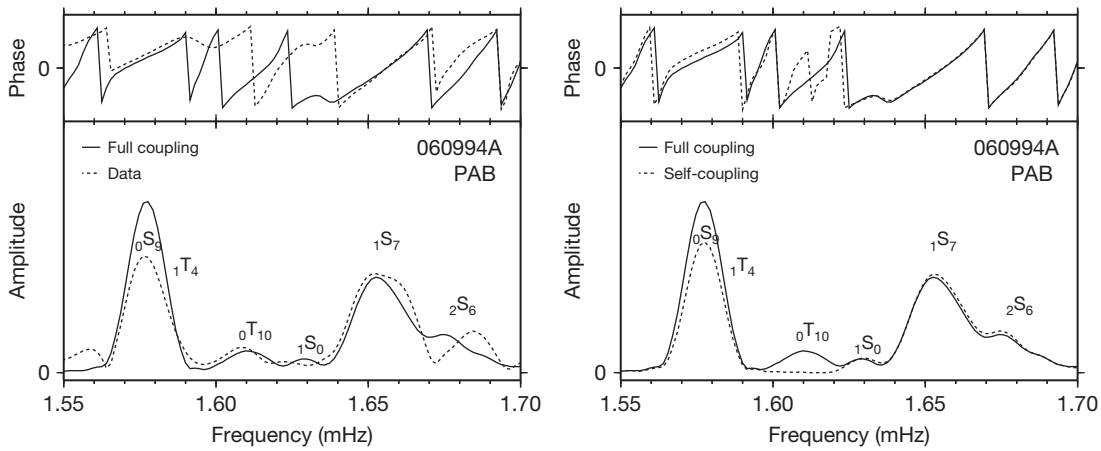

Figure 19 Data and synthetics for modes ${}_0S_9$, ${}_1T_4$, ${}_0T_{10}$, ${}_1S_0$, ${}_1S_7$, and ${}_2S_6$ at station PAB for an earthquake in Bolivia. The time window is 5–45 h. The differences between full coupling and self-coupling are similar to the differences between the data and full coupling and are of the same order as the differences that one would attempt to model. This indicates that full coupling is essential in future attempts to model inhomogeneous structure. Reproduced from Deuss A and Woodhouse JH (2001) Theoretical free oscillation spectra: The importance of wide band coupling. *Geophysical Journal International* 146: 833–842.

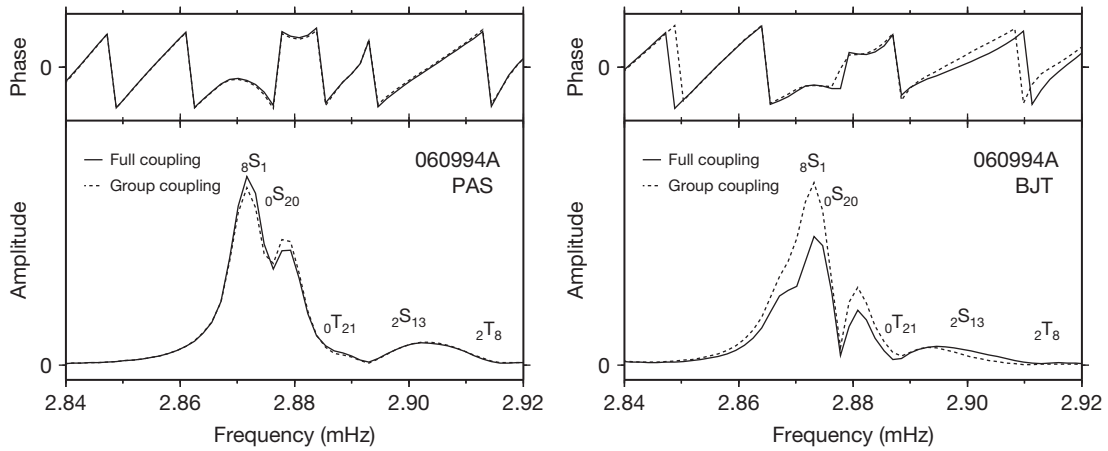

Figure 20 Synthetics for modes $_2S_{13}$, $_0T_{21}$, $_0S_{20}$, $_8S_1$, and $_2T_8$ for stations PAS and BJT of the Bolivia event of 9 June 1994. The time window is 5–80 h. All modes in the frequency interval shown were allowed to couple for the group coupling calculations; the full coupling calculation includes all modes up to 3 mHz. Reproduced from Deuss A and Woodhouse JH (2001) Theoretical free oscillation spectra: the importance of wide band coupling. *Geophysical Journal International* 146: 833–842.

In principle, normal mode spectra can be inverted directly to derive tomographic models, avoiding the intermediate step of estimating the splitting function coefficients (Durek and Romanowicz, 1999; Hara and Geller, 2000; Kuo and Romanowicz, 2002; Li et al., 1991). This leads to a one-step inversion procedure in which model parameter adjustments that enable the data and theoretical spectra to be brought into agreement are sought directly. This scheme has the advantage that the *full coupling* approach can be used for the solution of the forward problem and for calculations of the derivatives needed for formulating the inverse problem. Of course, it has the disadvantage that a nonlinear inverse problem needs to be solved within a large model space, rather than being able to restrict the nonlinear stage of inversion to the much smaller number of parameters represented by splitting functions. The calculations are also much more burdensome in terms of computer time and memory. This means that the splitting function technique is still largely the preferred method in spectral fitting studies; however, to investigate the large regions of the spectrum where wide-band coupling is expected to be significant, a final stage inversion involving full coupling will be needed.

Significant theoretical work has been directed toward developing methods able to give accurate splitting and coupling results using a practicable amount of computer time and memory (e.g., Lognonne, 1991; Lognonne and Romanowicz, 1990; Park, 1990). Deuss and Woodhouse (2004) have developed a technique for solving the *full coupling* generalized eigenvalue problem ([137], [140]) by an iterative technique, not requiring the eigenvalue decomposition of very large matrices, which is well suited to the accurate modeling of small spectral segments. The first iteration of this technique is similar to the *subspace projection method* of Park (1990), which similarly aims to approximate full coupling effects while avoiding the need to find the eigenvectors and eigenvalues of very large matrices. Al-Attar et al. (2012) developed an iterative version of the direct solution method which also does not require the decomposition of very large matrices and has been shown to be very effective in coupling large groups of normal modes.

1.03.8.4 Centroid-Moment Tensor Method

A very useful application of normal mode theory is the centroid moment tensor method, which uses waveform data to derive both the source mechanism of an earthquake and also the hypocentral coordinates of the 'best point source' at a given frequency. This method was introduced by Dziewonski et al. (1981) and applied on a larger scale by Dziewonski and Woodhouse (1983a). Consider the moment tensor as defined in eqn [31]. The moment tensor approach depends on finding the best point source, which is called the *centroid location* and the corresponding *centroid time* for which the first spatial and temporal moments are minimized in the least squares sense. In this case, we can rewrite the synthetic seismogram [119] as

$$u_k(\mathbf{x}, t) = \sum_{i=1}^{6} \psi_{ki}(\mathbf{x}, \mathbf{x}_s, t) * f_i(t) \qquad [152]$$

where $f_i(t)$ represent the six independent components of the moment rate tensor, that is, $f_1 = M_{rr}$, $f_2 = M_{\theta\theta}$, $f_3 = M_{\phi\phi}$, $f_4 = M_{r\theta}$, $f_5 = M_{r\phi}$, $f_6 = M_{\theta\phi}$. The receiver is at position $\mathbf{x}$ and the source at $\mathbf{x}_s = (\theta_S, \phi_s, r_s)$. The excitation kernels ψ_{ik} depend on the properties of the Earth in terms of the eigenfunctions and eigenvalues of the normal modes and represent synthetic seismograms corresponding to the individual components of the moment tensor of unit amplitude. If the earthquake location is fixed, then eqn [152] becomes linear in the six moment tensor components f_i. Hence, the starting solution is obtained by solving eqn [152], for a starting source position $\mathbf{x}_s$ determined from, for example, first P and S arrivals. Having found the initial estimate of the seismic moment tensor $f_i^{(0)}$, the process is then iterated using

$$u_k - u_k^{(0)} = b_k \delta r_s + c_k \delta\theta_s + d_k \delta\phi_s + e_k \delta t_s + \sum_{i=1}^{6} \psi_{ki}^{(0)} * \delta f_i \qquad [153]$$

where b_k, c_k, d_k, e_k are the partial derivatives with respect to the hypocentral coordinates. $u_k^{(0)}$ is the theoretical displacement calculated for the starting source coordinates. The theory so far is standard, but the special point is that the kernels will be

calculated using normal mode summation, see the appendix of Dziewonski et al. (1981) for specific formula. There are ten unknowns to be determined, that is, the centroid time, the three centroid location parameters, and the six moment tensor components. The process keeps on being repeated until convergence is achieved.

Dziewonski et al. (1981) initially developed the method for $45 < T < 60$ s long-period body waves. The method was then extended by Dziewonski and Woodhouse (1983a) to include long-period surface waves with $135 < T < 150$ s. It was modified by Woodhouse and Dziewonski (1984) to include simultaneous inversion for three-dimensional Earth models by using the great circle approximation (see **Section 1.03.8.5**). The method was then enhanced again in 2004 to incorporate intermediate period surface waves (Ekstrom et al., 2012). The CMT mechanisms are now determined on a routine scale for all earthquakes with moments as small as $M_w = 5.0$, with results published on the website: http://www.globalcmt.org.

1.03.8.5 Great Circle Approximation

The development of practical and less time-consuming methods has so far been most successful in the long-period waveform and surface wave approach. Woodhouse and Dziewonski (1984) developed the elegant path-average great circle approximation using phase integrals along the minor and major arcs. Consider the phase ψ of a surface wave with frequency ω. We can then approximate perturbations to the phase because of lateral heterogeneity by

$$\delta\psi = \int_0^t \delta\omega_{\text{local}}\,\mathrm{d}t \qquad [154]$$

where the integration is with respect to the group travel time along the great circle path between the source and receiver. The local perturbation in eigenfrequency $\delta\omega_{\text{local}}$ is defined using the notation of Jordan (1978)

$$\delta\omega_{\text{local}}(\theta, \phi) = k\delta c(\theta, \phi) \qquad [155]$$

where δc is the perturbation to the phase velocity and the wave number k is given by eqn [121]. Woodhouse and Dziewonski (1984) showed that the phase perturbations for both odd and even orbits may be mimicked in terms of a fictitious frequency shift $\delta\hat{\omega}$ and fictitious perturbation in epicentral distance $\delta\theta$, that is

$$\delta\hat{\omega} = \frac{1}{T}\int_0^T \delta\omega_{\text{local}}\,\mathrm{d}t = \text{great circle average} \qquad [156]$$

$$\delta\theta = \frac{t_1}{\left(l + \frac{1}{2}\right)}(\delta\hat{\omega} - \delta\widetilde{\omega}) \qquad [157]$$

where

$$\delta\widetilde{\omega} = \frac{1}{t_1}\int_0^{t_1} \delta\omega_{\text{local}}\,\mathrm{d}t = \text{minor arc average} \qquad [158]$$

and T is the great circle group travel time and t_1 is the minor arc travel time. This result is in agreement with Jordan (1978) that the apparent frequency shift is the great circle average of $\delta\omega_{\text{local}}$, and that the apparent distance shift depends upon the difference between the great circle and minor circle averages. Along branch coupling (i.e., between modes with the same overtone number n) is automatically included by taking the difference between the major and minor arc mode frequency shifts, and thus this method also provides information on odd-degree structure in addition to even-degree structure. It gives a simple way of calculating seismograms, which incorporate the effects of phase delays along incomplete arcs, by replacing the frequency of each mode and the epicentral distance of each path by their perturbed equivalents. It should be noted that this approximation only incorporates an approximation to the phase perturbations and completely omits the consideration of amplitudes. Nevertheless, this simplified version of ray theory is a very useful one for waveform inversion and has been applied in many tomographic studies of mantle structure to both surface wave and long-period body wave data. It is a good approximation for the fundamental mode and low overtones, which constitute a major part of the long-period body wave signal.

Figure 21 illustrates the improvement in phase match after a joint inversion for the CMT source and three-dimensional Earth structure using the great-circle approximation. Performing a combined inversion for sources and structure has great advantages and prevents trade-off between the recovered structure after tomographic inversion and the use of a simplified (i.e., 1D) model for the source inversion. Performing the CMT inversion jointly with a structure inversion leads to a significant improvement in phase match between data and synthetics (**Figure 21**). Procedures for performing a combined inversion are outlined in Woodhouse and Dziewonski (1989) and Valentine and Woodhouse (2010).

The shortcoming of the great circle approximation is that it is not very accurate for direct body wave phases, since it predicts that the observed seismogram depends only upon the horizontally averaged structure. The great circle, or path-average approximation, was extended by Li and Tanimoto (1993) and Li and Romanowicz (1995) to include across branch-coupling (i.e., between modes with different overtone number n), which asymptotically corrects the body wave phases. In practise, nonlinear asymptotic coupling theory splits the synthetic seismogram calculation into two parts. The first part is just the great circle approximation, where the frequency and epicentral distance are replaced by their perturbed equivalents, and then a second part is added which represent the cross-branch mode coupling effects, see Romanowicz et al. (2008) for details. This method has been successfully applied to whole mantle tomography using waveforms.

1.03.9 Concluding Discussion

The normal mode formalism provides a well developed theoretical framework for the calculation of theoretical seismograms in both spherically symmetric and three-dimensional Earth models. For spherically symmetric models the ability to simply and quickly calculate complete theoretical seismograms plays an important role in the formulation and solution of many seismological problems involving both surface waves and long-period body waves. In the three-dimensional case,

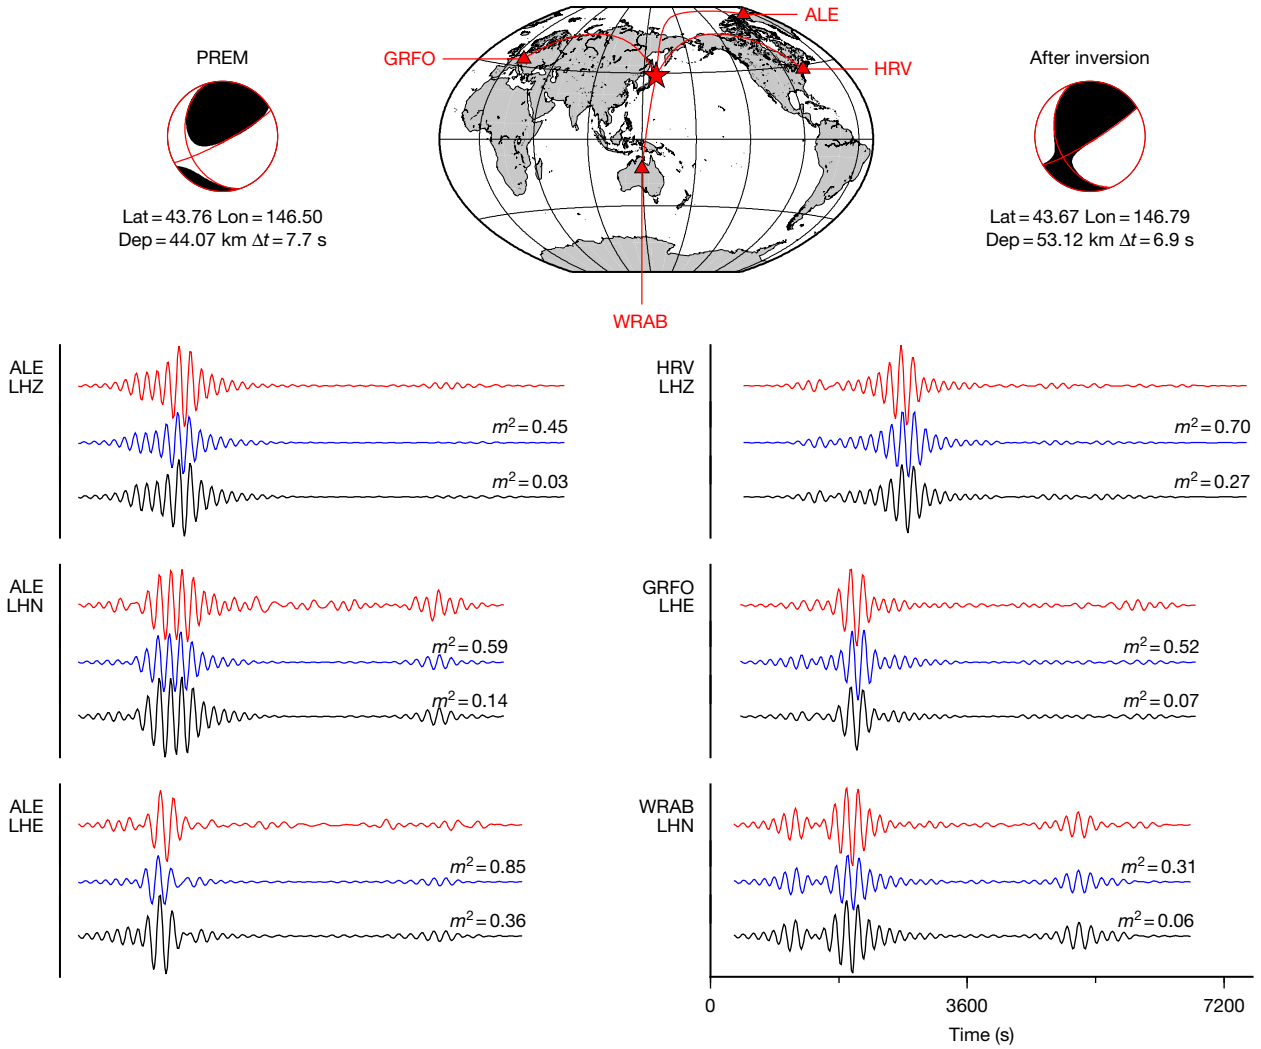

Figure 21 The effects of combining path-average heterogeneity and source determination inversion. One hundred and forty-six long-period surface wave seismograms ($135 < T < 150$) recorded for the 21st January 2000 Kuril Islands event (GCMT code 012800B; star on map) were inverted for the optimal centroid-moment-tensor source description. Six representative data traces are shown, in red, corresponding to stations marked with triangles on map. Inversion in PREM yields best-fitting source shown above left, with overall misfit $m^2 = |d - s|^2/|d|^2 = 0.415$, and waveforms shown in blue. If inversion for path-average structure perturbations is also performed, the source shown above right can be obtained, with $m^2 = 0.272$, and waveforms shown in black. Misfit values for individual paths are given above synthetic traces. We observe that incorporating structural corrections through the path-average approximation allows a significant improvement in agreement between data and synthetics, and that the details of the Earth model affect the results of CMT inversion (see, e.g., Valentine and Woodhouse, 2010; Valentine and Trampert, 2012). Figure courtesy of Andrew Valentine.

the theory of mode coupling is too cumbersome to be applied in full, but it enables a number of useful approximations to be developed and tested. The increasing capacity in high performance computing means that it becomes possible to develop and test increasingly more complete implementations of the fully coupled theory. Progress on fully numerical solutions for seismic wave fields in realistic three-dimensional spherical models (Komatitsch and Tromp, 2002a,b), while it is providing a new and invaluable tool in many areas of global seismology, has not yet made it possible to calculate accurate very long-period spectra. In part this is because a way has not (yet?) been found to fully implement self-gravitation in the spectral element method, and in part because the small time step needed in finite difference and spectral element calculations leads to very long execution times; also, there are very stringent limits on the tolerable amount of numerical dispersion in the solution.

Long-period modal spectra constitute a rich source of information on long wavelength heterogeneity, studies to date, we believe, having only scratched the surface. To realize the potential of this information will require large-scale coupling calculations or, possibly, other methods for calculating very long-period wave fields yet to be developed. This will make it possible to bring modal spectral data increasingly to bear on furthering our understanding of the Earth's three-dimensional structure.

Acknowledgments

We thank Barbara Romanowicz and Adam Dziewonski for thoughtful reviews which helped improve the manuscript. We also thank Andrew Valentine for making Figure 21 illustrating the great circle approximation and CMT method. AD has been funded by the European Research Council under the European Community's Seventh Framework Programme (FP7/2-7-2013)/ERC grant agreement 204995 and a Philip Leverhulme Prize.

1.04.1 Introduction

1.04.1.1 Free Oscillations

The destructive $M_W = 9.0$, 11 March 2011 Tohoku, Japan, earthquake most certainly raised recent awareness of extremely large earthquakes. And also remembering the $M_W = 9.1$ 26 December 2004 Sumatra–Andaman earthquake and the $M_W = 8.8$ 27 February 2010 Maule, Chile, earthquake, one can easily forget that a seismologist has to wait many years for a great, preferably deep earthquake to occur in order to observe Earth's free oscillations. After all, the last earthquake in this league of 'mega earthquakes' occurred 40 years before the Sumatra–Andaman event: the 'Good Friday' 27 March 1964 Alaska earthquake. It is therefore not surprising that, compared to other seismic studies, free oscillation studies started relatively late last century, after the great $M_W = 9.5$ 22 May 1960 Valdivia, Chile, earthquake. It was not until 1975 – after the analysis of digitized records of the deep, magnitude 8.0 31 July 1970 Colombia earthquake – that enough mode measurements were available to construct the first one-dimensional (1-D), normal-mode derived Earth that could withstand decades of testing as a reference Earth model (REM) (1066A by Gilbert and Dziewonski, 1975). Not much later, great progress was achieved to facilitate the collection of high-quality mode data by installing the global digital seismic network IDA (International Deployment of Accelerometers), a network of LaCoste–Romberg gravimeters that were specifically designed to observe Earth's free oscillations (Agnew et al., 1976, 1986). In the meantime, permanent stations of several other global seismic networks have been upgraded with very broadband seismic sensors – typically Wielandt–Streckeisen STS-1 vault seismometers or Geotech–Teledyne KS-54000 borehole

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00003-8

seismometers – and digital recording units. This includes early networks that were designed to monitor global seismicity and the comprehensive test ban treaty (CTBT), such as the high-gain long-period (HGLP) network (first digitally recording network; Savino et al., 1972), the seismic research observatory (SRO; Peterson et al., 1980), the World-Wide Standardized Seismograph Network (WWSSN; Oliver and Murphy, 1971), and the China Digital Seismograph Network (CDSN; Peterson and Tilgner, 1985). Many of these stations as well as the upgraded IDA network are now part of the US Global Seismic Network (GSN) operated by IRIS (Incorporated Research Institutions for Seismology), but other global networks exist such as the French GEOSCOPE (Romanowicz et al., 1984) and the German GEOFON (Hanka and Kind, 1994). All these and more operate under the umbrella of the international Federation of Digital Seismograph Networks (FDSN; Romanowicz and Dziewonski, 1986). Roughly 25 years into very broadband seismic networks, a normal mode seismologist now can enjoy a more than tenfold increase in high-quality vertical-component long-period seismic records for a given earthquake. But even in the late 1990s – a few years after the deep magnitude 8.2 09 June 1994 Bolivia earthquake provided spectacular spectra – great effort was invested in digitizing the legendary 1970 Colombia records. Before the 26 December 2004 Sumatra–Andaman earthquake, there have been a handful of other great earthquakes since 'Bolivia.' But even the great 23 June 2001 Arequipa, Peru, earthquake, the largest digitally recorded earthquake until then, did not excite the relatively few normal mode observers whose interest lies in unraveling the deep secrets of the inner core (IC). 'Peru' was simply not deep (or great) enough to make some of the modes ring that the observers are interested in. On the other hand, since normal modes involve the vibration of the whole planet, mode observations at a single station readily reveal a wealth of information about Earth structure that no other seismic techniques can provide. Modes are intrinsic low-pass filters of Earth structure. It is relatively easy to collect unbiased estimates of mode observables that constrain the spherical average of Earth as well as long-wavelength perturbations to it. It is therefore not surprising that in the current efforts to remove the more than three-decade-old 'preliminary' from PREM (preliminary reference Earth model, Dziewonski and Anderson, 1981) – the currently still most widely accepted REM of the spherical average – a suitable mode data set for an updated model exists (a 'best-estimate' data set can be obtained from the REM website), while we still struggle to obtain an unbiased body-wave data set.

Normal mode seismology has facilitated other great achievements that we can proudly look back to. For example, the analysis of modes provided the ultimate proof that the IC is solid (Dziewonski and Gilbert, 1971). Normal mode studies were at the forefront to assess Earth's attenuation (Smith, 1972) and to retrieve earthquake moment tensors (Gilbert and Dziewonski, 1975), which has been continued in the faithful delivery of the Harvard centroid moment tensors (CMTs) (Dziewonski et al., 1981) now continued as the 'global CMT project' led by Göran Ekström at Lamont Doherty Earth Observatory (LDEO) (Ekström et al., 2012; www.globalcmt.org) that many colleagues depend on for their own studies. Normal mode studies also were at the forefront to assess Earth's 3-D structure. For example, Jobert and Roult (1978) found early evidence for large-scale lateral variations from free oscillations and surface waves, and Masters et al. (1982) discovered harmonic degree 2 variations in the transition zone that are associated with subducting slabs. The first widely used 3-D models of Earth's upper mantle, M84A and M84C (Woodhouse and Dziewonski, 1984), were obtained using mode theory. Still today, careful analysis of high-precision mode measurements provides crucial clues to answer some of the most fundamental geodynamical questions that remain elusive to other seismic techniques. For example, the analysis of Masters and Gubbins (2003) provided updated estimates of the density jump across the IC boundary, which is relevant to the discussion of the growth rate and the age of the IC. They also argue against a significant overall excess density in the lowermost mantle that was proposed by Kellogg et al. (1999) for locally varying hot abyssal layers for which seismic evidence was presented by Ishii and Tromp (1999). Earth's density structure and the solidity of the IC are best constrained by mode data. Similarly, modes help determine Earth's internal anelastic and anisotropic structure. There are many more aspects where mode data can help out to understand how our planet works. One example is the differential rotation of the IC. Evidence for this was first observed using body-wave data and was initially reported to be between 1° and 3° per year (Song and Richards, 1996; Su et al., 1996) but hotly debated (e.g., Souriau, 1998). As subsequent studies accumulated, this number decreased dramatically and is currently estimated at 1/10 of the initial rate. Mode observations in particular (Laske and Masters, 1999, 2003; Sharrock and Woodhouse, 1998) provided the conclusive constraints to correct the rotation estimates downward.

In the first part of this chapter, the reader gets acquainted with the jargon used in normal mode seismology, some of which requires to summarize the theoretical background that is described in **Chapter 1.02**. We then introduce some of the most commonly used measurement techniques that we have been involved in. Mode analysis involves more than simply reading the peak frequencies and amplitudes from a spectrum. In fact, in most cases, such an approach leads to biased estimates. One also has to bear in mind that the most basic analysis techniques treat modes as being isolated from their neighbors in which case only Earth structure of even-degree symmetry can be retrieved. Earth's rotation and lateral variations cause modes to couple with each other. This complicates mode analysis but also facilitates the assessment of odd-degree structure. This is briefly described.

1.04.1.2 Surface Waves

Surface waves can be understood as a superposition of free oscillations. It is therefore not surprising that many long-period surface wave seismologists analyzed normal modes at some time in their career. With a few exceptions, including very deep earthquakes, fundamental mode surface waves are the largest signal in a seismogram. First-arriving surface wave packets are relatively short and do not require the consistently high signal levels, over several days, as normal modes do. Nor do they require the wait for very large earthquakes. The analysis of surface waves essentially involves the analysis of fundamental modes and the first few overtones, at high frequencies. Surface waves are therefore a natural choice to explore Earth's

crust, upper mantle, and transition zone. Much like in a body-wave study, the analyst collects travel times, but the complication is that these depend on frequency. Rather than a sharp onset, a wave packet is observed that is often likened to a Gaussian packet. The two travel time-equivalent observables of dispersed surface waves are phase velocity, the speed at which a certain point in the waveform travels, and group velocity, the speed at which wave energy or a point on the envelope of the waveform travels. Though both observables constrain structure at depth, they have different dependencies, and ideally one would want to measure both. Group velocity tends to change more significantly with structure at depth, but its measurement errors are also larger than those of phase velocity. On the other hand, source effects on group velocity are relatively small and are usually ignored. Details on earthquake source processes therefore do not have to be known to measure group velocity.

The analysis of surface waves has a major advantage over that of body waves. In the upper mantle, imaging capabilities using body waves are dictated by the distribution of earthquakes and seismic stations. Surface waves travel along the surface between sources and receivers, crossing remote areas and thereby picking up invaluable information about along-path upper-mantle structure that remains elusive to body waves. Like a body-wave arrival, group velocity can be measured on a single wave train recorded at a single station without having to resort to calculating synthetic seismograms that are necessary to measure phase travel times. For this reason, group velocity analysis has seen a wide range of applications in regional seismology, especially in the CTBT community, even before the advent of sophisticated signal processing.

In the second part of this chapter, we first summarize the relationship between normal modes and surface waves. Some of the surface wave observables are described and how they are measured. We touch on the observation of higher modes and discuss the relationship between dispersion and structure at depth, but the reader interested in Earth structure is referred to other contributions in this volume.

1.04.1.3 What We See in Seismograms: The Basics

For moderately large earthquakes, seismograms exhibit a number of wave trains, some of which circled the globe completely before arriving at a station. Figure 1 shows the nomenclature for these wave trains. We distinguish between minor and major arc wave trains that arrive at a station from the source directly or took the long path in the opposite direction. Figure 2 shows an example of a vertical seismic record collected at a station of the GEOSCOPE network. Rayleigh wave trains are usually labeled R, while overtones are often labeled X (e.g., Roult et al., 1986). Love wave trains carry the label G and are observed on the transverse component only, unless Earth's rotation and/or heterogeneity causes strong lateral refraction or, to use the mode analogy, toroidal–spheroidal mode coupling. For large earthquakes with magnitudes typically larger than $M_S = 6.5$, surface waves may be observed as they circle the globe multiple times. At group velocities of about 3.7 km s^{-1}, long-period Rayleigh waves take about 3 h to complete one orbit.

Very large earthquakes can be observed at many global seismic stations with fidelity high enough to discern many

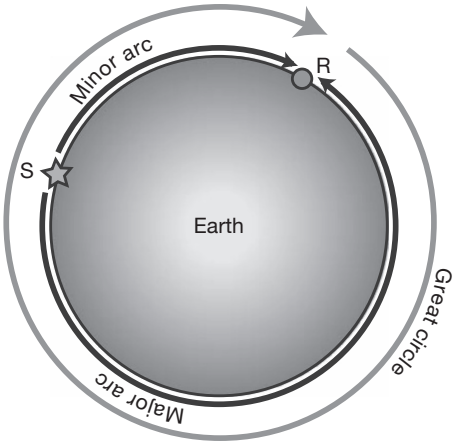

Figure 1 Surface wave paths from source S to receiver R. Paths associated with the shorter distance from the source are minor arc paths (R_1); paths associated with the larger distance are major arc paths (R_2). The number following R is the wave orbit number. The wave orbit number advances by two when successive wave trains include a complete great circle (e.g., R_3 and R_5 for minor arc paths).

wave trains in a record section. Figure 3 shows the tsunami-generating 2001 Arequipa, Peru, earthquake. We can follow R_1 across the globe from the source toward its antipode where the wave train merges with R_2. Near the source, R_2 and R_3 overlap. A similar collapse of waveforms can be observed for later wave trains. Gray lines mark some of the body-wave phases that combine to form the overtones X wave trains as shown in Figure 2. For earthquakes as large as the Arequipa event, multiple body-wave reflections off the surface, or globe-circling overtones, are also discernible. Very nicely displayed for the Arequipa event, we can follow these overtones at significant signal levels between the fundamental modes, and later, overtone packets also merge near the source and its antipode. If we consider these overtone packets as modes, some of them have very low attenuation rates and can persist well after the fundamental modes have decayed into the noise. To observe these modes with high fidelity, the collected records typically have to be at least 5 days long.

Figure 4 shows the spectrum of a large earthquake observed at the Black Forest Observatory (BFO) in Germany. Since Earth is a finite body, transient waves propagating away from a localized source eventually interfere. For paths whose orbital length is an integer multiple of the wavelength, the two signals interfere constructively while destructive interference occurs otherwise. The spectrum of the several-day-long coda therefore yields discrete lines that correspond to Earth's normal modes, while destructive interference is responsible for the gaps separating the peaks.

We distinguish between observably split and not observably split modes. A spectral line of the former type has more than one peak in a typical spectrum (Figure 5). This 'splitting' of a mode is caused by the fact that individual singlets, the different 'vibrational states' of a certain mode (multiplet), are no longer degenerate in a nonspherical Earth. Observably split modes are typically of low angular order, that is, the

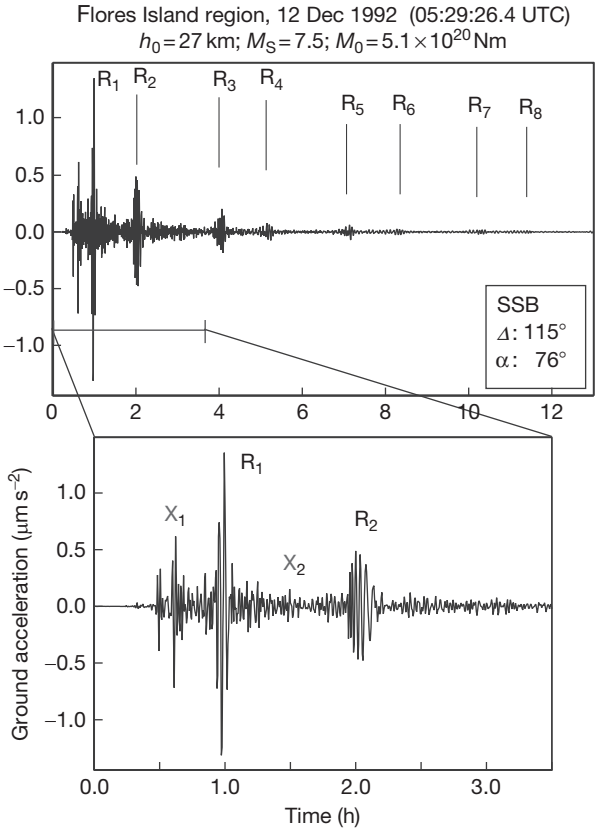

Figure 2 The 1992 Flores Island earthquake, recorded at GEOSCOPE station SSB (Saint Sauveur Badole, France). Marked are eight fundamental mode Rayleigh wave trains (R_n) and the first two overtone groups (X_n). Δ and α are the epicentral distance and the back azimuth to the event. Since the earthquake was more than 90° away, R_1 and R_2 are closer together than R_2 and R_3. At group velocities of about 3.7 km s^{-1}, it takes 3 h for Rayleigh waves to circle the globe. Hence, R_3 arrives at a station 3 h after R_1. The seismogram was low-pass-filtered with a convolution filter to suppress signal above 20 mHz.

geographic pattern of surface displacement is simple and the mode has few singlets. In the case of not observably split modes (Figure 4), there are so many singlets of a mode or the singlets are so close together that a standard spectral analysis is not able to resolve them. Another limiting factor to resolve a mode's splitting is its attenuation rate. The rather complex superposition of all the singlets causes an 'apparent frequency shift' of an otherwise ordinary-looking spectral peak where the shift depends on lateral variations in Earth structure (Jordan, 1978).

Having long wavelengths compared to transient seismic waves, such as body waves and surface waves, free oscillations inherently average over large volumes, which leads to comparatively poor resolution of Earth's heterogeneous structure. On the other hand, free oscillation studies are much less likely biased by the uneven global distribution of earthquake sources and seismic receivers. Mode observables are relatively weakly sensitive to structure with odd-degree symmetry because waves traveling on a sphere lose their sensitivity to this structure as time goes on. With every completed great circle, an observable accumulates information about the average structure over the entire great-circle path. This information is symmetric with respect to Earth's center and thus reflects only even-degree structure. We will revisit this problem in the surface wave section.

1.04.2 Free Oscillations

1.04.2.1 Modes of a Spherically Symmetric Earth

The elastic-gravitational response of Earth to localized, transient excitations consists of impulsive disturbances followed by dispersed wave trains and long-lasting standing waves, as seen in Figures 2–4. As long as an earthquake rupture is ongoing, Earth responds with forced vibrations. Once the rupture has ceased, Earth undergoes free oscillations around its new equilibrium state. The rupture duration of the largest earthquakes is on the order of a few minutes and thus very much shorter than the typical decay time of modes, which is a few tens of hours. A study of the source based on low-frequency seismic records reduces to the estimation of the initial amplitude and phase of the modes, while studies of Earth's internal mechanical structure concentrate on the frequency, ω, and attenuation, α, of the mode, where $\alpha = \omega/2Q$ and Q the quality factor.

The deviations of Earth structure from a spherically symmetric reference state are quite small. It is therefore convenient to discuss free oscillations of a spherically averaged Earth and treat any deviation away from this state with perturbation theory. On a spherically symmetric Earth, three integer quantum numbers, n, ℓ, and m, fully specify the set of normal modes. The azimuthal order, $|m|$, counts the number of nodal surfaces in the longitudinal direction $\hat{\phi}$. The number of nodal surfaces in the colatitudinal direction, $\hat{\theta}$, is $|\ell - m|$, where ℓ is the angular order. For fixed ℓ and m, the overtone number n indexes the modes with increasing frequency.

Solutions of the linearized, homogeneous equations of motion for a self-gravitating elastic Earth can be written as (Aki and Richards, 1980, 2002; Backus, 1967; Dahlen and Tromp, 1998; **Chapter 1.02**)

$$ {}_n u_\ell^m(\mathrm{r}, t) = \mathrm{Re}\left[\left(\hat{\mathrm{r}}_n U_\ell(r) Y_\ell^m(\theta, \phi) + {}_n V_\ell(r) \nabla_1 Y_\ell^m(\theta, \phi) \right.\right. $$
$$ \left.\left. - {}_n W_\ell(r) \hat{\mathrm{r}} \times \nabla_1 Y_\ell^m(\theta, \phi) \right) e^{i\, {}_n \omega_\ell^m t} \right] \quad [1] $$

where ${}_n u_\ell^m$ is the displacement eigenfunction of the mode singlet identified by the (n, ℓ, m)-triplet and ${}_n\omega_\ell^m$ is its eigenfrequency. Y_ℓ^m are surface spherical harmonic functions and ∇_1 is the surface gradient operator. While n and ℓ can be any non-negative number ($n \geq 0$, $\ell \geq 0$), the azimuthal order is limited to the interval $-\ell \leq m \leq \ell$. The spherical harmonics describe the angular shape of the eigenfunction. An example for some low-order spherical harmonics is shown in Figure 6.

The three scalar radial eigenfunctions, ${}_n U_\ell(r)$, ${}_n V_\ell(r)$, and ${}_n W_\ell(r)$, describe the way the modes sample Earth with depth. As n increases, they become more oscillatory with depth, leading to an increased number of nodal spheres. For toroidal modes, n is the number of nodes in W, while for radial modes, n is the number of nodes in U. For spheroidal modes, both U and V can have nodes, but the number of nodes is not as easily related to n. The radial eigenfunctions do not depend on the azimuthal order m and are thus identical for all singlets within a multiplet. Eigenfunctions for some mode examples are shown in Figures 7 and 8. The relevant quantity for the

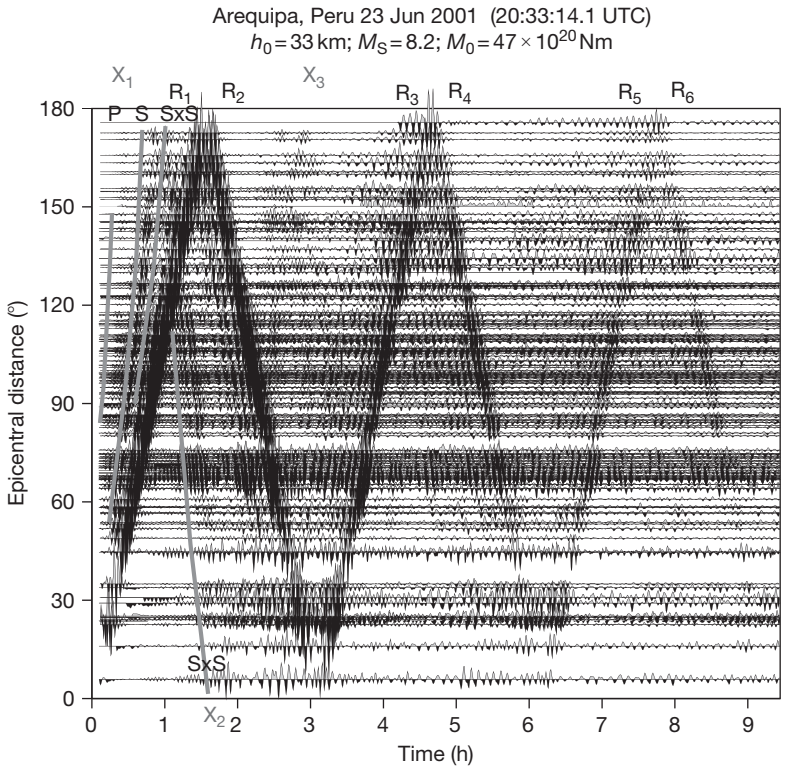

Figure 3 Record section of the 2001 Arequipa, Peru, earthquake, the largest digitally recorded earthquake before the 2004 Sumatra–Andaman earthquake. Marked are six fundamental mode Rayleigh wave trains (R_n) and early compressional (P) and shear (S) body-wave arrivals. Also marked are S multiples that bounced off the surface (S×S). Such phases are contributors to the major arc overtone phases X_n. At 90° epicentral distance, surface wave trains traveling in opposite directions arrive at a station at equidistant time intervals, while wave trains overlap at the antipode and near the source.

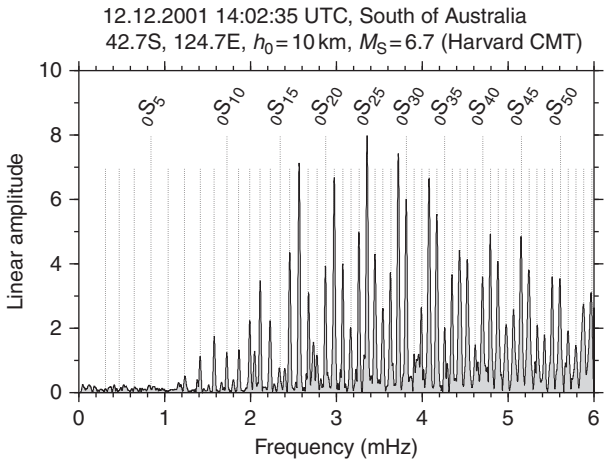

Figure 4 Spectrum of a magnitude $M_S = 6.7$ earthquake south of Australia that was recorded at station BFO (Black Forest Observatory, Germany). The succession of globe-circling Rayleigh wave packets in roughly 3 h intervals manifests itself in the spectrum through the regular spacing between adjacent fundamental spheroidal modes $_0S_\ell$ of about $(3\text{ h})^{-1} \cong 0.1$ mHz. The underlying time series is 18 h long.

sensitivity of a mode to structure with depth is actually not the eigenfunction but the energy density. This is because the modes are stationary solutions to the Lagrangian energy functional (Gilbert, 1980). A mode can store elastic energy in shear and in compression, and it can store gravitational potential energy. Significant amounts of the latter can be stored only by spheroidal modes below 1 mHz. For most other modes, their sensitivity to structure can be discussed based solely on their shear and compressional energy densities.

For the spherically symmetric reference state, the structure of the spectrum of a mode (fixed n and ℓ) exhibits a high degree of degeneracy in that all of its $2\ell+1$ singlets have the same frequency and the same radial eigenfunction. This degeneracy in m is a consequence of the fact that the singlet eigenfrequencies cannot depend on the choice of the coordinate system. The ensemble of $2\ell+1$ singlets comprises the mode multiplet. Further classification into spheroidal and toroidal modes is possible in the spherically symmetric case. The displacement field of toroidal modes, $_nT_\ell^m$, is purely horizontal and divergence-free with $_nU_\ell(r) = {}_nV_\ell(r) = 0$. Thus, it involves only shearing and does not lead to any deformation of the radial interfaces. Spheroidal modes, $_nS_\ell^m$, for which $_nW_\ell(r) = 0$, involve volumetric changes as they are composed of both horizontal and vertical displacements. They deform interfaces and also perturb the gravity field. A third subclass of modes are the radial modes, $_nS_0$, for which $\ell = 0$ and the displacement is purely radial, so that $_nV_\ell(r) = {}_nW_\ell(r) = 0$.

The formulation of computational methods for the practical calculation of normal-mode seismograms reaches back to the early 1970s. Takeuchi and Saito (1972) first formulated a Runge–Kutta matrix integration scheme to solve the ordinary

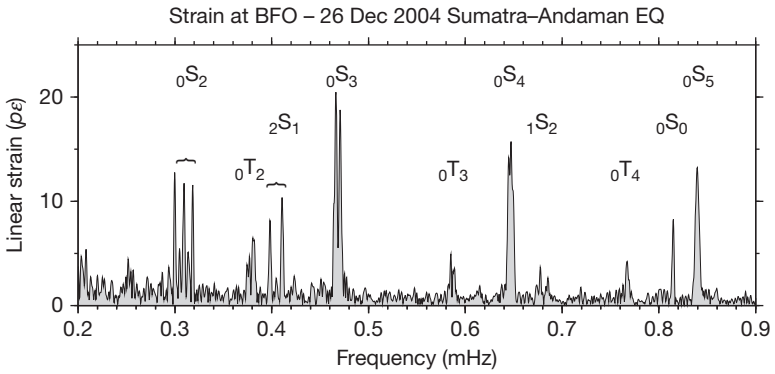

Figure 5 Linear Fourier amplitude spectrum of strain from the 2004 Sumatra–Andaman earthquake recorded by the invar wire strainmeter at station BFO with azimuth N2°E. The time-domain amplitude of ${}_0S_0$ at 0.814 mHz is $8 \times 10^{-12}\epsilon$. This is a rare spectrum showing evidence of Zeeman-type splitting due to Earth's rotation of not only to the lowest-order spheroidal modes ${}_0S_2$, ${}_2S_1$, ${}_0S_3$, and ${}_0S_4$ but also to the two lowest-order toroidal modes ${}_0T_2$ and ${}_0T_3$. The strainmeter array at BFO is described in Widmer et al. (1992a). A barometric correction similar to that of Zürn and Widmer (1995) has been applied to this spectrum. With an empirically determined strain pressure compliance of 0.8 nε hPa^{-1}, a lowering of the noise floor by a factor 4 was achieved. The first 240 h after the event was used for the spectrum.

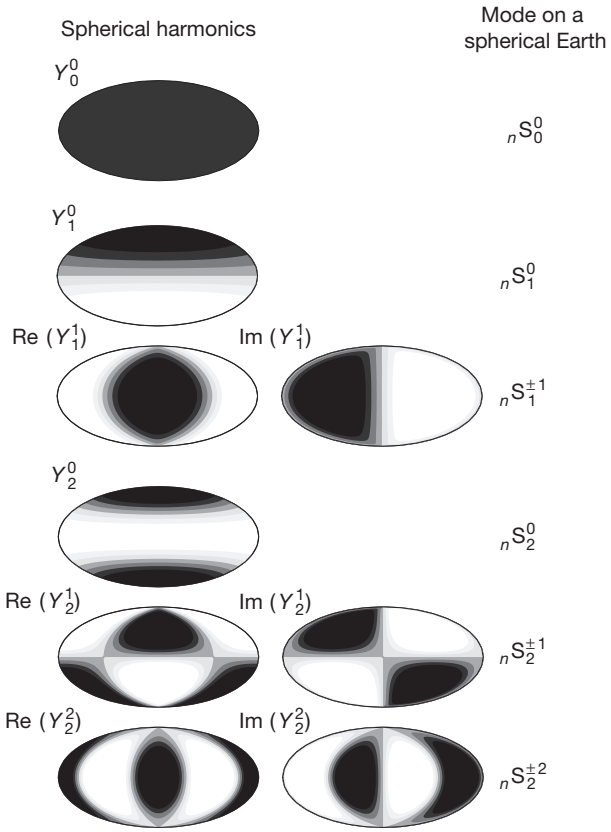

Figure 6 Surface spherical harmonics $Y_\ell^m = X_\ell^m(\theta)e^{im\phi}$ that compose the basis set for radial modes (e.g., ${}_0S_0$, ${}_1S_0$) and $\ell = 0$, 1, and 2 spheroidal modes (e.g., ${}_1S_1$, ${}_2S_1$, ${}_0S_2$, and ${}_3S_2$), plotted in Hammer–Aitoff projection. The singlets of modes have these shapes on the $\hat{\mathbf{r}}$ component of recordings on a spherical, nonrotating Earth. Modified from Masters TG, Laske G, and Gilbert F (2000c) Large-scale Earth structure from analyses of free oscillation splitting and coupling. In: Boschi E, Ekström G, and Morelli A (eds.) *Problems in Geophysics for the New Millennium*, pp. 255–288. Bologna: Editrice Compositori.

differential equations governing free oscillations. This method is still used today. Freeman Gilbert implemented a propagator matrix approach in his computer program EOS, and various descendants of this code have also been circulating informally since that time. We mention two versions here: OBANI by John Woodhouse and MINOS by Guy Masters. Woodhouse advanced the code by allowing to compute the eigenfunctions through the method of minors. He also introduced a mode counter for spheroidal modes, while Masters added one for toroidal and radial, Stoneley, and IC modes. A description of OBANI can be found in Woodhouse (1988). MINOS can be downloaded from the REM website.

1.04.2.2 Modes of a Heterogeneous Earth

1.04.2.2.1 Mode splitting

As an Earth model becomes successively more realistic and complex, the spherical symmetry is broken and a mode spectrum becomes more complex. The principal deviations from the spherically symmetric reference state are Earth's daily rotation, its hydrostatic ellipticity in response to the rotation, and its general aspherical structure. The latter includes the topography of interfaces and lateral variations in isotropic and anisotropic volumetric parameters. The distribution of singlets within a multiplet on a rotating Earth in hydrostatic equilibrium is given by Dahlen (1968). If the (n, ℓ)-tuple denotes the kth spheroidal or toroidal multiplet, then the eigenfrequency of the mth singlet of an isolated multiplet is

$$\omega_k^m = \bar{\omega}_k\left(1 + a + mb + m^2 c\right) \text{ with } -\ell \le m \le \ell \qquad [2]$$

where $\bar{\omega}_k$ is the multiplet degenerate frequency, a and c the ellipticity splitting coefficients (to first order), and b the rotational splitting coefficient (Dahlen, 1968). The ellipticity of figure removes the degeneracy of a mode only partially, with ${}_n\omega_k^m = {}_n\omega_k^{-m}$. This splitting is asymmetric with respect to the degenerate frequency. On the other hand, the rotational splitting is symmetric, or of Zeeman type, and removes the

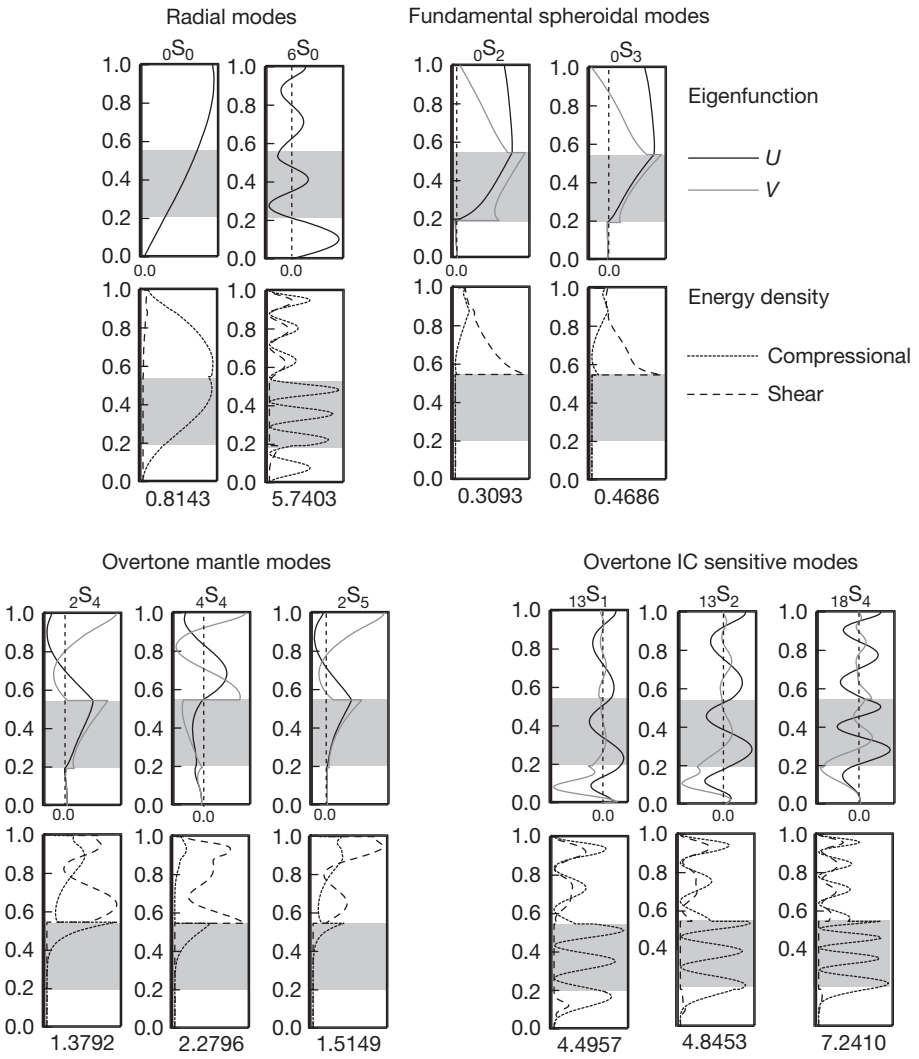

Figure 7 Radial eigenfunctions U and V and compressional and shear energy densities for some modes described in this chapter, displayed as function of normalized radius (0 is at the center; 1 is at the surface). Gray areas mark the outer core. Numbers at the bottom of the panels are PREM mode frequencies in mHz (Dziewonski and Anderson, 1981). Radial modes are very sensitive to core structure, while spheroidal fundamental modes are not very sensitive to κ and μ in the core. On the other hand, overtone mantle modes that are primarily sensitive to mantle structure are also influenced by κ in the core. IC-sensitive modes that can be observed at Earth's surface are typically quite sensitive to mantle structure.

degeneracy completely. Splitting due to rotation dominates at low frequencies ($b \gg c$) so that the spacing between adjacent singlets is nearly constant (see **Figures 5** and **9**). Other examples of modes whose splitting is dominated by rotation are modes $_0S_5$ and $_1S_4$ (**Figure 10**). At higher frequencies, ellipticity and heterogeneous structure become the dominant cause and frequencies become partially degenerate when $b \ll c$. Examples of such modes are $_{13}S_2$ and $_{18}S_4$. IC-sensitive modes $_3S_2$, $_{13}S_2$, and $_{18}S_4$ are anomalously split, as first observed by Masters and Gilbert (1981). In these cases, the splitting width, the range of singlet frequencies, is significantly larger than that predicted by rotation and ellipticity. In fact, the extreme splitting of $_{10}S_2$ led Gilbert and Dziewonski (1975) to misidentify the $m=0$ line of $_{10}S_2$ as mode $_{11}S_2$. Based on their observations, Masters and Gilbert (1981) argued for high Q in the IC but did not interpret the anomalous splitting. Ritzwoller et al. (1986) speculated that the anomalous splitting is due to axisymmetric structure in the outer core (see also Romanowicz and Bréger, 2000). Woodhouse et al. (1986) were the first to attribute this splitting to the anisotropic IC, which now appears to be widely accepted (see, e.g., Tromp, 1993).

Gilbert (1971) investigated how small structural perturbations to a spherically symmetric Earth affect the spectrum of a multiplet. He formulated the 'diagonal sum rule,' which states that, to first order, the arithmetic mean of the $2\ell+1$ singlet frequencies is the multiplet degenerate frequency $\bar{\omega}_k$:

$$\bar{\omega}_k = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} \omega_k^m \qquad [3]$$

Any first-order perturbation in structure leaves the degenerate frequencies of the spherical Earth unchanged. On the other hand, the second-order effects of the Coriolis force may cause a frequency shift. Dahlen (1968) showed that the singlet

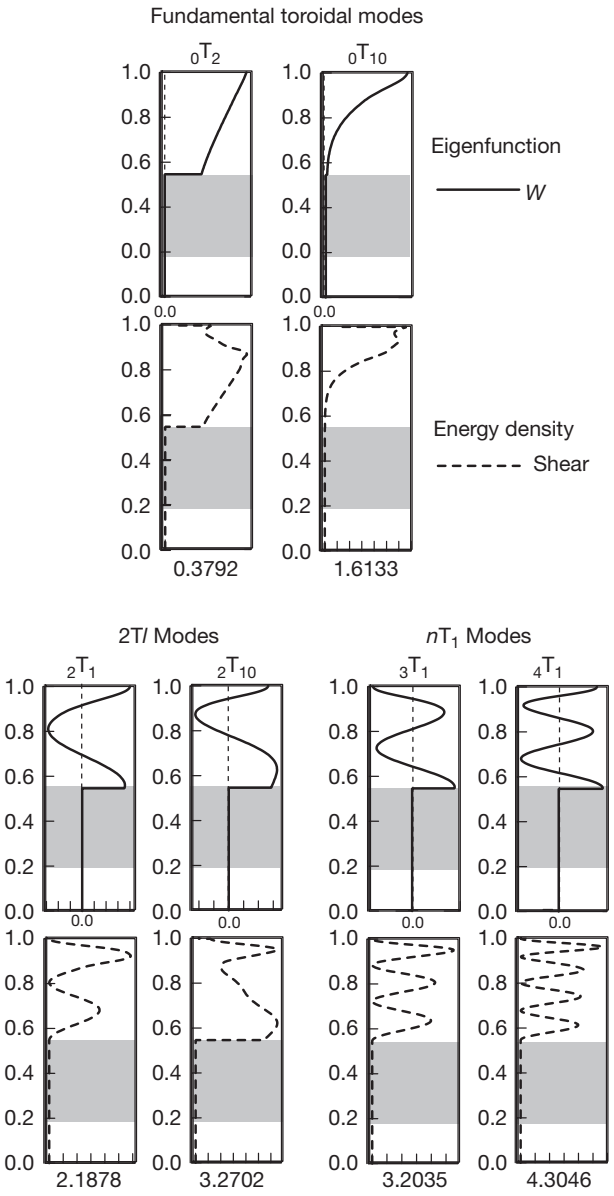

Figure 8 Radial eigenfunction W and shear energy densities for some toroidal modes. Toroidal modes are sensitive only to the shear modulus, μ. For details, see **Figure 7**.

distribution within a multiplet still follows the parabolic distribution of eqn [2], but second-order terms contribute to factors a and c, and the diagonal sum rule is no longer valid. Dahlen (1968) and Dahlen and Sailor (1979) provided the splitting parameters for modes below 2 mHz for a variety of Earth models. Since the splitting parameters caused by rotation and Earth's hydrostatic ellipticity are well understood, their effects are usually corrected for before mode parameters are interpreted in terms of Earth structure.

Once the eigenfrequencies and eigenfunctions of a 1-D Earth model have been computed, the synthesis of seismograms based on free oscillations is rather straightforward as it involves only the summation over all multiplets in a desired frequency band. The representation of the time series of an

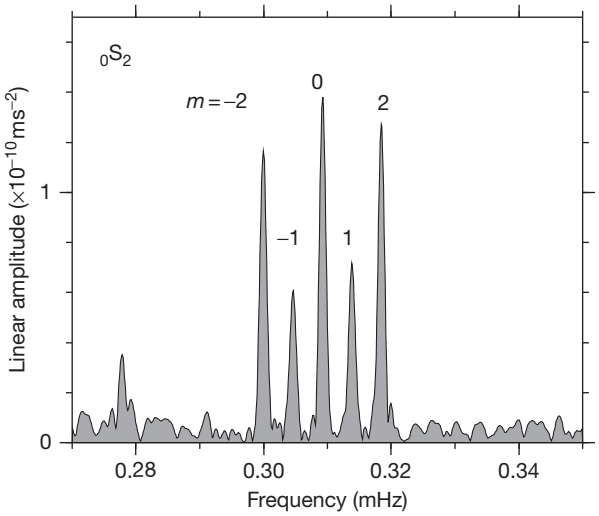

Figure 9 Zeeman splitting of the 'football mode' $_0S_2$. This is a Fourier spectrum of a 500 h long record of the 2004 Sumatra–Andaman earthquake by the superconducting gravimeter at Strasbourg, France (Rosat et al., 2005). A scaled version of the locally recorded barometric pressure was subtracted from the gravity record to achieve a noise reduction by a factor 2. The time-domain acceleration amplitude of the singlets is close to 10^{-10} ms^{-2}. Zeeman-type splitting of a mode is caused by Earth's rotation.

isolated split multiplet with degenerate frequency $\bar{\omega}_k$ at station j is given by

$$u_j(t) = \sum_{m=1}^{2\ell+1} R_{jm} a_m(t) e^{i\bar{\omega}_k t} \quad \text{or} \quad \mathbf{u}(t) = \mathbf{R}\cdot\mathbf{a}(t) e^{i\bar{\omega}_k t} \qquad [4]$$

where the real part is understood (e.g., Landau and Lifshitz, 1958, section 40; Woodhouse, 1983; Woodhouse and Girnius, 1982). The jth row of $\mathbf{R}$ is a $2\ell+1$ vector of spherical harmonics, which describes the motion of the spherical-Earth singlets at the jth receiver and is readily calculated. $\mathbf{a}(t)$ is a slowly varying function of time given by

$$\mathbf{a}(t) = \exp(i\mathbf{H}t)\cdot\mathbf{a}(0) \qquad [5]$$

where $\mathbf{a}(0)$ is a $2\ell+1$ vector of spherical-Earth singlet excitation coefficients, which can be computed if the source mechanism of the event is known. $\mathbf{H}$ is the complex 'splitting matrix' of the multiplet and incorporates all the information about elastic and anelastic 3-D structure to which the mode is sensitive, that is,

$$H_{mm'} = \bar{\omega}_k \left[(a + mb + m^2 c)\delta_{mm'} + \sum \gamma_s^{mm'} c_s^t + i \sum \gamma_s^{mm'} d_s^t \right] \qquad [6]$$

where $-\ell \le m \le \ell$, $-\ell \le m' \le \ell$, and $t = m - m'$. The first term describes the splitting due to Earth's rotation and ellipticity (eqn [2]), and the second and third terms describe the effects from elastic and anelastic structures through the 'structure coefficients,' c_s^t and d_s^t (e.g., Ritzwoller et al., 1986; Smith and Masters, 1989b). Equation [6] changes to equation (14.84) of Dahlen and Tromp (1998) if real instead of complex basis eigenfunctions and spherical harmonics are considered in eqn [1]. $\mathbf{H}$ and consequently $\exp(i\mathbf{H}t)$ are $(2\ell+1)\times(2\ell+1)$-dimensional square matrices. The $\gamma_s^{mm'}$ are integrals over three

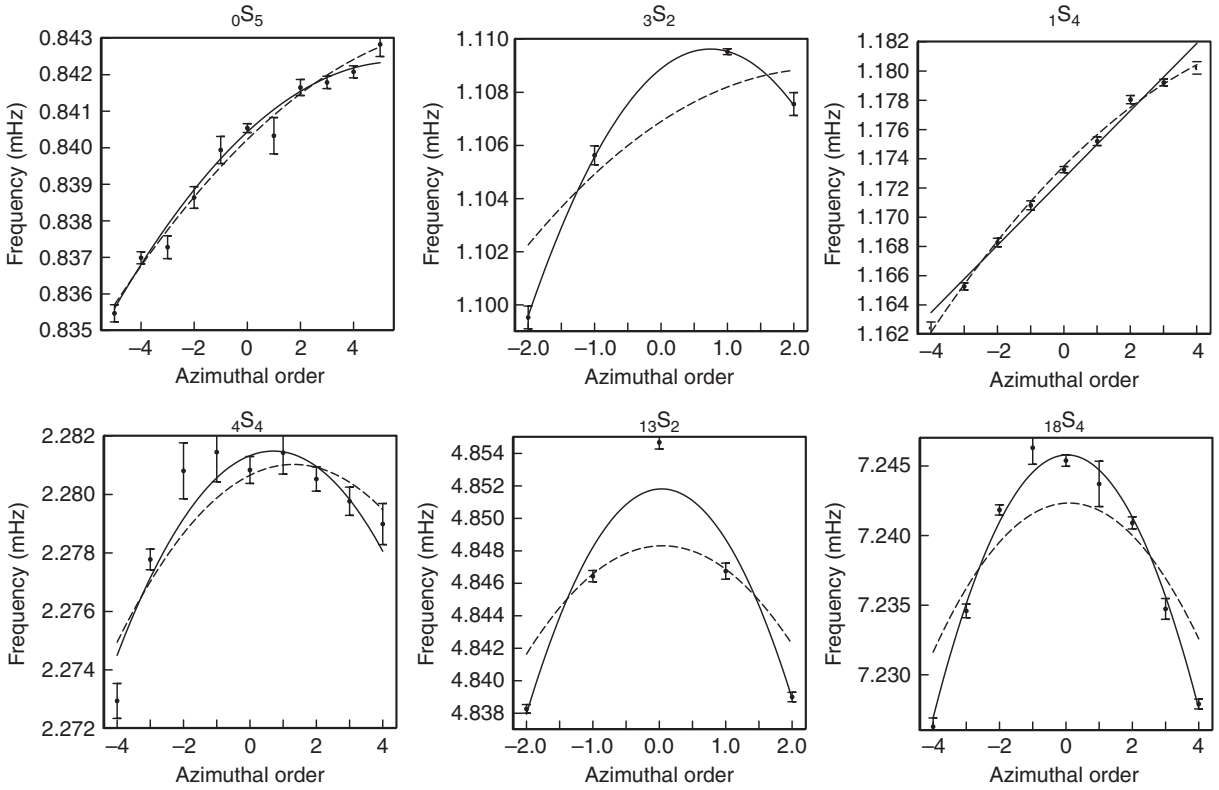

Figure 10 Observed singlet frequencies as a function of azimuthal order, m, for six modes. The dashed lines mark the splitting predicted for Earth's rotation and hydrostatic ellipticity. Solid lines mark the best-fitting parabolas. The splitting of low-frequency modes $_0S_5$ and $_1S_4$ is dominated by rotation, while that of IC-sensitive modes $_{13}S_2$ and $_{18}S_4$ is dominated by ellipticity. The splitting of mantle mode $_4S_4$ and low-frequency IC-sensitive mode $_3S_2$ is mixed. The $m=0$ singlet of $_3S_2$ has not yet been observed reliably. IC-sensitive modes are anomalously split, that is, the observed splitting is significantly larger than that predicted for rotation and ellipticity alone.

spherical harmonics (e.g., Dahlen and Tromp, 1998). These integrals are often zero, and the 'selection rules' summarize the nonzero conditions:

$$\begin{aligned} &1.\ m-m'=t \\ &2.\ \ell+s+\ell \text{ must be even; i.e., } s \text{ must be even} \\ &3.\ 0\le s\le 2\ell \text{ (triangle rule)} \end{aligned} \qquad [7]$$

Rule (1) implies that axisymmetric structure ($t=0$) gives nonzero contributions to the splitting matrix only if $m=m'$, so that $\mathbf{H}$ is diagonal. Rule (2) implies that an isolated mode is sensitive only to structure of even degree. The rule can be extended to two coupled modes in which case $\ell+s+\ell'$ must be even (for same-type coupling; see **Section 1.04.2.2.2** for details). In order to retrieve structure of odd harmonic degree, $\ell+\ell'$ must therefore be odd. Rule (3) implies that a mode cannot be sensitive to structure of arbitrarily high degree. The rule can also be extended to the case of two coupled modes where $|\ell-\ell'|\le s\le \ell+\ell'$. The structure coefficients for elastic structure, c_s^t, are given by

$$c_s^t=\int_0^a \mathbf{M}_s(r)\cdot\delta\mathbf{m}_s^t(r)r^2\,\mathrm{d}r \qquad [8]$$

and a similar expression exists for the anelastic structure coefficients, d_s^t. The coefficients $\delta\mathbf{m}_s^t$ are the expansion coefficients of the 3-D aspherical Earth structure: $\delta\mathbf{m}(r,\theta,\phi)=\sum\delta\mathbf{m}_s^t(r)Y_s^t(\theta,\phi)$ and $\mathbf{M}_s$ are integral kernels, which can be computed (Henson, 1989; Li et al., 1991a; Woodhouse, 1980; Woodhouse and Dahlen, 1978). Equation [8] and its counterpart for the d_s^ts can be regarded as a pair of linear inverse problems for $\mathbf{c}$ and $\mathbf{d}$. Strictly speaking, eqn [4] is not quite correct since both $\mathbf{R}$ and $\mathbf{a}(0)$ should include small renormalization terms (see equations 14.87 and 14.88 in Dahlen and Tromp, 1998). The renormalization requires the knowledge of the splitting matrix, which we ultimately want to determine in a mode analysis. While the renormalization terms are expected to be small for isolated modes, we may have to iterate the retrieval of the splitting matrix for coupled modes.

It is convenient to visualize the geographic distribution of structure as sensed by a mode by forming the elastic and anelastic 'splitting functions' (Woodhouse and Giardini, 1985):

$$\begin{aligned} f_{\mathrm{E}}(\theta,\phi)&=\sum_{s,t}c_s^tY_s^t(\theta,\phi) \\ f_{\mathrm{A}}(\theta,\phi)&=\sum_{s,t}d_s^tY_s^t(\theta,\phi) \end{aligned} \qquad [9]$$

The $Y_s^t=X_s^t(\theta)\mathrm{e}^{\mathrm{i}t\phi}$ is a spherical harmonic of harmonic degree s and azimuthal order number t. An example is shown in **Figure 11**. The elastic splitting function shows local peak shift variations caused by the local structure beneath a geographic location, as 'seen' by an isolated mode. Recall that isolated modes are not sensitive to odd-degree structure. In a similar way, the anelastic splitting function shows attenuation.

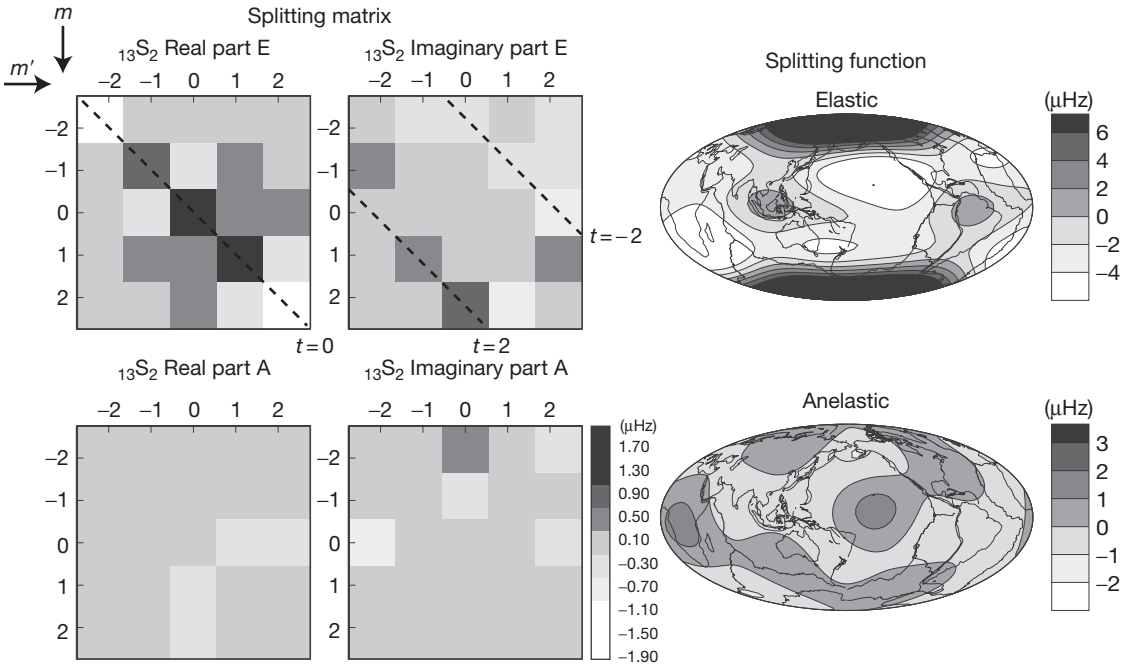

Figure 11 Left: Observed complete splitting matrix for mode $_{13}S_2$, decomposed into its elastic (E) and anelastic (A) parts, both of which are Hermitian. The data from 13 earthquakes were used to determine this matrix. The signal down the diagonal of the matrices is caused by zonal (axisymmetric) structure ($t=0$), as constrained by the selection rules for a mode. Also indicated are the contributions from $t=\pm 2$–structure (which is sectoral for $s=2$). Right: Splitting functions obtained from the splitting matrix on the left. The signal from anelastic structure is typically much smaller than that from elastic structure.

Bearing this restriction in mind, a splitting function can be understood as the mode equivalent of a surface wave phase velocity map.

To summarize, an isolated mode of harmonic degree ℓ is sensitive to even-degree structure only, up to harmonic degree $s=2\ell$. If the structure within Earth is axisymmetric, then the splitting matrix is diagonal, the individual singlets can be identified by the index m, and the only singlet visible at a station at Earth's poles is the $m=0$ singlet.

1.04.2.2.2 Mode coupling

While the treatment of isolated modes is appealing because of its simplicity, it is insufficient to describe free oscillations of the real Earth. The coupling between modes has two fundamental effects: (1) varying coupling effects on individual singlets causes a shift of the mode's degenerate frequency and Q, and (2) coupling to certain other modes gives a mode sensitivity to odd-degree structure. We distinguish between along-branch (same mode type and n but different ℓ) and cross-branch coupling (any other mode combination). The coupling between two modes is particularly strong if their frequencies are close and the radial and geographic shape of their displacement field is similar. Numerically, the complex frequencies must be close, but in fact, the real part (frequency) is more dominant than the imaginary part (attenuation). As in the case of isolated modes, selection rules dictate through which mechanism and in which way two modes couple:

- Coriolis force causes spheroidal–toroidal mode coupling for mode pairs of the form $_nS_\ell - _{n'}T_{\ell\pm1}$, that is, between multiplets that differ by a single angular degree ($|\ell-\ell'|=1$), for example, $_0S_4$–$_0T_3$, $_0S_8$–$_0T_9$, and $_1S_4$–$_0T_3$.
- Earth's ellipticity also causes spheroidal–toroidal mode coupling for $|\ell-\ell'|=1$.
- Earth's ellipticity causes same-type (spheroidal or toroidal) mode coupling for $|\ell-\ell'|=0$ and for $|\ell-\ell'|=2$, for example, $_0S_4$–$_1S_4$ and $_0S_3$–$_0S_5$.
- Rotation causes spheroidal–spheroidal mode coupling for $|\ell-\ell'|=0$, for example, $_0S_4$–$_1S_4$.
- Lateral heterogeneity of degree s causes spheroidal–toroidal mode coupling under the condition that $|\ell-\ell'|+1\le s\le \ell'+\ell-1$ and $\ell'+\ell+s$ is odd, for example, $_0S_4$–$_0T_3$ are coupled through structure of degrees 2, 4, and 6; as a consequence, if $|\ell-\ell'|$ is even, then modes can couple through odd-harmonic degree structure, for example, $_0S_5$–$_0T_3$ are coupled through structure of degrees 3, 5, and 7.
- Lateral heterogeneity of degree s causes same-type mode coupling under the conditions that (1) $m+t-m'=0$; (2) $\ell'+\ell+s$ is even; (3) $|\ell-\ell'|\le s\le \ell'+\ell$, for example, $_0S_2$–$_0S_3$ are coupled through structure of degrees 1, 3, and 5.

Coriolis coupling between fundamental spheroidal and toroidal modes was first observed and modeled by Masters et al. (1983). Coupling spheroidal–toroidal mode pairs form hybrid modes that share some of the characteristics of both modes. Toroidal modes can then be observed on vertical-component seismic spectra in the form of additional peaks, which Masters et al. nicely showed. For angular orders $7\le\ell\le26$, $_0T_{\ell+1}$ modes are closer neighbors to $_0S_\ell$ modes than $_0T_{\ell-1}$ modes are. The strongest coupling occurs between pairs $_0S_{11}$–$_0T_{12}$ whose PREM degenerate frequencies are about

4.5 μHz apart (1 μHz for 1066A) and ${}_0S_{19}$–${}_0T_{20}$ whose PREM frequencies are within 0.5 μHz of each other (2.5 μHz apart in 1066A). Figure 12 shows that predicted frequency shifts for Coriolis-coupled modes can be up to 5 μHz, which is significant with respect to measurement errors (see Figure 24; regard a 'strip' as a spectral line of a mode for now). Figure 12 also indicates that coupling modes 'repel' each other. For example, while the frequency of ${}_0S_{10}$ gets pulled downward, the frequency of ${}_0T_{11}$ gets pushed upward. The coupling between two multiplets actually has a different effect on each singlet of the modes, as is shown in Figure 13. As discussed in the preceding text, for uncoupled modes, rotation and Earth's hydrostatic ellipticity remove the frequency degeneracy. The coupling of the mode pairs causes the sets of mode singlets to rearrange. Strongly coupled modes form a hybrid pair in which the sets of singlet frequencies repel each other but the attenuation is 'shared.' As shown by Masters et al. (1983), Earth's aspherical structure causes further rearrangement of the singlets.

Coupling between two modes also manifests itself in the splitting matrix. Instead of two matrices with ranks $2\ell+1$ and $2\ell'+1$ that describe the effects of rotation, ellipticity, and

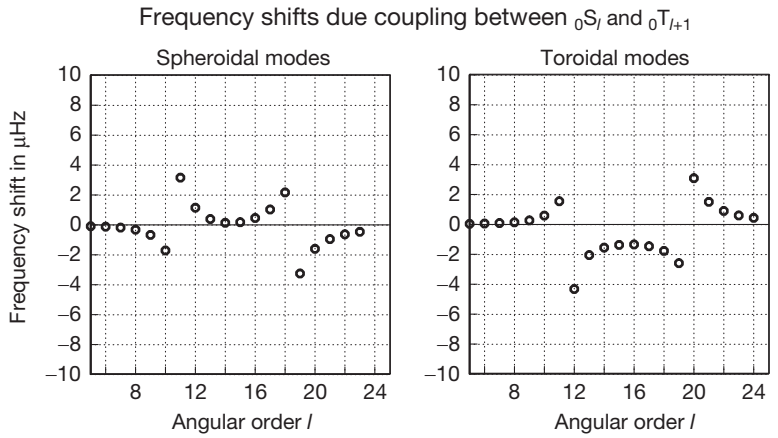

Figure 12 Predicted frequency shifts for mode pairs ${}_0S_\ell - {}_0T_{\ell+1}$ caused by Coriolis coupling. Predictions are for Earth model 1066A (Gilbert and Dziewonski, 1975). The strongest coupling occurs between pairs ${}_0S_{11} - {}_0T_{12}$ and ${}_0S_{19} - {}_0T_{20}$.

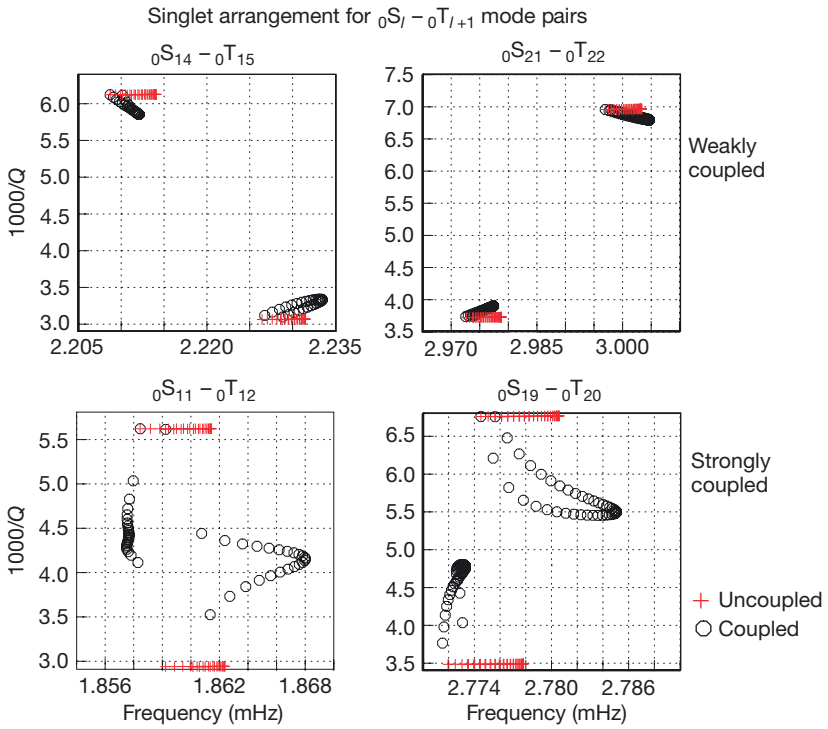

Figure 13 Predicted rearrangement of singlet frequencies and quality factor Q for weakly coupled-mode pairs ${}_0S_{14} - {}_0T_{15}$ and ${}_0S_{11} - {}_0T_{12}$ and for strongly coupled pairs ${}_0S_{21} - {}_0T_{22}$ and ${}_0S_{19} - {}_0T_{20}$. The coupling calculations included effects from both rotation and ellipticity, but for the modes discussed here, Coriolis coupling is the dominant cause. Strongly coupled modes form a hybrid pair in which the sets of singlet frequencies repel each other but the attenuation is 'shared.'

structure for two modes, we now deal with a larger matrix with rank $2(\ell+\ell'+1)$ that has four subblocks: the two original matrices that are now the two self-coupling blocks in the upper-left and lower-right corners, and two cross coupling blocks of dimensions $(2\ell+1)\times(2\ell'+1)$ and $(2\ell'+1)\times(2\ell+1)$. As an example of spheroidal–toroidal mode coupling, Figure 14 shows how Earth's rotation and ellipticity affect the four coupling blocks in the splitting matrix for modes ${}_0S_4$ and ${}_0T_3$.

Earth structure can complicate the splitting matrix substantially, which we show in a schematic example for a $\ell=2$ mode coupling with a $\ell'=3$ mode of the same type (i.e., either spheroidal or toroidal). Figure 15 compares the structure of the splitting matrix in the case of the self-coupling of an isolated $\ell=2$ mode and the upper-right cross coupling block with a $\ell'=3$ mode. According to the selection rules, structure of certain symmetries affects certain elements in the splitting matrix. As already discussed, the effects from axisymmetric structure are found down the diagonal, while non-axisymmetric, even-degree structure affects off-diagonal elements (Figure 11). Depending on ℓ and ℓ' of the coupling modes, some elements in the cross coupling blocks are now affected by structure of odd-harmonic degree. An example of an observed splitting matrix is discussed in Section 1.04.2.3.5.

We should mention that the coupling calculations presented here were done with a code based on the work of Jeff Park (Park and Gilbert, 1986). His method uses a Galerkin procedure that allows the assessment of mode coupling in a dissipating Earth. To reduce the computational burden, the method applies a trick. The exact representation of interaction on a rotating Earth requires a matrix equation that is quadratic in eigenfrequency ω. Coriolis interaction terms are grouped in a matrix linear in ω. This linear dependence is removed by replacing ω with a fixed fiducial frequency (reference frequency) $\hat{\omega}_0$. Park's numerical experiments showed that this approximation is adequate for modes above 1 mHz as long as the relative frequency spread, $\Delta\omega/\hat{\omega}_0$, is not large. Modes in a certain frequency band all couple through various mechanisms. When modeling the interaction in a group of modes, all these have to be taken into account simultaneously. The examples of coupling mode pairs shown here are only to illustrate how mode coupling works and where Park and Gilbert's method is appropriate. A treatment of coupling modes in a wider frequency band requires more general procedures. Some are discussed in Section 1.04.2.3.5, but the interested reader is also referred to Chapter 1.02.

1.04.2.3 Measuring Mode Observables

The most basic approach to extract mode observables from a seismogram is to calculate the spectrum of a tapered seismogram. The finiteness of the underlying time series prohibits a

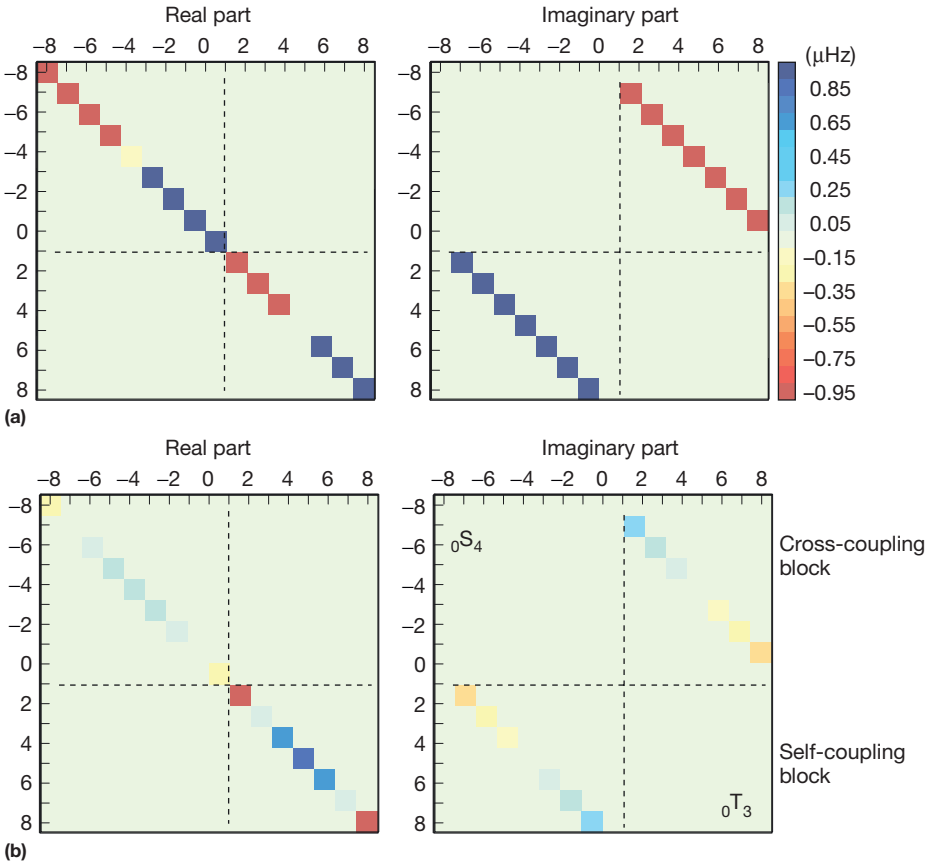

Figure 14 Synthetic splitting matrices to illustrate the coupling effect of Earth's (a) rotation and (b) ellipticity on the mode pair ${}_0S_4 - {}_0T_3$. Self-coupling fills the diagonals of the self-coupling blocks, while multiplet–multiplet coupling fills the cross coupling blocks. For this pair, the effect of rotation is ten times larger than that of ellipticity.

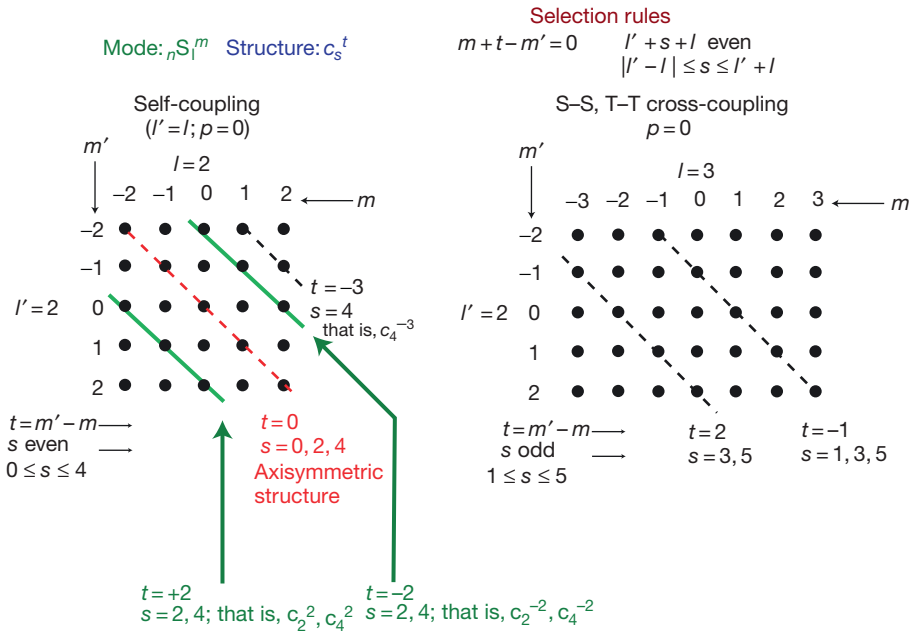

Figure 15 Elements in the splitting matrix that are affected by coupling. Left panel: An isolated $\ell=2$ mode experiences self-coupling through the Earth's rotation and ellipticity. Together with axisymmetric structure, this manifests itself in the diagonal. Other even-degree structure (s even) affects off-diagonal elements. When two modes couple, the splitting matrix has four blocks: two self-coupling blocks (one for each mode) and two cross coupling blocks. The right panel shows how elements in a cross coupling block with an $\ell'=3$ mode are affected for same-type coupling ($p=0$). Some of the elements are now affected by odd-degree structure (s odd).

parameter estimation with arbitrary precision (e.g., see Jenkins, 1961 for an early assessment of the Blackman and Tukey, 1958 approach). Modal decay rates, the vicinity of other modes, and the presence of noise necessitate the application of spectral optimization procedures, which involve the choice of a proper set of time windows. Harris (1978) presented a comprehensive overview on the use of windows in discrete Fourier analysis. Based on this, Dahlen (1982) first provided formal expressions for the variances and covariances of free oscillation parameters when using arbitrary data windows. He also showed that the optimum- or minimum-variance record length for measuring frequencies and decay rates (to determine Earth structure) using a Hanning taper is 1.1 Q cycles but only 0.5 Q-cycles for measuring amplitudes and phases (to determine the earthquake source). Park et al. (1987b) and Lindberg and Park (1987) adapted and applied Thomson's (1982) multitaper technique to optimize the bias from ambient noise and spectral leakage of decaying sinusoids in the free oscillation spectrum. Though we have not used this technique ourselves, they found that their approach provides a much improved detector for modes in a time series contaminated by white noise. Properly tapering free oscillation spectra is particularly important for measuring attenuation rates, which is discussed in Masters and Gilbert (1983). Complicating direct spectral estimation is the fact that, even today, it is not as trivial as it may appear to find continuous undisturbed seismic records that stretch over more than a week or so. A proper analysis of Earth's breathing mode ${}_0S_0$ requires records of more than two and half months! A somewhat disturbing fact is also that some continuous records that were available at the IRIS data management center (DMC) or other DMCs less than 10 years ago now have data gaps due to data storage failures. It is therefore essential to understand how data gaps cause additional distortions in a complex spectrum. The best way to address this is by comparing a real data spectrum with a synthetic one that uses the same windowing and data gap structure, provided the source mechanism is known.

An obvious approach to assess Earth's 1-D and 3-D structure is to measure the apparent frequency of a certain mode for many stations and many earthquakes. Each of these 'peak shift data' can be plotted at the two poles of its source–receiver great circle. We make use of Backus' (1964) discovery that such data represent the great-circle integrals over surface spherical harmonics:

$$P_s(0)Y_s^t(\Theta, \Phi) = \frac{1}{2\pi}\oint_C Y_s^t(\theta, \phi)\mathrm{d}\Delta \qquad [10]$$

where (Θ, Φ) is the positive pole of the source–receiver great-circle C and $P_s(0)$ is a Legendre polynomial. This representation can be used for peak shift data as long as the structural wavelength along the great circle is much longer than the modal wavelength (Jordan, 1978). Thus, we can extract the effects of Earth structure on a particular mode in an inversion for the structure coefficients of a splitting function (see eqn [9]). Examples of using this technique are the work of Masters et al. (1982), who found evidence for subducting slabs in the transition zone and Romanowicz et al. (1987) discussion of the degree 2 pattern of structure in the upper mantle. In principle, the c_0^0 term in the splitting function gives the degenerate mode frequency. In practice, an unbiased estimation of c_0^0 requires a large data set of peak shift measurements. More efficient tools to measure degenerate mode frequencies are based on mode stripping, which is laid out in the next section. Peak shift measurements to extract the effects of 3-D structure

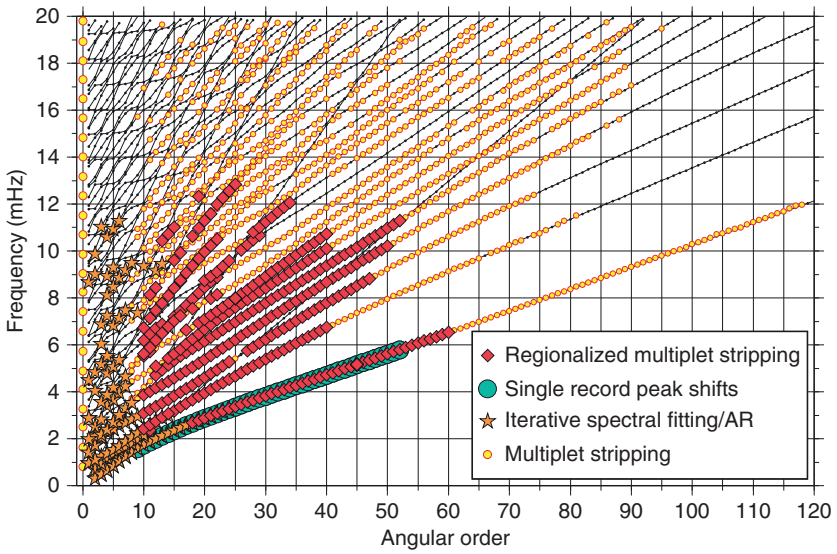

Figure 16 Spheroidal mode dispersion diagram (ω–ℓ plot) for spherical Earth model PREM. Different symbols indicate by which method a particular mode has been observed. Black dots are predicted modes that still await observation. The mode frequencies are published on the REM website except for the multiplet stripping results. Single record peak shifts refer primarily to the work of Smith and Masters (1989b). The first comprehensive ω–ℓ diagram showing observed modes was presented by Dziewonski and Gilbert (1972).

are only possible in spectra with high signal levels and at relatively high frequencies, where asymptotic theory is valid, which is typically the case only for fundamental modes. For other modes, this technique has been superseded by the regionalized stripping technique. The use of the different methods is summarized in **Figure 16** that includes only methods that we have used ourselves. Other methods include the time-lapse spectra approach used by Dratler et al. (1971) to measure attenuation rates of high-Q overtone modes. This method was also used by Roult (1974) and Jobert and Roult (1976) and others to determine attenuation rates for fundamental spheroidal and toroidal modes and the first few overtones. In this method, a sliding window of several hours (e.g., 6 h) is moved over a time series. An attenuation rate is then fitted to the collected amplitude values of a certain mode in a least-squares procedure. Our own (limited) experiments have shown that this technique gives accurate estimates as long as the spectral peaks are large and the frequency picked for the estimation is close to the observed peak shift frequency. Otherwise, oscillating amplitudes hamper the least-squares fitting procedure. For a discussion on mode attenuation rates, the interested reader is referred to **Chapter 1.21**. Roult and colleagues made use of the time-variable filtering technique to extract individual mode branches from a seismogram prior to analysis. This technique is laid out in the surface wave section. Romanowicz and Roult (1986) showed in a later intriguing study that information on lateral heterogeneity can be obtained from records of a single station by modeling the fluctuations of frequency shifts along a mode branch, for different earthquakes, as explained theoretically by Romanowicz (1987).

1.04.2.3.1 Multiplet stripping and degenerate mode frequencies

In the multiplet stripping procedure, we 'strip' an overtone from a 'stack' of spectra. This process requires a large set of recordings from different stations and events. The average location of a multiplet coincides with the multiplet degenerate frequency as long as the set of seismograms samples the globe evenly (condition 1) and as long as the distribution of singlets within a multiplet is relatively even (condition 2). Spectral stacking using a phase equalization procedure to extract free oscillation parameters was first used by Mendiguren (1973). Mode or multiplet 'stripping' was first introduced in the seminal paper of Gilbert and Dziewonski (1975) who used hand-digitized WWSSN recordings of the 1970 Colombian event and the 15 August 1963 Peru–Bolivia event. The set of mode frequencies they obtained constituted the bulk information in the construction of spherical Earth models 1066A, PEM-O/PEM-C/PEM-A (Dziewonski et al., 1975), and, finally, PREM (Dziewonski and Anderson, 1981) that is used as a REM still today.

In the multiplet stripping approach, we measure mode degenerate frequencies by linearly estimating multiplet resonance functions. In a second nonlinear step, a complex synthetic resonance function is fitted to the estimated resonance function to obtain the mode frequency and attenuation rate. With given starting models for the 1-D Earth and the earthquake source, the acceleration spectrum at the jth station, $u_j(\omega)$, can be computed as a weighted sum of multiplet resonance functions $c_k(\omega)$ (see eqn [4]):

$$u_j(\omega) = A_{jk} c_k(\omega) \qquad [11]$$

Within narrow frequency bands, the multiplet excitation, A, can be considered constant and frequency-independent. Multiplet stripping consists in estimating the 'multiplet strips' $\hat{c}_k(\omega) = A_{jk}{}^{-1} u_j(\omega)$ in a least-squares sense, given observed spectra $u_j(\omega)$ and given the predicted multiplet excitations A_{jk}.

By applying multiplet stripping to large sets of seismograms, we can isolate individual multiplets even at frequencies where the spectrum of modes is dense compared to the line width. **Figures 17** and **18** show the result of multiplet

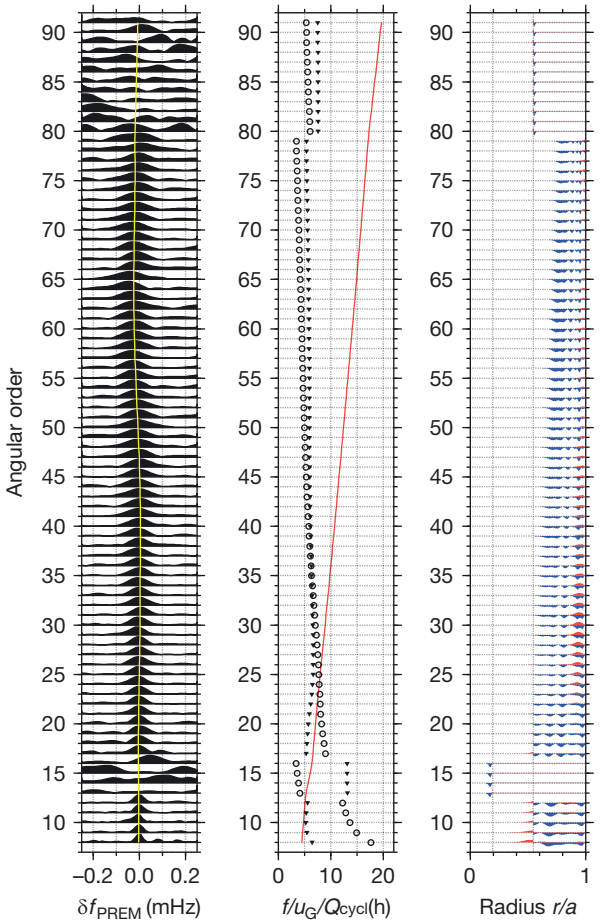

Figure 17 Multiplet strips for mode branch ${}_7S_\ell$, obtained from a data set of 12 000 records of 260 events between 1991 and 1998. The left panel shows the strips for the individual modes centered on the predicted PREM frequencies. The middle panel shows the predicted degenerate frequencies (red line, mHz), group velocity (triangles, km s^{-1}), and Q cycles (circles, h). The right panel shows compressional (red) and shear (blue) energy densities. Multiplet stripping works well up to 17 mHz or angular order $\ell = 79$ where the ${}_7S_\ell$ modes become Stoneley modes. Systematic deviations from PREM are evident in the left panel. The yellow line in that panel shows the predicted frequencies of MEMO0 (Valette and Lesage, 1992). This model seems to go a long way toward explaining the new observations even though it was constructed from a data set of modes below 5.4 mHz.

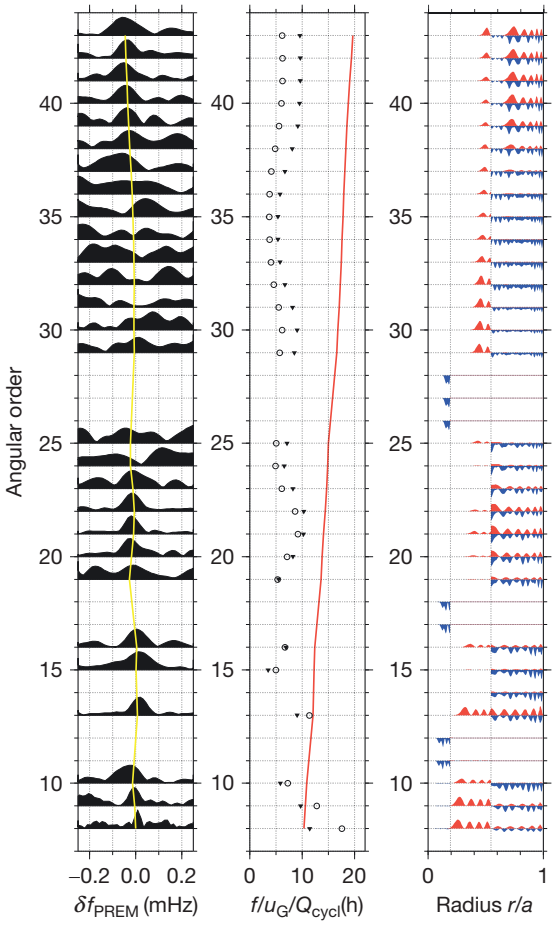

Figure 18 Multiplet strips for mode branch ${}_{23}S_\ell$, obtained from a data set of 12 000 records of 260 events between 1991 and 1998. For well-excited multiplets with intermediate to high-quality factors, Q, and sensitivity to lower mantle and core structure, multiplet stripping works well up to 20 mHz. Systematic deviations from PREM are evident in the left panel, particularly between ${}_{23}S_{39}$ and ${}_{23}S_{43}$. For details, see Figure 17.

stripping for the two spheroidal mode branches ${}_7S_\ell$ and ${}_{23}S_\ell$. The frequency band covered by the strips is 0.5 mHz and contains as many as 200 toroidal and 300 spheroidal modes. Nevertheless, the good sampling of the globe provided by 12 000 seismograms of 260 different events allows us to separate one mode from the others based solely on the shape of its eigenfunction and its excitation. The along-branch consistency such as exhibited by the mode group ${}_{23}S_{39} - {}_{23}S_{44}$ is a strong indication of the success of the method.

With the same large data set, we have tried to extract the radial modes ${}_nS_0$, which consist of only one singlet and hence cannot get split by aspherical structure. They are of particular interest because of their high sensitivity to density structure and to structure of the IC. Figure 19 shows the multiplet strips that we obtain for modes ${}_{10}S_0$ at 9 mHz through ${}_{23}S_0$ at 19.8 mHz. While for the two branches shown in Figures 17 and 18, the prediction of MEMO0 (Mean Earth MOdel) (Valette and Lesage, 1992) is in good agreement with the stripping results, neither PREM nor MEMO0 provides a satisfactory fit to our radial mode observations. The data set used for the construction of MEMO0 consisted of 617 mode degenerate frequencies in the period band 185–3230 s and included 198 toroidal, 10 radial, and 409 spheroidal modes from Masters and Widmer (1995). Whether the inability to fit radial mode observations requires new structure in the IC or whether it is due to coupling with nearby high-Q modes is still an open question.

As stated in the preceding text, one of the conditions for unbiased results is an even data coverage. In the long-wavelength limit of Jordan (1978), the sampling of the globe can be quantified by the density of great-circle poles. A scheme to optimize the selection of high signal-to-noise spectra that provide best possible sampling could minimize a possible bias. Unfortunately, large-size earthquakes and high-quality stations

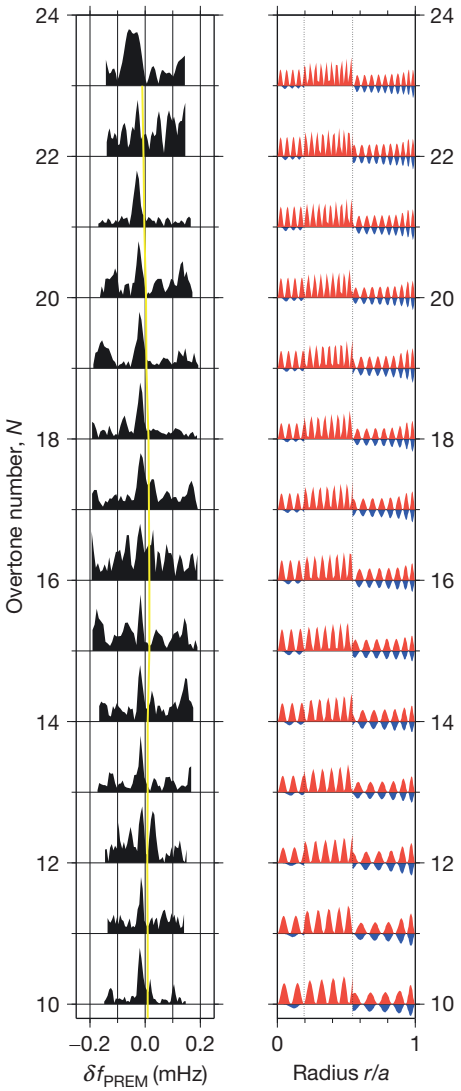

Figure 19 Multiplet stripping results for radial modes between 10 and 20 mHz. Strips with multiple peaks are likely due to coupling to nearby high-Q spheroidal overtones (Laske et al., 2001). The yellow line shows the predictions of MEMO0. Neither PREM nor MEMO0 gives a satisfactory fit to these modes. While a model with an additional first-order discontinuity in the inner core can explain the new radial mode frequencies, such a model leads to degradation of the fit of other IC-sensitive modes (B. Valette, personal communication, 2002). For details, see **Figure 17**.

are very unevenly distributed. These issues have been addressed with regionalized multiplet stripping by Widmer-Schnidrig (2002), where regular multiplet stripping is carried out for subsets of seismograms that sample only a particular great circle. While there is no substitute for missing data, regionalized multiplet stripping has at least allowed us to minimize the bias from long-wavelength structure. To date, about 30 years of high-quality digital seismic data enable us to successfully isolate individual modes to frequencies as high as 20 mHz. However, only the regionalized multiplet stripping results presented by Widmer-Schnidrig (2002), which stop at 12 mHz, are largely free of bias from 3-D structure because the data were selected and weighted to specifically minimize this bias. The multiplet strips presented here maximize the signal-to-noise ratio at the expense of some geographic bias (i.e., some source–receiver great circles may dominate the coverage).

Condition 2 at the beginning of this section addresses pathological cases when one or more singlets are located far away from their neighbors. Isolated singlets with low spectral amplitudes are likely missed and omitted from the stripping. Examples are anomalously split IC-sensitive modes such as ${}_{13}S_2$ for which the $m=0$ singlet lies anomalously far away from the mode's degenerate frequency (see **Figure 10**). Multiplet stripping for such a mode can produce strips with two peaks: a large peak near the four singlets $m=\pm1,2$ and a small peak near the $m=0$ singlet. Estimating the multiplet frequency by fitting only a single resonance function to the large peak produces a biased degenerate frequency estimate. A still elusive mode is ${}_3S_2$ for which no reliable observations of the $m=0$ line exist, not even after the Sumatra–Andaman event. The reason for this is not fully understood, but possible causes include weak excitation, peculiar anelastic structure, and coupling to other modes. Fortunately, the splitting of many low-ℓ modes can be resolved fully so that their degenerate frequency can be estimated using other techniques. For high-ℓ overtones, which are analyzed exclusively with the multiplet stripping technique, this kind of extreme singlet distribution does not appear to be a problem.

1.04.2.3.2 Singlet stripping and receiver stripping

Historically, singlet stripping was the first method to dissect a multiplet into its singlets (Buland et al., 1979). While it is a robust technique, it has been superseded by the AR receiver stripping technique (Masters et al., 2000b). This is because the latter makes less assumptions about the shape of Earth's heterogeneity and also needs no accurate earthquake source model. Singlet stripping assumes that the dominant structure leading to splitting is axisymmetric. In this case, the splitting matrix $\mathbf{H}$ (eqn [6]) remains diagonal. For the vertical component, one singlet frequency is then associated with a single Y_ℓ^m, as on the spherically symmetric Earth. The spectrum of a multiplet with angular order ℓ at the jth station, $u_j\ (\omega)$, can then be written as a weighted sum of singlet resonance functions $c_m(\omega)$:

$$u_j(\omega) = A_{jm} c_m(\omega) \quad \text{with} \quad -\ell \le m \le \ell \qquad [12]$$

where the singlet excitations, A_{jm}, have been computed based on eqn [4]. Equation [12] is an overdetermined system that can be solved for the 'singlet strips,' $\hat{c}_m(\omega) = A_{jm}{}^{-1} u_j(\omega)$. This procedure typically includes the records of many earthquakes.

In the receiver stripping approach, we treat each earthquake individually. Using eqns [4] and [5], we 'collapse' the set of spectra into a set of $2\ell+1$ 'receiver strips,' for each earthquake and each mode:

$$\mathbf{b}(t) = \mathbf{R}^{-1} \cdot \mathbf{u}(t) = \exp[\mathrm{i}(\mathbf{H} + \mathbf{I}\bar{\omega})t] \cdot \mathbf{a}(0) \qquad [13]$$

We actually work in the frequency domain using spectra of Hanning-tapered records in a small frequency band about a multiplet of interest. Examples are found in **Figure 20**. The spectral lines in these diagrams are proportional to the spectra of individual singlets, if axisymmetric structure dominates the

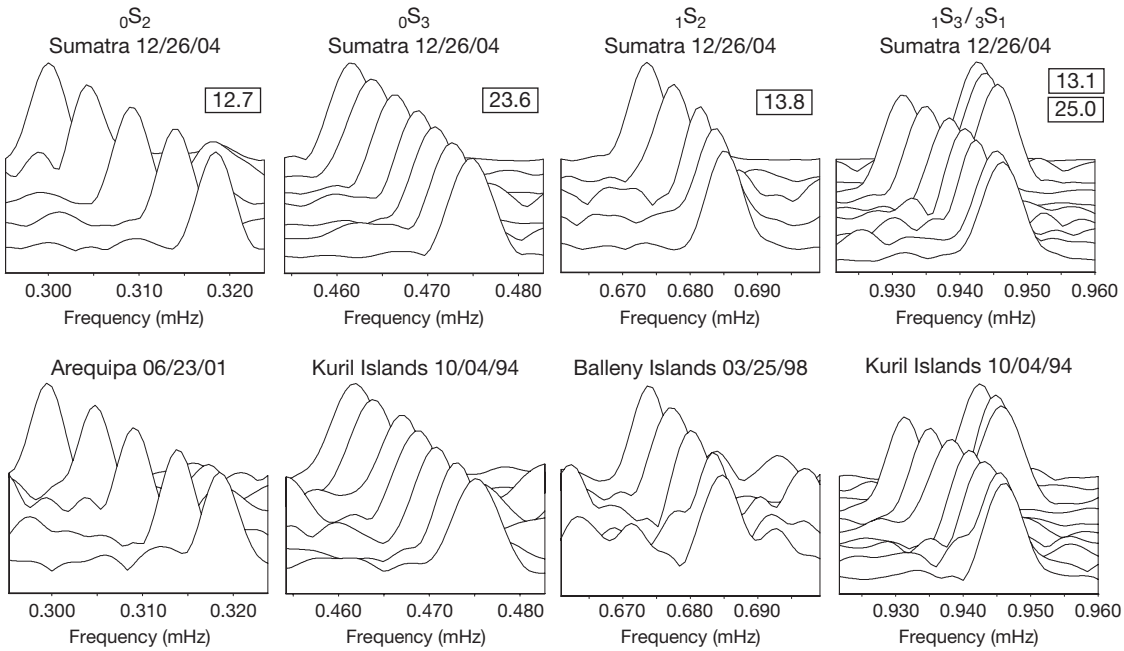

Figure 20 Normalized receiver strips for very low-frequency modes. For these modes, the splitting is dominated by axisymmetric structure, and the $2\ell+1$ strips closely resemble the spectral lines of each singlet. The upper row shows the strips for the 2004 Sumatra–Andaman earthquake, while the lower row shows the best set of strips that we have had so far. The boxed numbers indicate how much larger the amplitudes of the Andaman strips are with respect to the best other earthquake.

splitting matrix. Modes $_1S_3$ and $_3S_1$ are so close together in frequency that their receiver strips overlap. A joint analysis prevents bias introduced when ignoring one of the modes.

1.04.2.3.3 Retrieving the splitting matrix with the matrix autoregressive technique

Figure 21 shows typical examples of spectra for IC-sensitive mode $_{13}S_2$, and the steps involved going from seismograms (or spectra) to retrieve Earth's internal structure. We use the autoregressive nature of the receiver strips to make our analysis technique for the splitting matrix independent of earthquake location and source mechanism. The receiver strips satisfy a recurrence in time. Using eqn [13], we obtain $\mathbf{b}(t)$ after the time increment δt:

$$\begin{aligned}\mathbf{b}(t+\delta t) &= \mathbf{R}^{-1}\cdot\mathbf{u}(t+\delta t)\\ &= \exp[\mathrm{i}(\mathbf{H}+\mathbf{I}\bar{\omega})(t+\delta t)]\cdot\mathbf{a}(0)\\ &= \mathbf{P}(\delta t)\mathbf{b}(t)\end{aligned}$$

so

$$\mathbf{b}(t+\delta t)=\mathbf{P}(\delta t)\mathbf{b}(t),\ \mathbf{P}(\delta t)=\exp[\mathrm{i}\delta t(\mathbf{H}+\mathbf{I}\bar{\omega})] \qquad [14]$$

which describes the autoregressive nature of $\mathbf{b}(t)$. Equation [14] has no term that depends on the seismic source. An inverse problem is set up for the propagator matrix $\mathbf{P}$, using the strips of many events simultaneously. The splitting matrix $\mathbf{H}$ is determined from $\mathbf{P}$ using the eigenvalue decomposition of $\mathbf{P}$ (Masters et al., 2000b). The complex matrix $\mathbf{H}$ we retrieve in this process is non-Hermitian (no symmetry) and includes elastic and anelastic structure. We use the unique representation

$$\mathbf{H}=\mathbf{E}+\mathrm{i}\mathbf{A} \qquad [15]$$

to decompose $\mathbf{H}$ into its elastic, $\mathbf{E}={}^1/_2(\mathbf{H}+\mathbf{H}^{\mathbf{H}})$, and anelastic, $\mathrm{i}\mathbf{A}={}^1/_2[\mathbf{H}-\mathbf{H}^{\mathbf{H}}]$, components where superscript $\mathbf{H}$ indicates Hermitian transpose. Both $\mathbf{E}$ and $\mathbf{A}$ are Hermitian and are the matrices for eqn [6] (where the effects of rotation and ellipticity are included in $\mathbf{E}$). Examples of splitting matrices retrieved with this technique are shown in Figures 11 and 25 in Section 1.04.2.3.5. A discussion on retrieving Earth's density from splitting functions that were obtained using this method can be found in Masters et al. (2000c). An application to investigate the IC differential rotation is described Section 1.04.2.4.

1.04.2.3.4 Retrieving the splitting matrix with iterative spectral fitting

The first technique to retrieve all elements of the splitting matrix of an isolated multiplet was iterative spectral fitting (ISF) introduced by Ritzwoller et al. (1986), Ritzwoller et al. (1988), and Giardini et al. (1987). It has been refined and applied in a number of studies, including Li et al. (1991a), Li et al. (1991b), Widmer et al. (1992b), He and Tromp (1996), and Resovsky and Ritzwoller (1998). ISF considers the Fourier transform of eqns [4]–[6]. In this coupled set of equations, the $\ell-1$ real and $\ell(\ell+1)$ complex structure coefficients c_s^t are nonlinearly related to the observed spectra $u_j(\omega)$. The problem of finding the structure coefficients from a set of observed spectra is then formulated as a nonlinear parameter estimation problem. Figure 22 shows an example of how ISF allows detailed modeling of a split mode spectrum. The prediction from a model including only Earth's rotation and hydrostatic

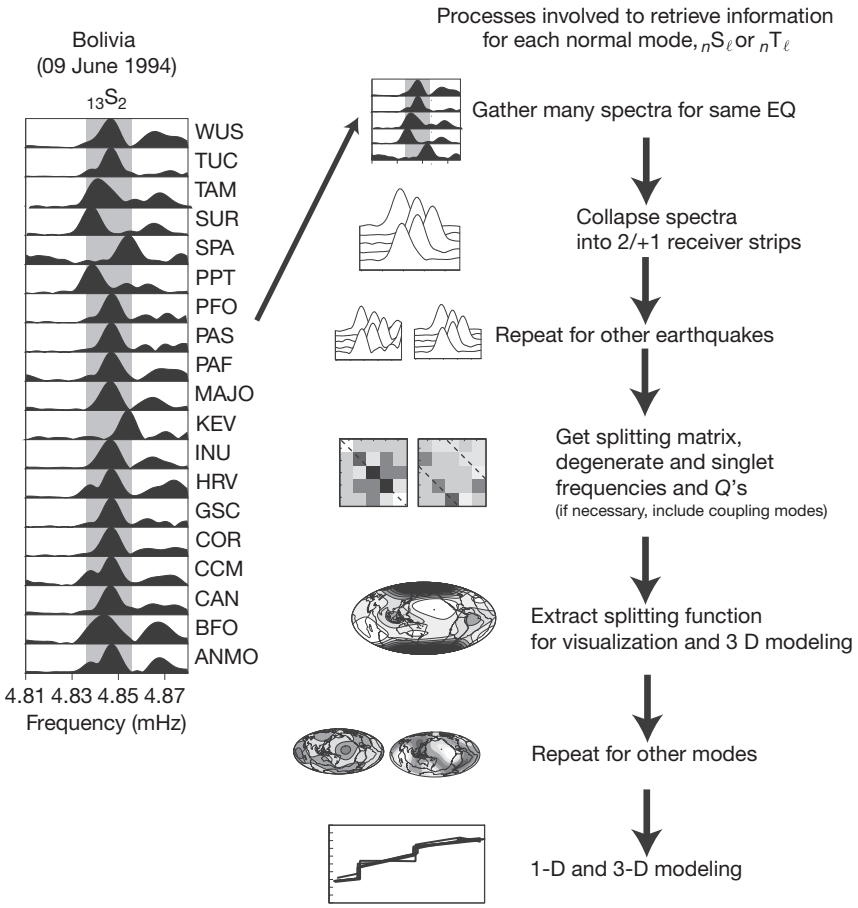

Figure 21 Left: Selected spectra for mode $_{13}S_2$, for the 1994 Bolivia earthquake. Right: Simplified flowchart of our approach to extract mode information from seismograms of large earthquakes.

ellipticity provides a poor fit to the observed spectrum. If ISF is implemented with a local search algorithm, this prediction can serve as starting solution. Spectral fitting is then iterated and converges to a new solution that fits the observation much better. The splitting of the mode shown here, $_1S_8$, reflects lower mantle V_S heterogeneity. A crucial aspect of ISF is the need of a source model so that the vector of singlet excitations **a** (0) in eqn [5] can be computed. Matters are further complicated, if local rather than the computationally more expensive global algorithms are used to search for the set of best-fitting structure coefficients. Nevertheless, for well-excited multiplets for which records from many events can be used simultaneously, it was possible with the data coverage of the 1980s to obtain robust estimates of degree $s=2$ and perhaps also $s=4$ structure coefficients.

ISF was also applied to high-Q, low-order modes up to 9 mHz (Widmer et al., 1992b). These modes sample the outer and inner core and many of the modes are anomalously split. The large majority of other modes attenuate so rapidly that the spectra are dominated by the relatively sparse class of high-Q modes, if the first 6–8 h of data after an earthquake are discarded. The set of structure coefficients of these high-Q

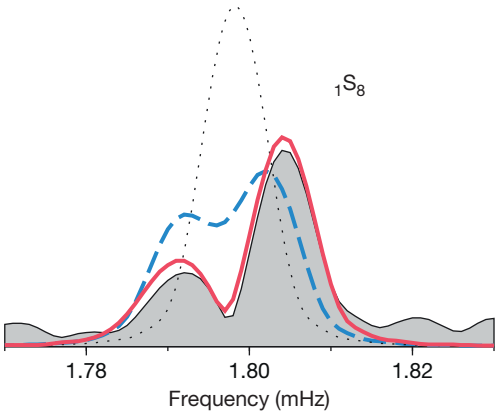

Figure 22 Modeling of the spectrum of multiplet $_1S_8$ with the ISF procedure, for a recording of the 9 June 1994 Bolivia earthquake at station MAJO (Matsushiro, Japan). Black line: Observed linear amplitude spectrum; dotted line: prediction for PREM; dashed blue line: splitting caused by Earth's rotation and hydrostatic ellipticity; red line: final solution for the spectrum after ISF. modes analyzed by Widmer et al. (1992b) with both ISF and singlet stripping were used primarily by Tromp (1993) to corroborate the hypothesis of Giardini et al. (1987) that axisymmetric IC anisotropy can explain the anomalous splitting of IC-sensitive modes. The most comprehensive set of structure coefficients based on ISF was compiled by Resovsky and Ritzwoller (1998). Restricting their analysis to modes below 3 mHz, they obtained 3100 structure coefficients for 90 multiplets. These authors also generalized the ISF procedure to coupled modes and obtained, for the first time, constraints on odd-degree structure using normal modes (Resovsky and Ritzwoller, 1995). An updated mode data set obtained from using ISF is that of Deuss et al. (2013).

1.04.2.3.5 Observed mode coupling

As mentioned in the preceding text, we observe toroidal mode energy on vertical components because Coriolis coupling causes the formation of hybrid mode pairs in which energy is exchanged between modes. While this has been well observed for modes above 2 mHz, Zürn et al. (2000) recently also observed this for the gravest modes below 1 mHz (**Figure 23**). In gravimeter spectra of the great 1998 Balleny Islands earthquake, they identified spectral lines at the toroidal mode frequencies of ${}_0T_3$ through ${}_0T_6$. A correction of the LaCoste–Romberg gravimeter ET-19 record at station BFO for local atmospheric pressure variations (Zürn and Widmer, 1995) helped raise mode ${}_0T_3$ above the noise floor, while the spectrum of the superconducting gravimeter GWR-C026 at station J9 near Strasbourg also may have shown this peak. After the Sumatra event, Hu et al. (2006) observed the gravest toroidal mode ${}_0T_2$ and overtones ${}_1T_2$ and ${}_1T_3$ in gravimeter spectra. Using the method of Park and Gilbert (1986), Zürn et al. (2000) compared the effects of rotation, hydrostatic ellipticity, and aspherical Earth structure on coupled-mode synthetic spectra. They identified Coriolis coupling as the most effective mechanism responsible for toroidal mode energy to appear in the vertical-component spectra.

In the preceding text, we have described how the coupling of modes can lead to a frequency shift of the entire multiplet. An example is the Coriolis coupling between spheroidal and toroidal fundamental modes. The observation of Coriolis coupling is well documented for fundamental modes between 2 and 4 mHz (Masters et al., 1983; Smith and Masters, 1989a), and we recall that it is particularly strong for the two pairs ${}_0S_{11}$–${}_0T_{12}$ and ${}_0S_{19}$–${}_0T_{20}$. **Figure 24** shows this mode coupling in an analysis where we applied the multiplet stripping technique. In general, the effect of multiplet–multiplet coupling on the degenerate frequency cannot be corrected for using this technique, except for the case shown here (e.g., Smith and Masters, 1989a). For multiplet–multiplet coupling caused by aspherical structure, it has to be assumed that the induced shift of the degenerate frequency can be treated as a source of random noise. This may be justified as the frequency separation to the nearest coupling partners is different for every multiplet so the cross branch coupling is different for every multiplet. For along-branch coupling, systematic effects may be significant, since the frequency separation of modes belonging to the same branch is nearly the same.

Coupling through Earth structure manifests itself in the cross coupling blocks of the splitting matrix. We have recently started to apply the matrix AR technique to coupled modes, and an example for weakly coupled modes ${}_1S_5$ and ${}_2S_4$ is shown in **Figure 25**. Since the selection rules state that $\ell+\ell'+s$

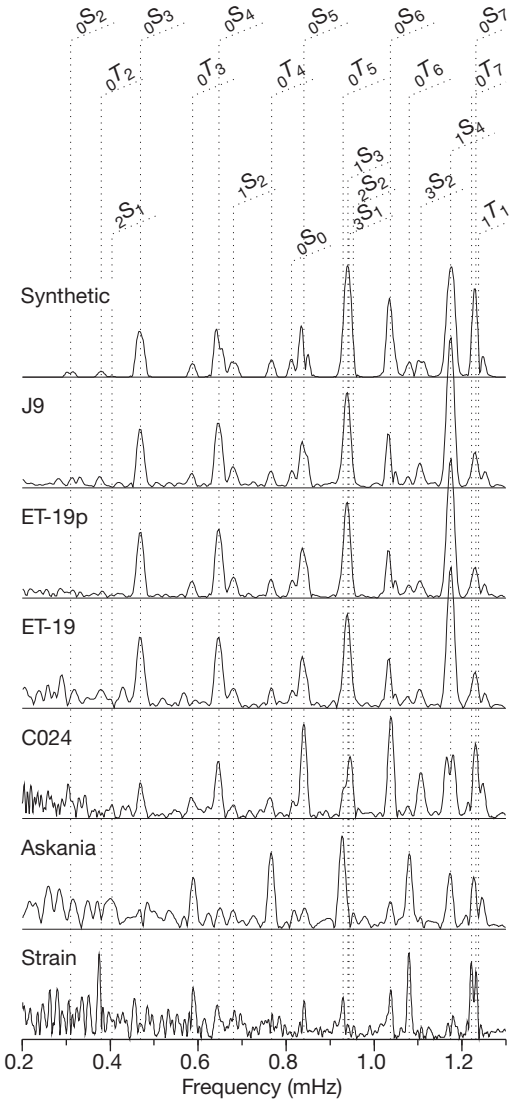

Figure 23 Coriolis coupling below 1 mHz, observed for the 25 March 1998 Balleny Islands earthquake. Spectral peaks appear in vertical-component spectra at the frequencies of toroidal modes ${}_0T_3$ through ${}_0T_6$. Shown are spectra of the LaCoste–Romberg spring gravimeter ET-19p at station BFO, the superconducting gravimeters GWR-C026 at station J9 near Strasbourg, 60 km from BFO, and GWR-C024 at Table Mountain Observatory near Boulder, CO (the United States). To reduce noise, the gravimeter records were corrected for variations in local atmospheric pressure (Zürn and Widmer, 1995). For comparison, the uncorrected spectrum at BFO is also shown (ET-19). The synthetic spectrum was obtained from a coupled-mode synthetic for BFO, using Park and Gilbert's (1986) method to account for effects from rotation, hydrostatic ellipticity, and aspherical structure. 'Askania' and 'strain' refer to data from the Askania borehole tiltmeter and the invar wire strainmeter array at BFO and show that the low-order fundamental toroidal modes were efficiently excited by the event. Reproduced from Zürn W, Laske G, Widmer-Schnidrig R, and Gilbert F (2000) Observation of Coriolis coupled modes below 1 mHz. *Geophysical Journal International* 143: 113–118.

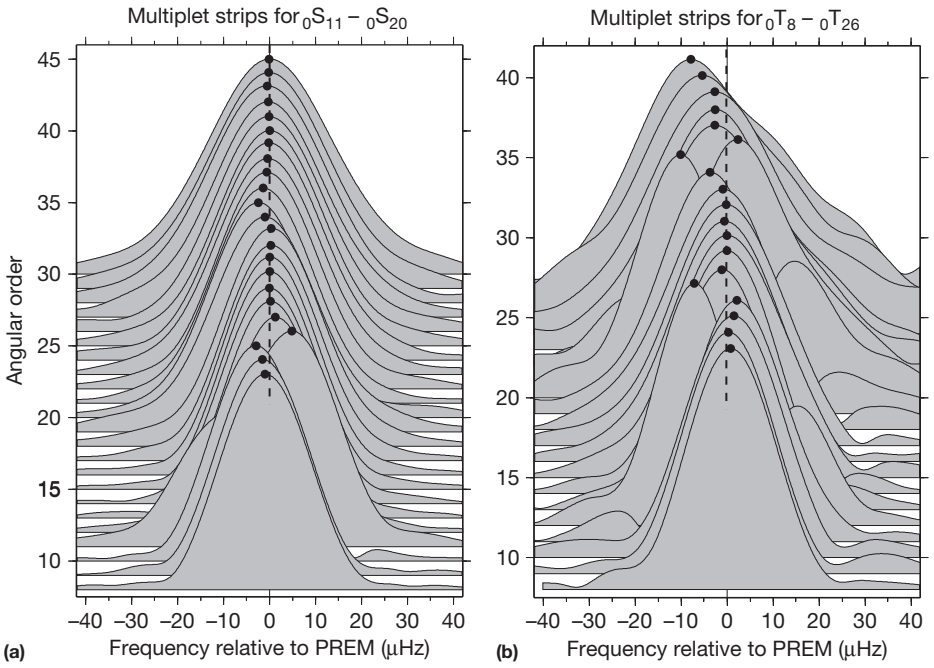

Figure 24 Observed effects of Coriolis coupling above 1 mHz. (a) Multiplet strips of fundamental spheroidal modes $_0S_8$ through $_0S_{30}$, aligned relative to PREM (Dziewonski and Anderson, 1981). (b) Multiplet strips of fundamental toroidal modes $_0T_8$ through $_0T_{26}$. Coupling effects are different for each singlet, resulting in a shift of the entire multiplet. Modes $_0S_{11}$ and $_0S_{20}$ are within a few microhertz of neighboring $_0T_{\ell+1}$ modes so coupling effects are particularly large. Coriolis coupling effects are significant for $_0S_9$ through $_0S_{22}$, relative to the observational uncertainties of <0.3 μHz. Modified from Widmer R (1991) The Large-Scale Structure of the Deep Earth as Constrained by Free Oscillation Observations. PhD Thesis, University of California San Diego, La Jolla, CA.

must be even, these two modes couple through structure of odd-harmonic degree. Coupling through Earth structure makes the splitting matrix quite complex, and the cross coupling blocks we determine with our technique may yet be too noisy to extract odd-degree structure. This should be improved in the future by including more earthquakes in the analysis. Resovsky and Ritzwoller (1995) successfully determined odd-degree structure implied in the cross coupling blocks by using the ISF method. In the example shown here, only a mode pair was considered, whereas Resovsky and Ritzwoller (1995) considered relatively small groups of modes below 3 mHz. Deuss and Woodhouse (2001) showed that wideband coupling can significantly alter the shape of spectral lines, though it is not immediately clear if this effect is significant with respect to measurement errors of mode observables.

Since the coupling strength scales with the inverse of the frequency separation of coupling modes, splitting matrices above 3 mHz become so large that their decomposition turns into a numerically formidable task. Several different strategies have been suggested to reduce the computational burden. Lognonné and Romanowicz (1990) and Lognonné (1991) introduced the efficient spectral method using third-order perturbation theory to compute coupled modes and seismograms for an anelastic rotating Earth. Using this method, Millot-Langet et al. (2003) calculated coupled-mode synthetics on an anelastic 3-D Earth. Deuss and Woodhouse (2004) introduced a method that is similar to subspace projection methods but can be iterated several times to completely represent the exact solution. They found that only one iteration usually brings the solution sufficiently close to the exact solution.

Alternatives to the approach based on mode summation include the direct solution method (Geller and Takeuchi, 1995) for which an application to 3-D heterogeneity can be found in Takeuchi et al. (2000). The spectral element method of Komatitsch and Vilotte (1998) also has been shown to provide an efficient tool to study wave propagation, diffraction, and body-wave conversion in a 3-D Earth. Applications of this method can be found in Komatitsch and Tromp (2002), Komatitsch et al. (2002), Capdeville et al. (2003), and Chaljub and Valette (2004). Gilbert (2001) suggested that a Vandermonde matrix analysis allows the independent determination of earthquake mechanisms and Earth structure. The method also allows the analysis of 'latent' modes that are not observed but coupled to observed modes (e.g., modes with extremely little energy density near the surface). For a detailed discussion of numerical methods, the reader is referred to **Chapter 1.07**.

1.04.2.4 Example of a Mode Application: Inner-Core Rotation

Differential rotation of the IC with respect to the rigid mantle has been inferred by several body-wave studies, with most agreeing that a superrotation may exist with a rate between 0.2° and 3° per year (e.g., Creager, 2000; Song and Richards, 1996). The wide range of inferred rotation rates is caused by the sensitivity of such studies to local complexities in structure, which have been demonstrated to exist. Free oscillations, on

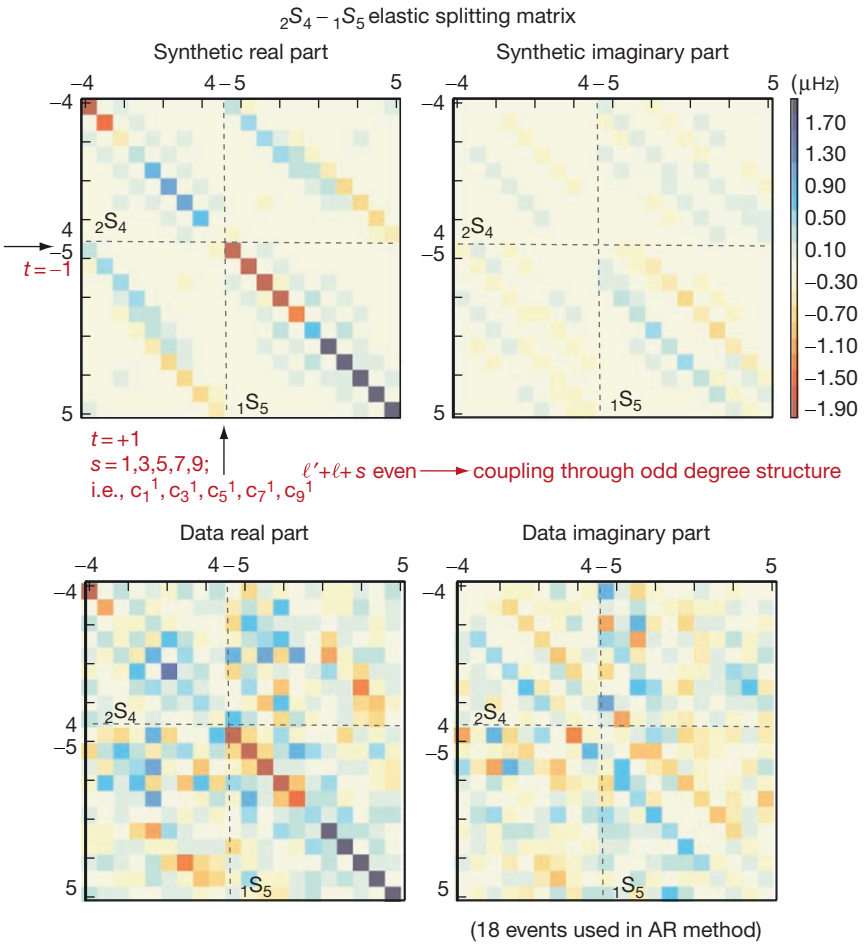

Figure 25 Predicted and measured elastic splitting matrix **E** of the coupled-mode pair $_1S_5$–$_2S_4$. The signal in the diagonal self-coupling blocks is generally somewhat larger in the observations than in the predictions (e.g., imaginary part for mode $_2S_4$). Some predicted features show up in the measured off-diagonal cross coupling blocks (e.g., blue in upper-left corner and red toward the lower right in the real part), but noise probably inhibits a reliable extraction of odd-degree structure from these blocks at this time. The 3-D model used for the synthetic splitting matrix is S16B30 (Masters et al., 1996). Reproduced from Masters TG, Laske G, and Gilbert F (2000d) Large-scale Earth structure from analyses of free oscillation splitting and coupling. In: Boschi E, Ekström G, and Morelli A (eds.) *Problems in Geophysics for the New Millennium*, pp. 255–288. Bologna: Editrice Compositori.

the other hand, are natural low-pass filters of 3-D structure, so that long-wavelength phenomena, such as IC rotation, are prime study targets. Free oscillations 'see' Earth as a whole, so the observation of how a free oscillation splitting pattern changes with time, and any inference on IC rotation is not biased by the effects of localized structures. It is also not necessary to know the physical cause of the patterns (anisotropy or heterogeneity). All that needs to be observed is if and how they change with time. Free-oscillation splitting functions are therefore better candidates for estimating differential IC rotation accurately. The most obvious approach to do this analysis is to compare splitting functions obtained with earlier earthquakes to those obtained with recent events. A problem with this approach is that the sparsity of early data does not allow us to construct early splitting functions with the required accuracy. Sharrock and Woodhouse (1998) therefore studied the time dependence of the fit of splitting functions to spectra of earthquakes over time for some IC-sensitive modes. Their estimates of a westward rotation of the IC with respect to the mantle appear to be inconsistent with the results from body-wave studies. We prefer to use our autoregressive technique for this analysis.

In a hypothesis test, we sought the optimal IC rotation rate that matches our splitting functions for the recent earthquakes with receiver strips over time. Our initial finding was that the IC rotation is essentially zero over the last 20 years ($0.01 \pm 0.21°\text{year}^{-1}$; Laske and Masters, 1999). A complication in this analysis – that also plays a role in many body-wave studies – is that IC-sensitive modes are also very sensitive to mantle structure. Prior to applying the assumed IC rotation rate in the test, we therefore have to correct for the contributions from the heterogeneous mantle. In a detailed and updated analysis, Laske and Masters, (2003) applied mantle corrections using a variety of published mantle models (**Figure 26**). Our preferred model is SB10L18 (Masters et al., 2000a), a 10-degree equal area block model that was derived simultaneously for shear velocity and bulk sound speed, $V_C = \sqrt{\kappa/\rho}$, and our mode data were included in the

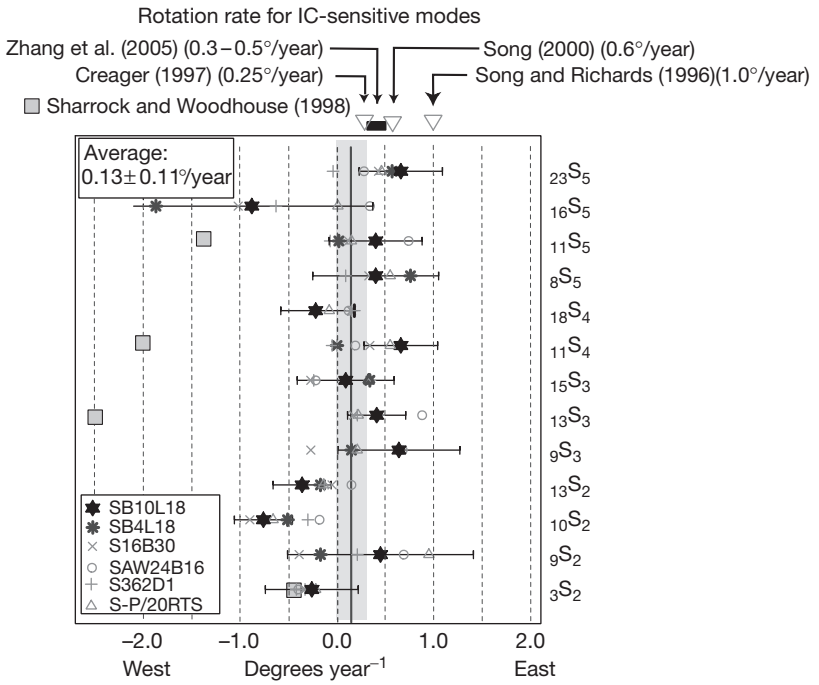

Figure 26 IC rotation rates obtained for 13 IC-sensitive modes, using our preferred $V_S/V_C/V_P$ mantle model SB10L18 (Masters et al., 2000a). Also shown are the results obtained using other mantle models: shear velocity models SB4L18 (Masters et al., 2000a), S16B30 (Masters et al., 1996), SAW24B16 (Mégnin and Romanowicz, 2000), and S362D1 (Gu and Dziewonski, 1999) and V_S/V_P models S-P/20RTS (Ritsema and van Heijst, 2000). Other symbols and lines mark results from other publications: Song and Richards (1996), Creager (1997), Sharrock and Woodhouse (1998), Song (2000), and Zhang et al. (2005).

inversions. The majority of models in the literature are shear velocity models that were derived using only shear-sensitive modes (e.g., SAW24B16 by Mégnin and Romanowicz, 2000) or using established scaling relationship for V_P and ρ (or ignoring sensitivity to the latter entirely) to include spheroidal modes (e.g., S20RTS by Ritsema and van Heijst, 2000). Our comparison also includes our older model S16B30 (Masters et al., 1996) that was the result of a direct matrix inversion for a model described by spherical harmonics. As can be seen from Figure 26, inferred rotation rates vary with different mantle models, but most results lie within our error bars for SB10L18. Laske and Master's best estimate is a barely significant super-rotation of 0.13 ± 0.11 year^{-1}, which is still consistent with the idea that the IC is gravitationally locked to the mantle. A more recent estimate of 0.00 ± 0.06 year^{-1} that is based on data up to and including the 2011 Tohoku, Japan, earthquake was presented at the 2011 General Assembly of the EGU (Masters, 2011). These results are broadly consistent with many body-wave results (e.g., Creager, 1997, 2000) though the discrepancy to a recent body-wave estimate of 0.3–0.5 year^{-1} by Zhang et al. (2005) is marginal but still significant.

There are limitations to this type of analysis, and not all IC-sensitive modes can be utilized. For example, although $\ell = 1$ modes (e.g., ${}_8S_1$ and ${}_{13}S_1$) are quite sensitive to IC structure, they can constrain IC rotation only poorly because the mantle-corrected splitting functions are dominated by a large zonal (axisymmetric) component. Also, so far, we have ignored mode coupling in our analysis. Some IC-sensitive modes significantly overlap in frequency with other modes of high angular order ℓ, thereby hampering an analysis using the receiver strip method. For example, with a degenerate frequency in PREM (Dziewonski and Anderson, 1981) of 1.242 mHz, mode ${}_2S_3$ is very sensitive to IC shear velocity but overlaps with ${}_0T_7$, ${}_0S_7$, and ${}_1T_1$, which couple through Earth's 3-D structure. For a given mode pair ${}_0S_\ell/{}_0T_{\ell'}$, we need at least $2 \times (\ell' + \ell + 1)$ high-quality records to construct receiver strips. These many records are often not available for earlier earthquakes. Many $\ell = 2$ modes that are very sensitive to IC structure are strongly coupled to radial modes. We can analyze such mode pairs with our AR technique, but the IC rotation hypothesis test becomes more cumbersome and was not done in our 2003 study. We notice that mode ${}_{13}S_2$, which couples with ${}_5S_0$, and mode ${}_{10}S_2$, which couples with ${}_4S_0$, systematically suggest a westward IC rotation, regardless of the mantle model chosen for the corrections. The analysis of ${}_3S_2$, whose coupling properties with neighboring modes is quite complex (see also Zürn et al., 2000), also gives westward rotation rates. Mode ${}_9S_2$ is difficult to observe and errors are quite large. When not taking these modes into account, we obtain an eastward IC rotation rate of $0.34 \pm 0.13°$year^{-1}. This marginally agrees with the estimate of Zhang et al. (2005).

A caveat when analyzing modes using the isolated-mode assumption is that only even-degree structure can be determined. It is known from body-wave studies that the heterogeneity at the top of the IC has a strong $s = 1$ signal that is roughly divided into a Western and an Eastern Hemisphere (Creager, 2000; Tanaka and Hamaguchi, 1997). The fact that isolated modes are insensitive to such structure does not invalidate our IC rotation results, provided the IC rotates as a rigid body. Structure of odd-harmonic degree can potentially be determined

by analyzing coupled modes, but the coupling effects for the modes considered here are rather weak. Core structure and IC differential rotation are discussed in **Chapter 1.23**.

1.04.2.5 Example of a Mode Application: Earth's Hum

It took as long as 38 years after the first observation of Earth's free oscillations of the 1960 Great Chilean earthquake before convincing evidence was found that Earth's normal modes never cease to vibrate but instead remain excited at a low but nearly constant level (Ekström, 2001; Suda et al., 1998; Tanimoto et al., 1998). This normal mode background signal is now often termed Earth's 'hum.' Early on, Benioff et al. (1959) looked for modal signals in noise spectra of LaCoste–Romberg gravimeters, but the sensitivity of these instruments (which at the time were operated with a mechanical feedback) was too low by three orders of magnitude for a positive hum detection. It was not until Nawa et al. (1998) first inspected data from the superconducting gravimeter at Syowa (Antarctica) and subsequently from seismic stations of the global network (Suda et al., 1998) that evidence for the incessant excitation of seismic free oscillations was presented.

Fundamental spheroidal modes ${}_0S_\ell$ are observed to be permanently excited in the frequency band 2–7 mHz, with an root mean square acceleration amplitude of ~1 ngal ($=10^{-11}$ ms^{-2}) over a 100 μHz bandwidth (**Figure 27**). Additional characteristic hum features are a slight semiannual modulation of the amplitude and a resonant enhancement near 3.7 mHz (Ekström, 2001; Nishida et al., 2000). At frequencies below 2 mHz, vertical seismic noise is primarily of local barometric origin, and some of this noise can be removed by regression with the locally recorded pressure fluctuations (Zürn and Widmer, 1995). However, this crude correction does not allow to remove all of the barometric noise, making a hum detection below 2 mHz nearly impossible. At frequencies near 7 mHz, the splitting of the fundamental spheroidal modes due to heterogeneous upper-mantle structure is as wide as the frequency separation between adjacent fundamental modes. Modes then overlap and cause an overall rise of the noise base level into which peaks disappear. Nishida et al. (2002) showed that the vertical-component seismic noise consists of globe-circling Rayleigh waves all the way up to 20 mHz, and it seems likely that the same mechanism is responsible for the generation of Rayleigh wave background noise as for the hum at lower frequency. The detection of the hum is an instrumental challenge because of its exceptionally small amplitude. The self-noise of all instruments that have so far been able to detect the hum is at or very near the amplitude of the hum itself. These include superconducting gravimeters, LaCoste–Romberg spring gravimeters, and Streckeisen STS-1 and STS-2 seismometers. Widmer-Schnidrig (2002) computed coherences for pairs of colocated sensors and in the hum band obtained values not exceeding 0.5. The low signal-to-noise ratio in individual traces necessitates much averaging in time or the use of array techniques to enhance the hum signal.

The physical processes responsible for the excitation of the hum remain somewhat of a puzzle. Considering that wave motion in the oceans is responsible for the marine microseisms at periods shorter than ~25 s and that below 2 mHz atmospheric phenomena dominate the seismic noise, one can speculate that the signals in between are also generated by atmospheric and/or hydrospheric processes. The semiannual modulation supports this hypothesis, while the resonant enhancement near 3.7 mHz (Nishida et al., 2000) is evidence for at least partial involvement of the atmosphere (e.g., Widmer and Zürn, 1992). The lack of overtones in the hum favors near-surface excitation and also speaks for the atmosphere and/or hydrosphere excitation hypothesis. From the observation that individual mode excitations do not correlate between pairs of stations, Nishida and Kobayashi (1999) had drawn the conclusion that the source of the hum cannot be localized but must be of global origin: they hypothesize that pressure exerted on the solid Earth by global atmospheric turbulence is responsible for the hum excitation. This conclusion, however, is not compelling because of the low signal-to-noise ratio mentioned in the preceding text.

Trying to elucidate the hum excitation mechanism, Rhie and Romanowicz (2004) used the BDSN (Berkeley Digital Seismic Network) in California and the F-net in Japan to estimate the back azimuth of the Rayleigh wave background signal. They located hum sources in the North Pacific during Northern Hemisphere winter and in the southern oceans during summer. A subsequent analysis of 5 years of data from the GRSN (German Regional Seismic Network) in Germany found back azimuths consistent with these source regions (Kurrle and Widmer-Schnidrig, 2006). **Figure 28** shows that the back azimuths of Rayleigh waves at GRSN also have a very pronounced seasonality. Prevalent winter back azimuths around 30° point toward the North Pacific, while summer back azimuths of 210° and 120° point to the southern Pacific and southern Indian Ocean, both in accordance with Rhie and Romanowicz (2004). More recently, Rhie and Romanowicz (2006) studied two winter storms off the west coast of N America during four seismically quiet, consecutive days. As the storms encountered the coast, the amplitude of both the marine microseisms and the low-frequency Rayleigh waves increased, and both wave types could be traced back to the same coastal segment where the storms hit the shore.

While the generation of microseisms by ocean surface gravity waves is well understood (e.g., Kedar et al., 2008; Longuet-Higgins, 1950), it is not entirely clear how the band-limited surface gravity waves are linked to the occurrence of infragravity waves and subsequently the generation of low-frequency Rayleigh waves. One particular difficulty in this chain of linked phenomena is the mismatch of wave numbers between open-ocean infragravity waves on the one hand and Rayleigh and Love waves on the other: at a given frequency in the hum band, the wavelength of Rayleigh and Love waves is 25 times larger than that for infragravity waves in the deep ocean.

Infragravity-wave generation is most efficient on the continental shelf and involves nonlinear wave–wave interactions (e.g., Galagher, 1971; Tanimoto, 2005; Webb, 1998). Rhie and Romanowicz (2006) observed hum excitations not only along the west coast of North America, where the infragravity waves were originally generated, but also along the North Pacific Rim after the waves apparently traveled there and dissipated. The timing was found to be consistent with the propagation speed of ~200 ms^{-1} for infragravity waves in the open ocean. If infragravity waves are capable of exciting the hum to observable levels after crossing entire ocean basins, this may explain why previous attempts at locating the source

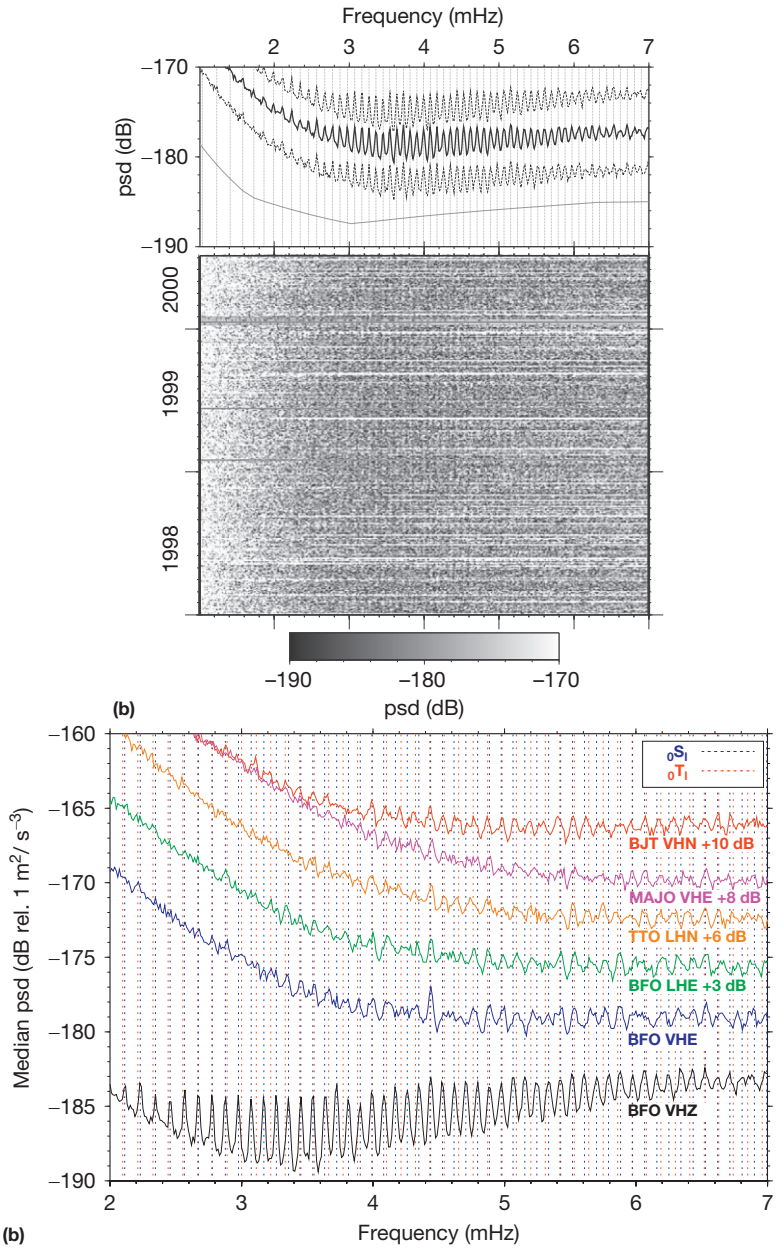

Figure 27 (a) Time–frequency plot covering 2.5 years of data from the STS-2 seismometer of the German Regional Seismic Network (GRSN) at BFO. The range of the gray scale is chosen to emphasize structure in the noise during seismically quiet times. The upper panel shows median psd levels (black) together with the first and third quartiles (dashed). The new low noise model of Peterson (1993) (gray) is shown for reference. The vertical dashed lines indicate the predicted frequencies of the fundamental spheroidal modes ${}_0S_\ell$ and coincide with light-gray vertical bands in the lower panel. (b) Comparison of vertical and horizontal hum. The bottom trace (BFO VHZ) with the regular comblike structure shows the spheroidal hum recorded on the vertical-component STS-1Z seismometer at BFO. The traces above show spectra of the horizontal hum recorded at four different stations of the GSN, F-net, and GRSN seismic networks: BFO, TTO, MAJO, and BJT. The richer spectrum of the horizontal hum is due to the interference of fundamental spheroidal and toroidal modes. The different horizontal hum spectra are offset for clarity. (Kurrle and Widmer-Schnidrig, 2008).

regions of the hum produced only very diffuse maps (e.g., Nishida and Fukao, 2007). More recent studies based on data from the large, transportable USArray (292 stations with an aperture of 2000×1200 km) confirmed the shelves as the dominant source region in times of large oceanic storms (Bromirski and Gerstoft, 2009). However, whether the processes invoked to explain the observations from large winter storms are representative for the persistent background hum excitation remains an open question.

Owing to higher noise levels in horizontal component seismic recordings, it took another 10 years after the discovery of the spheroidal hum to discover its counterpart in horizontal

recordings. A horizontally polarized hum consisting of spheroidal modes was to be expected because the particle motion of spheroidal modes (and Rayleigh waves) follows an ellipse in a vertical plane. However, the discovery of the horizontal hum included also a big surprise: it consisted also of toroidal modes, and the latter were present with equal or even larger amplitudes than the spheroidal modes (**Figure 27(b)**). Kurrle and Widmer-Schnidrig (2008) estimated the ratio of toroidal-to-spheroidal signal power at 4 mHz to be close to unity, while at 12.5 mHz, Nishida et al. (2008) estimated the power of Love waves to be three times larger than for Rayleigh waves.

Initially, the large fraction of toroidal energy posed a serious challenge to the models of hum excitation. At the time, these models consisted of predominantly vertical forces from pressure fluctuations of infragravity waves on the shelf or in the deep ocean that in turn lead to an excitation of spheroidal modes (e.g., Tanimoto, 2005; Webb, 2007). However, vertical pressure forces acting on a horizontal sea floor excite exclusively spheroidal modes and lead to no excitation of toroidal modes. Fukao et al. (2010) proposed a model for spheroidal and toroidal hum excitation, which could resolve this conundrum. In its simplest form, this model can be described as follows: consider a patch of sea floor with a periodic bathymetry consisting of linear sinusoidal hills (e.g., abyssal hills), and let a monochromatic infragravity wave with the same wavelength as the bathymetry propagate over this patch in a direction perpendicular to the bathymetric hills. The pressure field acting on the sloping sea floor can now be decomposed into vertical and horizontal pressure forces: while the resulting vertical forces oscillate rapidly with position, the horizontal pressure forces are not oscillating spatially but point in the same direction for the entire patch. This model achieves two things: (1) it overcomes the mismatch in wave numbers between infragravity waves and seismic surface waves, and (2) it provides a mechanism with a predominantly horizontal force, which naturally leads to the excitation of Love and Rayleigh waves with comparable amplitudes.

While identifying the processes that lead to the excitation of the hum needs further study, Nishida et al. (2009) succeeded in using the hum signal to infer 3-D upper-mantle shear wave velocity structure. Their work is closely related to the emergent field of ambient noise tomography, which is discussed in the surface wave section and in **Chapter 1.12**. For a more detailed discussion of the hum, the interested reader is referred to the excellent review article by Nishida (2013).

1.04.3 Surface Waves

1.04.3.1 Standing Waves and Traveling Waves

Surface waves provide a rich data set to explore Earth's crust and upper mantle as well as seismic sources on a multitude of scales (see Romanowicz, 2002 for a comprehensive review). Many papers document that there is no real boundary between free-oscillation and surface wave measurements. For example, early free-oscillation papers that discuss great-circle surface wave dispersion actually discuss free-oscillation peak shifts (e.g., Roult and Romanowicz, 1984). Studying long-period surface waves, Souriau and Souriau (1983) found a plate subduction-related degree 2 anomaly in the transition zone that was similar to that of Masters et al. (1982) using their mode approach. In fact, surface wave theory on the spherical Earth can be understood as a high-frequency approximation of mode theory. As mentioned in the mode section, the motion of standing waves on a sphere is expressed in spherical harmonics. At epicentral distance Δ, standing waves along a source–receiver great circle are described by zonal harmonics where the Legendre polynomials $P_\ell(\cos\Delta)$ are the relevant terms (**Figure 29**). In the high-frequency or high-ℓ asymptotic expansion, this term is approximated by cosines which are the relevant terms of traveling waves (e.g., Aki and Richards, 1980, 2002; Jordan, 1978; Romanowicz and Roult, 1986) to zeroth order in $1/\ell$ (see Romanowicz, 1987, for higher-order expansion):

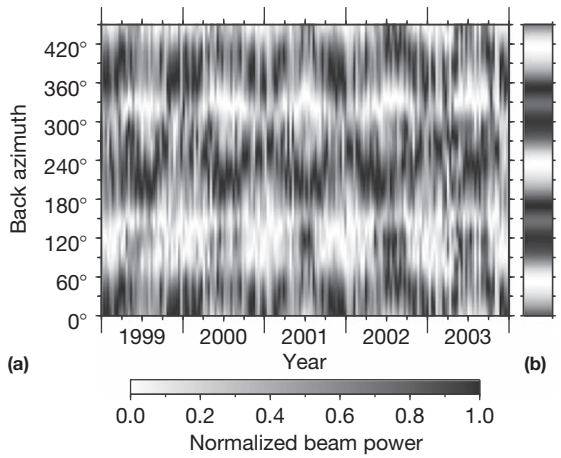

Figure 28 (a) Beam power distribution of Rayleigh wave background between 5 and 8 mHz estimated from vertical-component recordings of a nine-station array in Central Europe. (b) Back azimuths of an incident plane wavefield cannot be recovered perfectly from a sparse nine-station array. This is evident from the array response shown here. (Kurrle and Widmer-Schnidrig, 2006).

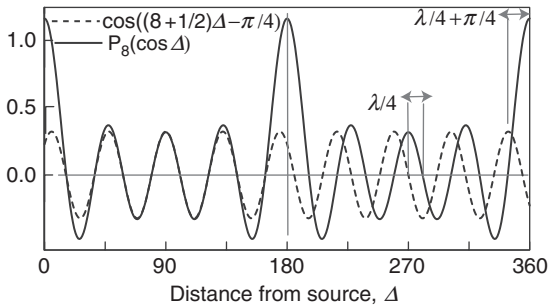

Figure 29 A comparison of the degree 8 Legendre polynomial with its asymptotic representative. The scaling factor of eqn [16] was omitted, but a constant factor was applied for optimal illustration. The graph also illustrates the validity of Jeans' formula. The asymptotic representation is applicable strictly only near $\Delta = 90°$. After passing a pole, the asymptotic leads by $\pi/2$ or approximately a quarter wavelength where $\lambda = 2\pi/(\ell + 1/2)$. Entering and exiting a pole each add $\pi/4$.

$$P_\ell(\cos\Delta) \simeq \left(\frac{2}{\pi\ell\sin\Delta}\right)^{\frac{1}{2}} \cos\left[\left(\ell+\frac{1}{2}\right)\Delta - \frac{\pi}{4}\right] \qquad [16]$$

Away from the poles, Jeans' formula (Jeans, 1923) gives the approximate wave number, k, of such a cosine:

$$k = \frac{\ell+\frac{1}{2}}{a} \qquad [17]$$

where a is Earth's radius.

Dahlen and Tromp (1998) described the conversion from the standing wave to the traveling wave representation through the Watson transformation

$$\sum_{\ell=0}^{\infty} f\left(\ell+\frac{1}{2}\right) = \frac{1}{2}\int_C f(k)\mathrm{e}^{-\mathrm{i}k\pi}\cos(k\pi)^{-1}\mathrm{d}k \qquad [18]$$

where f is any function that is analytic near the real k-axis and C is a closed contour along the positive real k-axis (see also box 9.7 in Aki and Richards, 2002 and box 9.3 in Aki and Richards, 1980). This demonstrates how a sum over discrete modes (standing waves) is expressed as an integral over continuous wave number (traveling waves).

Approaching the problem from the other end, to observe a free-oscillation spectrum, the time series has to include at least a pair of wave trains traveling in opposite directions as well as a third wave train that circled Earth, that is, the time window has to be at least roughly 5 h long (**Figure 30**; see also **Figure 3**). The synthetic seismograms that **Figure 30** is based on were calculated for an epicentral distance of nearly 90°. In this case, the fundamental mode spectra are modulated such that often, every other mode has a significantly reduced amplitude though this modulation also depends on the source. For the examples shown here, we assume a double-couple point source. A seismogram including only one wave train carries no information on the finite body Earth; hence, we do not observe normal modes. As soon as a major arc wave train and a minor arc wave train are recorded, an amplitude modulation pattern emerges that depends on the epicentral distance and the source mechanism. If two wave trains are recorded that are separated by a complete great circle, modes can be observed though

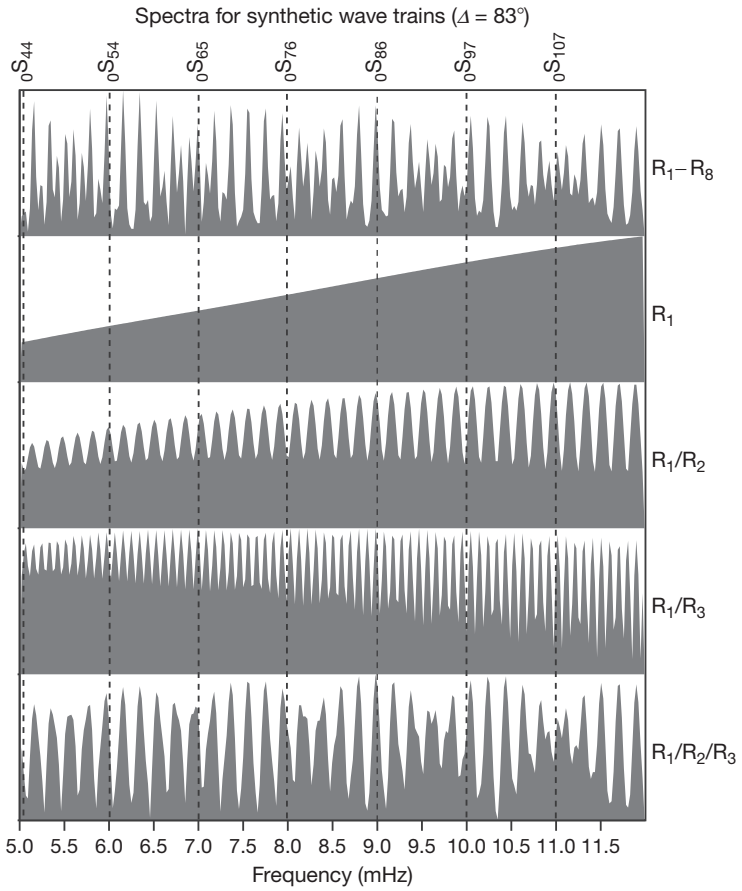

Figure 30 Spectra of synthetic acceleration seismograms at an epicentral distance of 83°, with a variety of wave trains as indicated on the right. All time series are 12 h long. Only the top spectrum contains all wave trains that arrive at a station within 12 h. Wave trains in the other records were zeroed out. A Hanning taper was applied before calculating the spectra. The full amplitude modulation is apparent only after three wave trains are recorded at a station. The combination R_1/R_3 is an unrealistic case but demonstrates that wave trains separated by a full great circle carry mode information (see also the caption in **Figure 4**). The seismograms were calculation with a mode summation code based on MINOS (see **Section 1.04.2.1**).

without this amplitude modulation. This peculiar behavior becomes clear when we discuss the representation of a surface wave seismogram on the spherical Earth.

Away from the poles, surface waves traveling on the spherical Earth can be expressed by

$$s(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}A_s(\omega)e^{-\alpha(\omega)t}\times e^{i(\omega t-k(\omega)x+(N-1)\pi/2+\Phi_s(\omega))}d\omega \quad [19]$$

where A_s is the source amplitude, $\exp(-\alpha(\omega)t)$ describes the attenuation along the path, Φ_s is the source phase, and $i(\omega t-kx)$ describes the evolution of the phase along the travel path. Brune et al. (1961) first described and experimentally verified that surface waves traveling on a sphere experience a $\pi/2$ phase shift each time the wave passes a pole. This is accounted for by the term $(N-1)\pi/2$, where N is the wave orbit number. The polar phase shift can be explained by the fact that eqn [16] is a good approximation only for distances $<180^\circ$ where the $P_\ell(\cos\Delta)$ are in phase with the cosines (**Figure 29**). For distances $180^\circ<\Delta<360^\circ$, this representation lags by a quarter of a wavelength, or $\pi/2$. Note that we ignore the scaling factor of eqn [16] in **Figure 29**. Including this factor provides a better match in amplitudes for a wider distance range away from 90°, but the factor is singular near the poles. From a traveling wave perspective, the poles are locations of caustics where an approaching surface wave from one direction is not defined (e.g., Romanowicz and Roult, 1986; Schwab and Kausel, 1976b; Wielandt, 1980). Using eqn [19], we can also understand how two wave trains that are separated by a complete great circle interfere to form standing waves. The contributions of the two wave trains to the seismogram are largest (constructive interference), when the phase difference between the two, $\delta\Psi(\omega)=-2\pi ak(\omega)+\pi$, is an integer multiple of 2π, that is, $\ell 2\pi$. This results in Jeans' formula.

The surface wave analog to measuring mode frequency shifts is the measurement of phase velocity, $c(\omega)=\omega/k$, which is achieved by measuring the phase, $\Psi=-kx$. Two principal hurdles impede a straightforward analysis. The first hurdle has to do with the time series in general. Surface wave packets are nonstationary and the phase changes rapidly with frequency. It is therefore not practical to extract accurate phase estimates using a simple periodogram technique. The second hurdle comes from the fact that we use the approximation in eqn [16], which is a high-ℓ asymptotic. Wielandt (1980) pointed out that, at a given frequency, Jeans' formula gives only an average wave number on a sphere, which changes with travel distance, so the phase velocity also changes. The measured phase velocity, which he termed 'dynamic phase velocity' (Wielandt, 1993), is the asymptotic one only at distance $\Delta=90^\circ$ but slower at shorter distances and faster at longer ones. The 'dynamic phase velocity' is attached to the wavefield (which includes the nonuniform amplitude on a spherical Earth; see **Figure 29**) and is not to be confused with the 'structural phase velocity' that we seek, which, in the case of a 1-D Earth, is the asymptotic phase velocity. Wielandt (1980) suggested to apply correction factors for waves that do not cross a pole. He estimated that ignoring such factors can amount to errors of 1%, which is of the same order of magnitude as phase perturbations caused by structure. This consideration is relevant only at extremely long periods beyond 300 s ($\ell\simeq 25$) where these factors become significant, given modern measurement errors. Schwab and Kausel (1976b) provided graphs of correction factors for Love waves for certain travel distances and earthquake source mechanisms. We prefer to measure phase perturbations with respect to a reference model by determining the transfer function between an observed and a mode synthetic seismogram. This implicitly reduces the variation of phase with frequency (hurdle 1). It accounts for the polar phase shift and source phase automatically and fully accounts for the approximation of eqn [16] (hurdle 2). A phase perturbation $\delta\Psi(\omega)/\Psi(\omega)$, caused by lateral heterogeneity, is then

$$\frac{\delta\Psi(\omega)}{\Psi(\omega)}=-\frac{1}{\Delta}\int_0^{\Delta}\frac{\delta c(\omega)}{c_0(\omega)}dx \quad [20]$$

where $\Psi(\omega)$ is the frequency-dependent phase accumulated along the perturbed travel path, Δ is the travel distance, and $c_0(\omega)$ is the frequency-dependent reference phase velocity. Equation [20] is correct to first order in lateral heterogeneity. Romanowicz (1987) and Pollitz (1994) calculated higher-order contributions that arise from gradients perpendicular to the great-circle path. Pollitz concluded that the second-order effect is insignificant in the determination of long-wavelength structure up to harmonic degree 12 (anomalies of scale 1500 km and larger). Ignoring higher-order contributions may cause a bias in phase velocity maps for structure significantly beyond harmonic degree 16 (anomalies smaller than 1200 km) though the impact of this on models obtained with large global data sets requires further investigation.

On a sphere, it is convenient to expand lateral heterogeneity in terms of surface spherical harmonics $Y_l^m(\theta,\phi)$ as a function of geographic coordinates θ and ϕ, so that $\delta c/c_0$ is

$$\frac{\delta c(\omega)}{c_0(\omega)}=\sum_{l=0}^{L_M}\sum_{m=-l}^{l}c_l^m(\omega)Y_l^m(\theta,\phi) \quad [21]$$

where the c_l^m are complex coefficients and L_M is the maximum harmonic degree to which lateral phase velocity variation (a 'phase velocity map') is expanded. Note that l and m here describe structure, while the ℓ and m in the modes section describe a normal mode.

Considering the parameterization of eqn [21], it is interesting to plot the integral kernels in eqn [20] to examine how phase perturbations depend on lateral heterogeneity. In **Figure 31**, we notice that sensitivity falls off with harmonic degree in structure though it is initially relatively high, for short travel distances. The sensitivity to even-degree structure decreases relative to odd-harmonic degrees, up to a travel distance of 180°, at the antipode of the source. Then sensitivity evens out up to 240° travel distance, which corresponds to R_2, the major arc wave train for an epicentral distance of 120°. After that, the relative sensitivity to odd harmonics falls below the sensitivity to even harmonic degrees, until it is zero at 360°, when a wave train completed a great circle. Recall that we had mentioned in the mode section that waves lose sensitivity to odd-degree structure as time goes on and that eqn [10] (Backus, 1964) shows that a complete great-circle integral over Y_l^ms has no sensitivity to odd-degree structure.

Phase velocity maps derived exclusively from great-circle data are equivalent to the mode splitting functions in

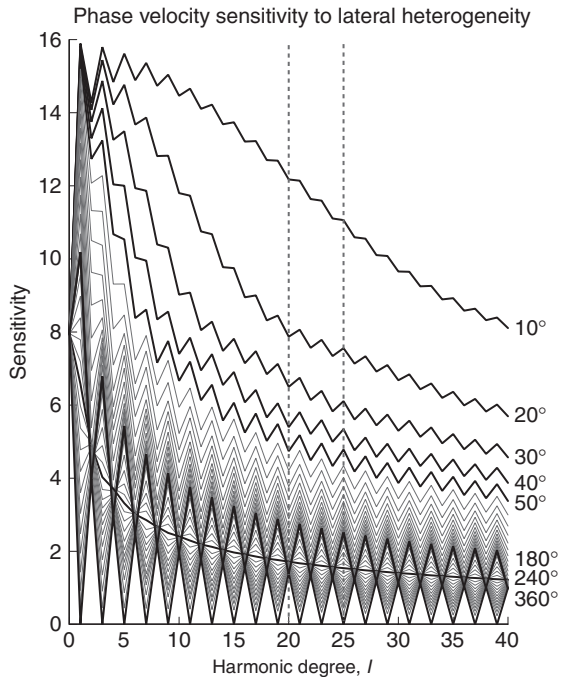

Figure 31 Phase sensitivity to lateral heterogeneity (integral kernel of eqn [20]), as function of harmonic degree in structure. Curves are shown for travel distances between 10° and 360°. Paths with distance <180° are for minor arc paths (R_1); larger distances are for major arc paths (R_2).

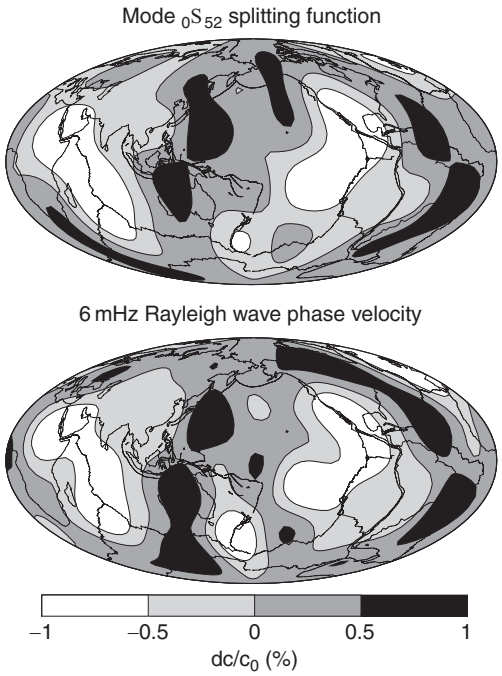

Figure 32 Comparison of effects of 3-D structure on standing waves (splitting function) and traveling waves (phase velocity map). The splitting function was converted to phase velocity perturbation using the conversion factor given by eqn [22]. Only even harmonic degrees are shown for the Rayleigh wave map to make it compatible with the splitting function of an isolated mode that is not sensitive to odd harmonics. Both maps are truncated at harmonic degree 8 (Laske and Masters, 1996).

eqn [9], except that phase velocity maps are measured at fixed frequency, ω, and splitting functions at fixed wave number, k (or ℓ). From the cyclic relation for partial differentiation (e.g., Riley et al., 2002),

$$\left(\frac{\partial\omega}{\partial m}\right)_k \cdot \left(\frac{\partial m}{\partial k}\right)_\omega \cdot \left(\frac{\partial k}{\partial \omega}\right)_m = -1$$

where m is a model parameter, we can derive a conversion factor between splitting functions and phase velocity maps,

$$\left(\frac{\delta\omega}{\omega}\right)_k = \frac{u}{c} \cdot \left(\frac{\delta c}{c}\right)_\omega \qquad [22]$$

where $c=\omega/k$ and $u=\partial\omega/\partial k$ are the phase velocity and group velocity (see next paragraph). An example of this relationship is shown in Figure 32 where both maps were obtained by inverting our standing and traveling wave observations. The patterns in the maps, caused by lateral heterogeneity within Earth, are quite similar visually, and the correlation between the maps is above the 99% confidence level (Laske and Masters, 1996). Small variations that are numerically barely significant may result from differences in the data sets and inversion schemes used. We can therefore convince ourselves that analyzing standing and traveling waves results in the same models of even-degree Earth structure.

The phase velocity is the speed at which a certain point in the wave train travels, while a certain point of the envelope (or the energy) travels with the group velocity (see Figure 36(b) for concept). Both together define the dispersion of surface waves, and a last comparison with modes is done here. In the mode section, we introduced the ω–ℓ dispersion diagram (Figure 16) that shows mode frequencies as a function of mode identifiers n and ℓ. Using Jeans' formula (eqn [17]), which is valid for $\ell \gg n$, this diagram implicitly summarizes the dispersion of surface waves (Figure 33). For most Rayleigh wave frequencies, we observe normal dispersion with $c>u$, or $dc/dk<0$. An exception is the range below 2 mHz, where we observe anomalous dispersion, $u>c$, or $dc/dk>0$. In the range of low-frequency modes below $\ell=25$, c/u increases until c is roughly 42% larger than u, and then it decreases. At frequencies above about 6 mHz, c/u approaches 1 and variations in local peak shift can be related directly to phase velocity variations. Group and phase velocities for Love waves are typically larger than those for Rayleigh waves at the same frequency, except above roughly 50 mHz when the Love wave group velocity drops off significantly for oceanic structure (see next section). Also, c/u starts to approach 1 at much lower frequencies than for Rayleigh waves.

1.04.3.2 The Measurement of Fundamental Mode Dispersion

For surface waves, dispersion is usually presented in frequency–velocity (or period–velocity) diagrams (Figures 34 and 35). Before we elaborate on measurement techniques, we briefly summarize some early observations of surface wave

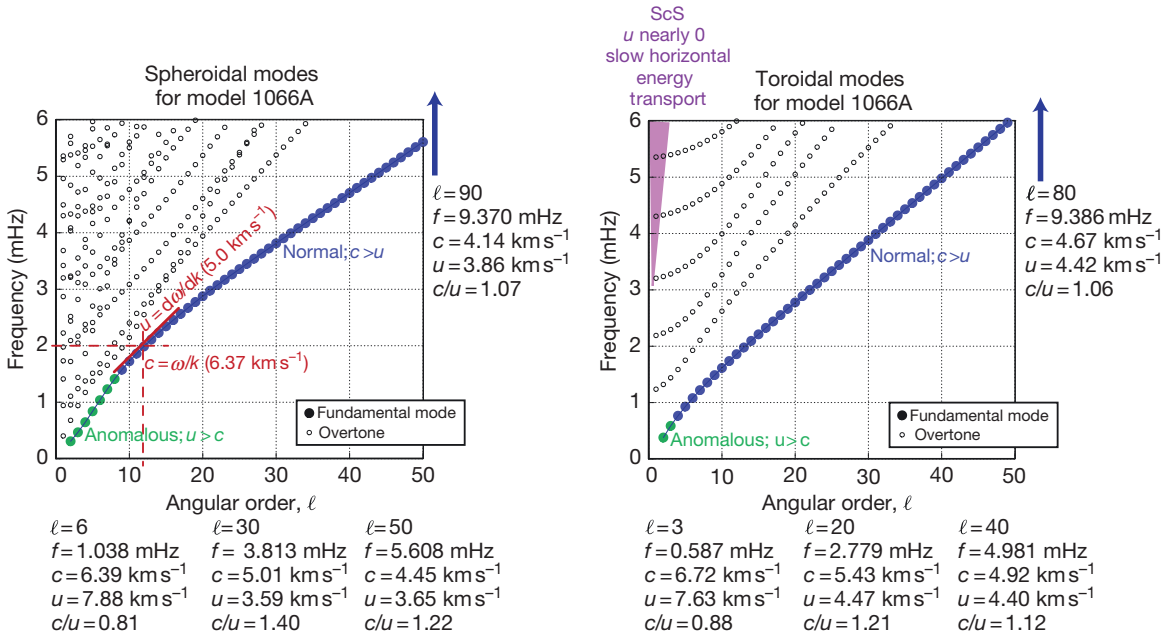

Figure 33 Dispersion diagram (ω–ℓ plot) for spheroidal and toroidal modes for model 1066A of Gilbert and Dziewonski (1975). Red lettering describes the concept of phase (c) and group (u) velocity for mode ${}_0S_{12}$. Blue symbols mark fundamental modes with normal dispersion ($u < c$), while green symbols mark modes with anomalous dispersion ($u > c$). The purple area marks the location of ScS equivalent modes whose group velocity is nearly zero. The scalar c/u is used to convert splitting functions to phase velocity maps (see **Figure 32**; eqn [22]).

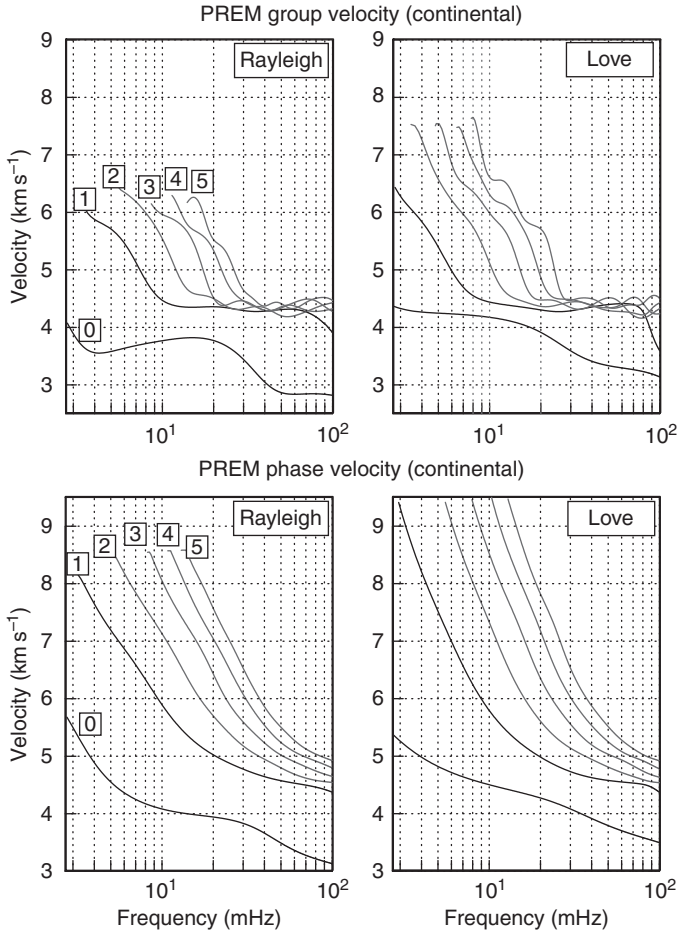

Figure 34 Group and phase velocity curves for isotropic PREM (Dziewonski and Anderson, 1981) with a 39 km thick continental crust. Shown are the fundamental modes (label 0) and the first five overtones (labels 1–5). Phase velocities span a greater range than group velocities. Overtones have nearly the same group velocities above 30 mHz (periods shorter than 33 s). For clarity of the diagrams, dispersion for IC modes and ScS equivalent modes at long periods are not shown.

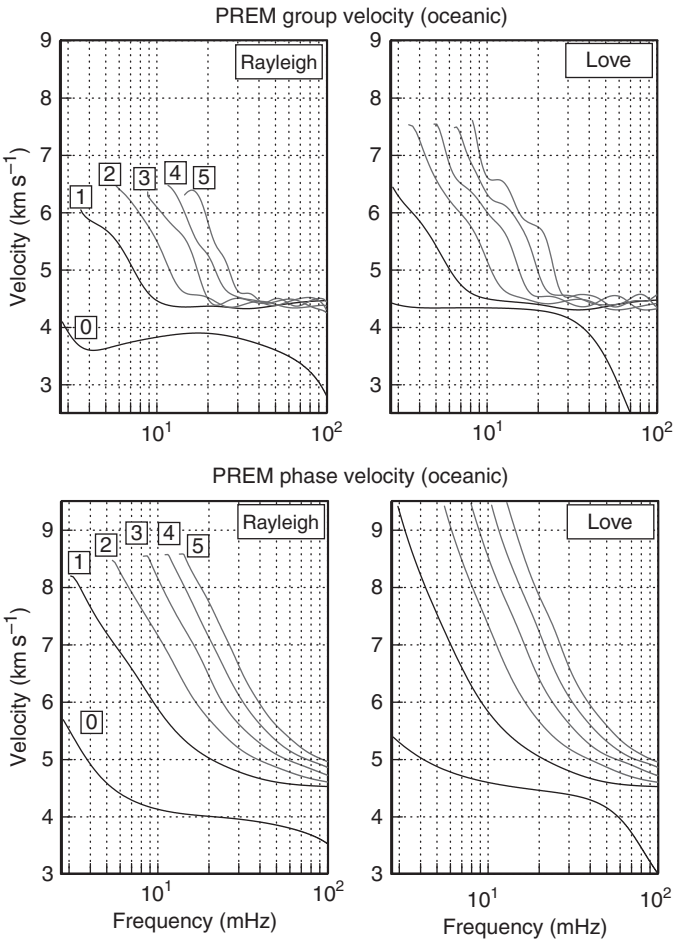

Figure 35 Group and phase velocity curves for isotropic PREM with a 7 km thick crystalline oceanic crust, overlain by 5 km of sediments (no water layer). Shown are the fundamental modes (label 0) and the first five overtones (labels 1–5). Phase velocities span a greater range than group velocities. Overtones have nearly the same group velocities above 30 mHz (periods shorter than 33 s). Love wave fundamental modes have similar group velocities as overtones between 10 and 20 mHz. For clarity of the diagrams, dispersion for IC modes and ScS equivalent modes at long periods is not shown.

dispersion. Probably one of the most well-known and subsequently most-cited summaries of early observed dispersion curves for both group and phase velocities is that of Oliver (1962) who published curves for both Love and Rayleigh wave fundamental modes and the first two overtones, for oceanic and continental paths. Oliver (1962) summarized results in a wide frequency range (corresponding to periods between 1 h and 1 s). At the time, overtone phase velocities remained largely unobserved. The summary was mainly based on the observations by Maurice Ewing and his group at LDEO, then the Lamont Geological Observatory, but the observation of Rayleigh wave dispersion goes back to at least the 1930s (e.g., Carder, 1934, for oceanic paths; Röhrbach, 1932; Gutenberg and Richter, 1936, for continental paths). Ewing and Press (1954, 1956) collected long-period Rayleigh wave group velocities between 10 and 500 s. They observed a significant difference in dispersion for continental and oceanic paths at periods shorter than roughly 75 s and attributed dispersion at longer periods to be influenced primarily by structure in the mantle. Subsequently, surface waves at periods 75 s and longer were called mantle waves, which is still used today (e.g., Ekström et al., 1997). Ewing and Press remarked that the dispersion of oceanic paths is strongly influenced by the presence of a water layer (e.g., Ewing and Press, 1952, and also Berckhemer, 1956). It was observed that, due to the steep dispersion at periods shorter than 20 s, oceanic Rayleigh wave packets are far more stretched out than continental Rayleigh waves. The latter required long travel paths to resolve details in the dispersion curve. Short-period dispersion of the first 'shear mode' (overtone) was first observed by Oliver and Ewing (1958), for paths traversing the deep ocean after a nuclear explosion in 1955, about 700 km off the coast of Southern California (Operation Wigwam). The wave trains appeared unusually complicated but also gave seismologists a chance to observe oceanic dispersion for the first time at periods shorter than 15 s. Oceanic short-period overtone signals are usually hard to observe in teleseismic records due to the dominance of swell-generated microseism noise. The Wigwam records also revealed, for the first time, the slow Airy phase (waves with stationary group velocities; Pekeris, 1946) at around 7 s for oceanic paths.

Love wave dispersion is usually more difficult to measure than that of Rayleigh waves because the process involves the analysis of the typically noisier horizontal seismometer components. Also, long-period Love waves have similar group velocities over a wide frequency band, especially in the oceans (see **Figure 35**). This often makes Love waves to appear pulse-like, which hampered early dispersion measurements before the computer era. Nevertheless, Love wave dispersion measurements go back to at least the 1940s (e.g., Wilson, 1940). **Figures 34** and **35** give a summary of the expected dispersion curves for fundamental mode Rayleigh and Love waves and their first five overtones. The curves are shown for isotropic PREM and both continental crust and oceanic crust. At frequencies above 10 mHz, variations in crustal structure have a significant effect on dispersion. Throughout a wide range in frequency, Rayleigh wave fundamental mode group velocity curves are fairly isolated from overtones, which allows easy dispersion measurement. This is not the case for overtones that overlap at frequencies above 15 mHz. Sophisticated 'tuning' techniques, such as array stacking, are then necessary to assess individual overtone dispersion (see **Section 1.04.3.4**). Also note that the first overtone branch overlaps with the Love wave fundamental mode branch between 10 and 30 mHz, for oceanic paths. Ignoring possible interference effects may lead to biased Love wave dispersion data, which is revisited in a later section.

For Rayleigh waves, we observe two Airy phases for which group velocity does not change much with frequency (**Figures 34** and **35**). One is near 4 mHz, and the other one is near 20 mHz. Between 4 and 20 mHz, the group velocity dispersion is inverse. The condition $du/dk < 0$ implies that modes with higher ℓ, hence higher frequency, are faster than modes with lower ℓ (compare also with **Figure 33**). This can be seen in the low-pass-filtered seismogram in **Figure 2**. Below 4 mHz and above 20 mHz, we observe regular dispersion with $du/dk > 0$ (low-ℓ modes are faster). This can be seen in **Figure 36** that shows Rayleigh wave seismograms between 20 and 50 mHz in an oceanic setting. The figure also emphasizes that modern ocean bottom seismic instrumentation allows us to observe long-period surface waves on the ocean floor to an unprecedented signal level. Depending on crustal structure, a third Airy phase may be observed for Rayleigh waves near 50 mHz. For Love waves, group velocities are very similar over a large range in frequency. In oceanic settings in particular, the dispersion is very weak between 4 and 20 mHz, so that Love wave trains usually appear quite pulse-like.

The first attempts to take a general regionalization of surface wave dispersion beyond a distinction between continents and oceans go back to Toksöz and Anderson (1966) who decomposed composite-path great-circle data into those of 'pure-path' oceanic, shield, and mountain-tectonic regions. They analyzed records of the great Good Friday 1964 Alaska earthquake (28 March 1964) at stations Isabella, California (later station ISA of the TERRAscope Network), Kipapa, Hawaii (later station KIP of the IDA, GSN, and GEOSCOPE networks), and Stuttgart, Germany (later station STU of the GEOFON network). Kanamori (1970) analyzed many more records of this event ($M = 8.5$ as reported by Kanamori) and another great

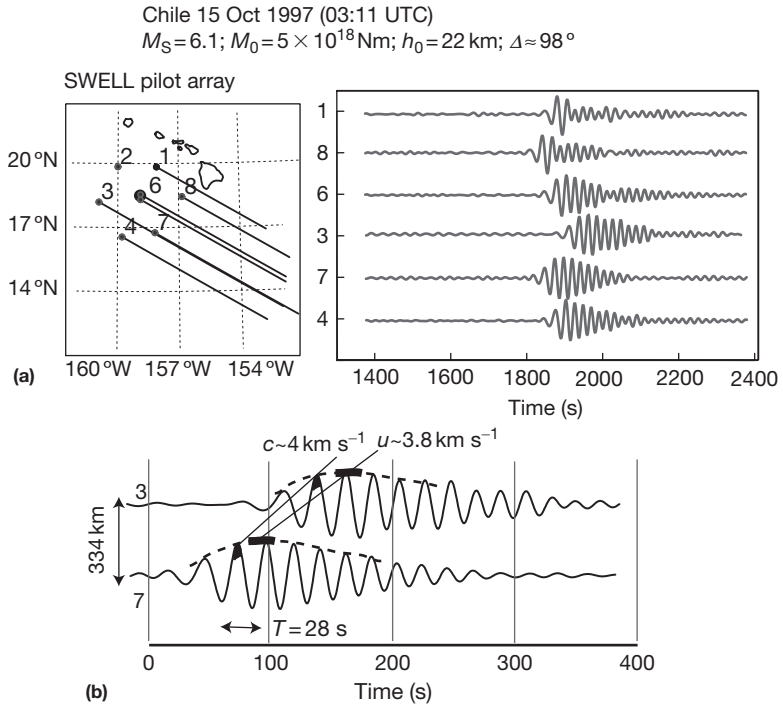

Figure 36 (a) Seismograms recorded on ocean bottom differential pressure sensors during the 97/98 SWELL Pilot Deployment southwest of Hawaii (Laske et al., 1998). The recorded frequencies range from 20 to 50 mHz. The waveforms exhibit regular dispersion, that is, low frequencies arrive earlier than higher frequencies. (b) Schematic concept of phase (c) and group (u) velocities along two-station leg 7-3.

earthquake in the Kuril Islands region (13 October 1963; $M = 8.3$), and a supplement of earlier published data. Apart from phase and group velocity, he also measured great-circle attenuation but did not interpret the latter further. Dziewonski (1970) analyzed phase and group velocity for the 15 August 1963 Peru earthquake (the same earthquake that provided mode data for Earth model 1066A by Gilbert and Dziewonski, 1975) though phase velocities were derived from mode observations. This chapter also showed, for the first time, that world-circling measured phase and group velocities are mutually consistent. Knopoff (1972) first provided a more detailed discussion of surface wave dispersion in different tectonic regions.

Early measurements of surface wave dispersion were extended to frequencies much below 4 mHz. For example, the analysis of Ewing and Press (1956) extended to 2 mHz and that of Toksöz and Anderson (1966) extended even to 1.5 mHz. At such long periods, Coriolis coupling between Rayleigh and Love waves becomes considerable (see **Figure 13**) so that Love waves appear on the vertical seismometer component as so-called quasi-Love waves (e.g., Levin and Park, 1998). Backus (1962) discussed the effects of a rotating Earth on the propagation path of very long-period surface waves. While Love wave paths remain largely unaffected, Rayleigh wave great-circle paths precess about Earth's axis of rotation, effectively lengthening the travel path. Dispersion estimations that assume the direct great-circle path are then biased low. While early measurements were not precise enough for this effect to be significant, modern observations probably need to be corrected for this effect, which depends on Earth's 1-D structure much like the spheroidal–toroidal mode coupling does.

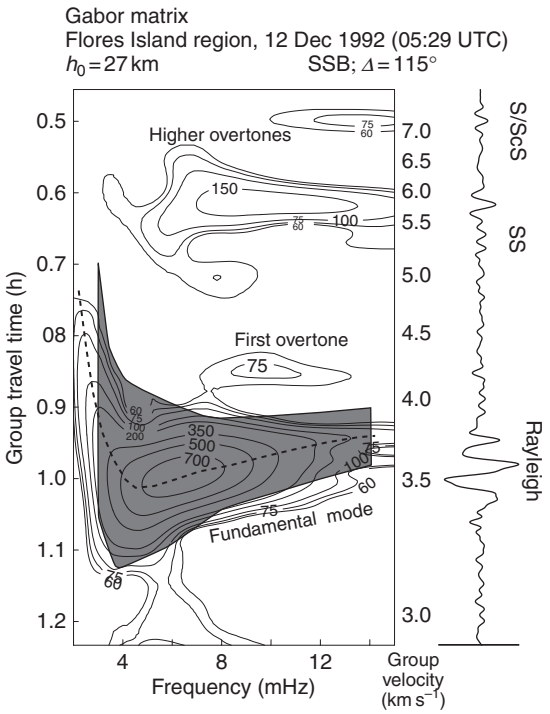

Figure 37 Visualization of a Gabor matrix for the seismogram in **Figure 2**. Amplitudes in the matrix are normalized to optimize the display. The largest signal is the fundamental mode that exhibits dispersion (see **Figure 34**) where the dashed line marks the group velocity an analyst would choose. A combination of overtones arrives before the Rayleigh wave. The gray area marks the time–frequency range used in a time-variable filtering approach to isolate the fundamental mode.

1.04.3.2.1 Group velocity

In the precomputer era, surface wave group velocity was measured using the peak-and-trough method (e.g., Ewing and Press, 1954; Ewing et al., 1957). In a paper record, each peak, trough, and zero was numbered and plotted against recorded time. The slope of this curve gives the period as a function of travel time, from which the group velocity can be computed. This technique can be applied on well-dispersed signals but fails near Airy phases and for most Love waves because the waveforms are compressed. Even for the well-dispersed case, measurement errors are rarely better than 0.2 kms^{-1}, or about 6.5%. Since the late 1960s, when computers and the fast Fourier transform by Cooley and Tukey (1965) facilitated quick and comprehensive harmonic analyses, group velocity has been measured in the time–frequency domain. The most basic approach is the 'moving window analysis' (Landisman et al., 1969). A sliding window is applied to a time series, and the spectrum for each increment is tabulated in a time–frequency matrix, often called a Gabor matrix after Hungarian physicist Dennis Gabor (Gabor, 1947). Such a diagram is also called energy diagram (when amplitude squared is plotted) or, when the travel time is converted to velocity, a vespagram. **Figure 37** shows the Gabor matrix for the 1992 Flores Island region record at station SSB (see **Figure 2**). The group velocity is then determined by tracing the ridge with the highest amplitudes in the 2-D plot. This approach has seen wide use in a number of applications that deal with nonstationary signals and is still used today, for example, in the study of ocean swell-generated signal in the microseism band (between 20 and 4 s) that is caused by approaching large storm systems (e.g., Bromirski and Duennebier, 2002).

When measuring dispersion, one has to be aware of the resolution limits in the Gabor matrix imposed by the Schwarz inequality (Gabor, 1947), where the smallest frequency separation, Δf, and the length of the sliding window, T, must satisfy $\Delta f \bullet T \geq 1$. For example, if the moving window is 1000 s long, the frequency resolution is not better than 1 mHz. To obtain the same relative resolution $\Delta f/f$ in the Gabor matrix, the sliding window can be made proportional to the period investigated, where the window length is usually four to eight times the period. Since this entails the separate calculation of a certain harmonic coefficient for each element in the Gabor matrix, this was sometimes prohibitively inefficient in the early days of computing. A quicker method is the multiple filtering technique (described in Dziewonski et al., 1969) that starts with the spectrum of a complete time series. A Gaussian filter is centered on a certain target frequency. The analytic signal, which provides the envelope function of the corresponding time series, is then determined for this frequency using the spectrum for positive frequencies only. Instead of just one element in the Gabor matrix, the envelope function now composes a whole column.

Measuring group velocity requires either interactive picking or a sophisticated routine that recognizes which ridge to pick. A widely used application in regional studies is the FTAN

(frequency–time analysis) package by Levshin et al. (1972) (see also Levshin et al., 1989). FTAN is similar to earlier multiple filtering methods except that FTAN uses an efficient folding algorithm to determine the complex time–frequency array from which the Gabor matrix is estimated. This allows the extraction of phase velocity as well. Signal enhancement in the Gabor matrix can also be achieved by the logarithmic stacking of several events in the group velocity-period domain (Shapiro et al., 1997). Modern techniques allow us to measure group velocity with an error that is usually much less than 0.1 km s^{-1}, or about 3.2%. The measurement of group velocity is advantageous over that of phase because many phase measurement applications require the knowledge of the source process (see eqn [19]). Group velocity observations are largely unaffected by source processes, which makes this approach very attractive in regional studies where earthquakes are typically small. For events deeper than about 25 km, the source may affect group travel times at long periods beyond 100 s though the bias is usually not significant, that is, smaller than the measurement error (Levshin et al., 1999).

Group velocities picked from the Gabor matrix can be biased, as first discussed by Dziewonski et al. (1972). As seen in **Figure 30**, the spectral amplitude for the first wave train increases with frequency. In this case, group velocity estimates from periodograms are biased toward high-frequency values. Changes in the spectral amplitude may be particularly large when dispersion is strong, which is the case for frequencies below 4 mHz. A similar bias occurs when phase velocities are estimated from the phase of the complex analysis of the Gabor matrix. Dziewonski et al. (1972) suggested to deconvolve the time series with a synthetic seismogram before measuring the much less pronounced 'residual dispersion.' There have also been developments to improve the multiple filtering technique itself. Wielandt and Schenk (1983) provided a formalism to correct the bias in phase velocity estimates to within 0.1%. A more recent reference is that of Shapiro and Singh (1999) who suggested to use a centroid frequency of the filtered spectrum rather than the center frequency of the Gaussian filter to tabulate the Gabor matrix.

1.04.3.2.2 The study of ambient noise

The determination of group velocity using ambient noise has become tremendously popular in recent years. Although many ambient noise studies are limited to the microseism band between 20 and 3 s, these studies may provide valuable dispersion data where inadequate earthquake distribution does not allow an analysis otherwise. Microseisms are generated by linear and nonlinear interaction of wind-generated ocean swell with itself and with the seafloor and the coast (see also **Chapter 1.12**). The most dominant microseism signal, at a period typically near 5 s, is generated when waves approaching from opposing directions interact nonlinearly to form standing waves in the water column (Longuet-Higgins, 1950). The resulting Rayleigh waves, which are excited continuously but incoherently, can be observed even in continental interiors. With the aid of a network, the dispersion of microseisms can be extracted to constrain local crustal structure (e.g., Sabra et al., 2005a; Shapiro et al., 2005). In essence, a cross correlation technique is applied to station pairs in an array to extract empirical Green's functions (e.g., Sabra et al., 2005b; Shapiro and Campillo, 2004). Without doubt, this technique has become so attractive because ocean noise is observed everywhere on the planet, and two-station Green's functions are more readily extractable using noise than waves from single earthquakes that have to align with the two-station great circle. It appears that time series collected over just 1 month are capable of providing high-resolution images of Earth structure (Shapiro et al., 2005).

The study of ambient noise to extract Earth structure has also been applied to seismic stations on the ocean floor (e.g., Harmon et al., 2007). Even observations of phase velocity that inherently require more sophisticated measurement techniques than group velocity have appeared in the literature (e.g., Bensen et al., 2007; Harmon et al., 2007). Phase velocity results based on cross correlation are reported to be in good agreement with those obtained with beamforming (Harmon et al., 2008). The recent advances in ambient noise include the analysis of overtones (e.g., Harmon et al., 2007) and Love waves (e.g., Lin et al., 2008). In some areas, such as Europe, ambient noise group velocity constraints appear to be quite compatible with or even superior to those from earthquake data as the former appear to be more internally consistent (Yang et al., 2007).

In principle, the analysis of ambient noise can be extended to longer periods though noise levels are considerably lower than in the microseism band. At periods longer than 100 s, the interaction of infragravity waves with the ocean floor and the continental slopes is thought to generate infragravity noise (e.g., Tanimoto, 2005; Webb, 1998). Shapiro and Campillo (2004) found that broadband dispersion information can be extracted from two-station ambient noise cross correlation records, to periods up to at least 100 s.

A precondition for ambient noise analyses to yield unbiased dispersion data is that the source distribution is isotropic, that is, the microseisms have to approach the array from all directions, which may not always be the case. For example, Schulte-Pelkum et al. (2004) found preferential directions of approach at the ANZA Seismic network in Southern California. Strong source directivity was also found in Europe (Essen et al., 2003). Such source directivity is most obviously coupled to the seasonal return of large winter storms (e.g., Hiller et al., 2012) that may even be responsible for Earth's hum (e.g., Kurrle and Widmer-Schnidrig, 2010; Rhie and Romanowicz, 2004, 2006). Uneven source distribution can result in phase velocity estimates that are biased high by up to 1%, which can map into seismic 3-D structure in tomographic images on the order of a few percent (Yang et al., 2008; Yao et al., 2006). For Southern California, Harmon et al. (2010) estimated the bias on isotropic phase velocity as a result of uneven source distribution to be +0.2% at a period of 25 s, at the same time mimicking an apparent azimuthal anisotropy of up to 1%. These effects can potentially be accounted for by performing a source density analysis. It seems that a year's amount of ambient noise data that spans a time frame long enough to include effects from seasonal variations, coupled with robust cross correlation techniques, should deliver reliable results (e.g., Bensen et al., 2007). For further details about noise correlations, see **Chapter 1.12**.

1.04.3.2.3 Phase velocity

Unlike group travel times, the phase explicitly includes a source term (see eqn [19]). Measuring phase between a source and receiver therefore requires accurate knowledge of the

seismic source. The measurement of phase velocities without spectral analysis requires the comparison of at least two waveforms, for example, from seismograms of neighboring stations that share a great circle with the source (two-station method, e.g., Brune and Dorman, 1963). Using a one-station approach, Nafe and Brune (1960) first measured complete great-circle phase velocity for the 15 August 1960 Assam earthquake at station PAS (Pasadena, California) with errors $<1\%$. Ten years later, the observation of phase velocity on a global scale was still in its infancy when Kanamori (1970) reported surface wave great-circle phase velocity observations for surface wave packets separated by a complete great-circle orbit, while others preferred to derive phase velocities from mode observations (Dziewonski, 1970; Dziewonski and Landisman, 1970).

The phase of a surface wave packet changes very rapidly with frequency, and its 2π-ambiguity almost never allows us to measure phase between source and receiver directly from a single waveform. Early works suggested that in the two-station approach, phase estimated from a cross correlogram of the two seismograms yields more stable estimates than from phase differences (Landisman et al., 1969). Before we elaborate on our own measurement technique on the global scale, we briefly review advances in regional studies. For dense arrays where the station spacing is on the order of the signal wavelength, individual peaks or troughs can be followed across the array and phase velocities can be measured as function of period. Some of the earliest such measurements of phase velocity, for periods <1 s, can be found in the oil exploration literature (e.g., Dobrin et al., 1951). For crustal or mantle studies, seismic arrays are typically sparse. Press (1956, 1957) used the triangulation or tripartite method to determine crustal structure in California from average phase velocities. But the use of the method goes back further (e.g., Evernden, 1953, 1954) and was also used to retrace hurricane tracks with seismic data (e.g., Donn and Blaik, 1953). In fact, the tripartite method was first used by Milne, and the interested reader is referred to Evernden (1953) for a brief review of early applications. In the studies of the 1950s, only few earthquakes were used for a particular station triangle, and measurement errors were on the order of 0.1 km s^{-1} (3%) or less. The technique assumes that plane waves approach a station triangle, whose aperture could reach several 100 km (e.g., Knopoff et al., 1966). These authors found that even though the method allows for an arbitrary arrival angle of the approaching wave, it yields biased results unless the wave propagation direction is aligned with one of the network legs. Knopoff et al. (1967) later found the two-station method to be superior to the tripartite method to minimize errors in phase shifts in the presence of lateral heterogeneity. Schwab and Kausel (1976a) suggested to expand the recording array to at least four stations and allow the consideration of curved wavefronts. In essence, in an optimization process, waveforms are matched to be in phase to form a single beam (beamforming). This is an approach that can still be found in the literature to determine the average structure beneath a recording array (e.g., Alsina and Snieder, 1993; Stange and Friederich, 1993). The preposition here is that incoming wavefronts are uniform and distortion of the wavefronts within the array due to heterogeneous structure is insignificant though this may not be the case (Wielandt, 1993).

Numerous studies followed, and the two-station method is still used today to retrieve regional and local structure, often along only one particular two-station path. A recent example of using the multiple filtering technique on a cross correlogram in the two-station case (between two real seismograms) is that of Meier et al. (2004) who studied Rayleigh wave phase velocity in the Eastern Mediterranean. It can be argued that phase velocities estimated with the two-station technique are systematically biased high when waves do not approach a station along the great circle, which is to be expected particularly in the analysis of teleseismic events. In our global studies, we have found that lateral refraction caused by heterogeneity in the mantle can change the direction of approach at a station by as much as 20°. The deviation of an arriving wave packet away from the great-circle direction effectively shortens the travel path. For a regional study that uses teleseismic earthquakes, the bias in the estimated phase velocity for a single travel path can therefore be as large as 6.4%. The bias on local or regional phase velocity can be reduced when many crossing paths are considered, but the estimates will remain biased high, unless the phase estimates are corrected for off-great-circle approach.

Another problem arises from multipathing when wave packets get refracted away from the great circle and then travel along multiple paths and interfere at the recording station upon arrival. Multipathing was detected in the early study of Evernden (1953) for surface waves traveling along the west coast of North America. Wavefronts get bent in complex structures and the plane wave approach is no longer valid. For example, waves get bent around an enclosed low-velocity anomaly so that the sides of a plane wave advance. In the extreme case, wavefront healing occurs when the wave travels long enough and 'forgets' that it passed this structure (Wielandt, 1987). To illustrate the gravity of the problem, one of the most remarkable examples of the controversy over the two-station method is probably that of Woods et al. (1991) along the Hawaiian Islands chain. They could not find a low-velocity anomaly associated with the proposed reheating of the Pacific plate by the Hawaiian hot spot and therefore argued against the plate reheating concept. On the other hand, Maupin (1992) argued that complex wave propagation along a relatively narrow low-velocity anomaly inhibits the application of the two-station approach for a single two-station path. Pedersen (2006) estimated that bias from ignoring the nonplane geometry of the incoming wavefield can be reduced to 1% in the two-station method for 200 km profiles, if at least ten earthquakes with different hypocenters are analyzed. This may be achieved for permanent station installations but is often difficult to achieve for temporary deployments that typically last less than 2 years. The unbiased recovery of structure within an array in the case of nonplane waves approaching the array requires the analysis of both phase and amplitude (Friederich et al., 1994; Wielandt, 1993). Friederich et al. (2000) demonstrated that even though seismic surface waves propagating in a laterally heterogeneous half-space do not obey the Helmholtz equation, using the latter still gives much improved tomographic images over the usually applied eikonal equation. Of course, such an approach is only possible when data from dense arrays are available. Forsyth and Li (2005) proposed a simplified technique that fits two approaching plane waves to the observed phase measurements of an array. More recently, Mike Ritzwoller's group applied Helmholtz tomography (Lin and Ritzwoller, 2011) to the data from

the dense USArray and produced high-resolution dispersion maps of the Western United States with stunning details (e.g., Lin et al., 2011).

For our global studies, we measure phase relative to a synthetic seismogram. In the simplest case, this can be a synthetic computed for a spherical Earth (e.g., Laske and Masters, 1996). We measure the transfer function between the observed and a synthetic fundamental mode waveform that is calculated for Earth model 1066A (Gilbert and Dziewonski, 1975). An early example of the transfer function technique measuring great-circle dispersion and attenuation can be found in Dziewonski and Steim (1982). A multitaper approach provides an optimal compromise between frequency resolution and resistance to bias from noise in the time series. The multitaper approach also allows us to assign measurement errors in a statistical sense. The analysis is done interactively on the computer screen where we choose the optimal time window to isolate the fundamental mode. An example is shown in **Figure 38**. Other workers choose automated approaches (e.g., Trampert and Woodhouse, 1995). These approaches take significantly less time but may either produce a noisy data set or quality control restrictions yield a significantly reduced data set, compared to our hand-picked one. Measured phase perturbations typically amount to a few percent, and measurement errors are 0.15% on average for R_1, while measurement errors in R_2 and great-circle data are somewhat smaller. Even though we measure phase with respect to a synthetic, some of our short-period data are 2π-phase-ambiguous. At short periods, the phase ambiguity is enhanced by the fact that small perturbations to a model may cause many 2π-phase wraps. The phase ambiguity can be removed by the condition that the phase has to vary smoothly with frequency. Since we observe no phase ambiguity at 4 mHz, our phase data set is unique, for the frequency range chosen in our global study (4–17 mHz). We usually need only one iteration to determine the transfer function, but occasionally, the great difference between data and synthetic requires one or two additional iterations (see **Figure 38**). Nevertheless, our 'one-step' spectral approach does not allow us to go much beyond 20 mHz. An alternative approach to obtain unbiased estimates in a wider frequency range is that of Ekström et al. (1997) who determined phase perturbation in several passbands rather than just one. As in our approach, they use synthetic seismograms in a phase-matched filtering procedure. The process is iterated to minimize residual dispersion and to suppress interference from overtones. They succeeded to collect an impressive global data set between 150 and 35 s. With 50 000 high-quality dispersion curves, their data set was the largest at the time, and their data and phase velocity maps have been used subsequently by many other workers either in their own global studies or to calibrate regional crustal models (e.g., Yang et al., 2004). An update of Ekström's data set, phase and group velocity maps, and programs to evaluate the maps are described and provided in Ekström (2011).

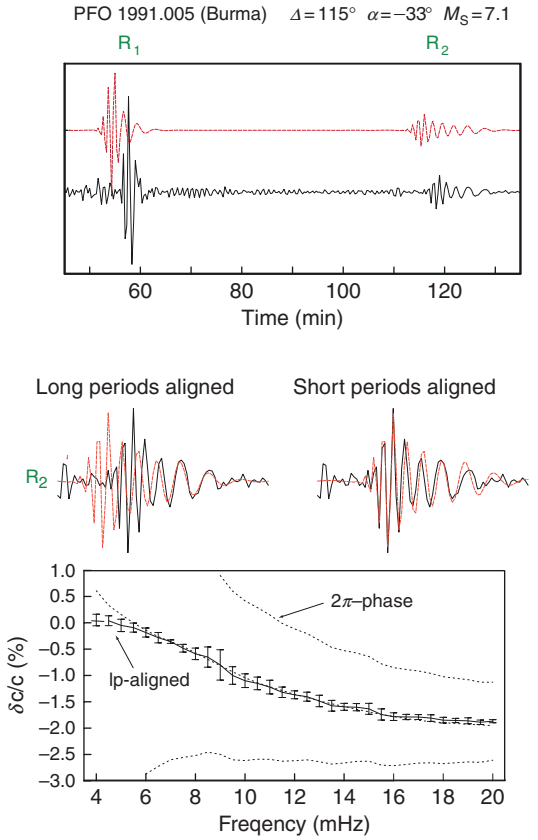

Figure 38 Example of our interactive phase measurement procedure in which the transfer function between an observed seismogram and a synthetic is retrieved. A seismogram at station PFO (Piñon Flat Observatory, California) is compared to a fundamental mode synthetic. The example is extreme in that the transfer function has to be determined iteratively, due to the large difference between observed and synthetic waveforms. The bottom panel shows the resulting path-averaged phase velocity perturbation. The dashed line in the middle marks the results when the waveforms are aligned on the short periods. Also shown are the results when 2π are subtracted or added to the phase (upper and lower dashed lines).

1.04.3.2.4 Time-variable filtering

Time-variable filtering (TVF) was proposed to stabilize fundamental mode surface wave dispersion estimation when waveforms appear contaminated. Interference effects from other mode branches, multipathing, or other concurrent signals are the most likely causes. Arguably, one should probably refrain entirely from analyzing such contaminated waveforms. This may be feasible in global low-frequency seismology below 20 mHz, where large waveform collections are available. However, in regional studies using temporary networks, in monitoring efforts of the CTBT or to study the dispersion at shorter periods, this may not be possible. Aside from TVF, various techniques are available to extract a primary signal from a time series. Herrin and Goforth (1977) applied phase-matched filters (PMFs) to Rayleigh waves of an earthquake and a nuclear explosion. In this process, a time series is matched to a synthetic by iteratively windowing a narrow-band-filtered correlation function between the two to eliminate interfering signals. PMF makes no assumptions about the time–frequency structure of the interfering signals in a seismogram. TVF takes into account the dispersion. The idea behind TVF is that different signals may arrive at the recording station at the same time but the frequency content and group velocities are sufficiently different that the signal to be studied can be isolated by time–frequency filtering. For example, the Gabor matrix in

Figure 37 shows the fundamental mode as the largest signal, but at the same time as the very low-frequency fundamental mode reaches the station, the first overtone, with frequencies around 10 mHz, also comes in. A time–frequency filter that enhances the signal below 3 mHz at this time but then enhances 10-mHz signals at a later time significantly reduces the biasing effects of a single window covering the whole time series. Pilant and Knopoff (1964) first applied TVF to separate the seismic signal from two different earthquakes that arrived at a station nearly at the same time and therefore created a beating pattern in the waveform. Since then, the method has been applied to investigate structure of the crust and upper mantle (e.g., Knopoff et al., 1966). TVF is also included in the FTAN package of Levshin et al. (1989) in a second iteration to improve measurement precision. A technique that combines PMF with TVF is the frequency variable filtering of Russell et al. (1988) to reduce spectral amplitude biasing introduced by frequency domain filtering.

Technical details of the TVF approach are described in Landisman et al. (1969). The filtering can be done either in the time or the frequency domain. In the latter, the starting point is the spectrum of the original time series. Each harmonic coefficient is multiplied by a function that has a certain shape in the time domain. Landisman et al. (1969) suggested a cosine taper with

$$w(t) = \begin{cases} \cos\left(\dfrac{\pi(t - t_n(\omega))}{2L(\omega)}\right), & \text{for } t_n - L \le t \le t_n + L \\ 0 & \text{else} \end{cases}$$

where

$$L(\omega) = T(\alpha + \beta|\mathrm{d}u(T)/\mathrm{d}T|)$$

$L(\omega)$ is the window length in the time domain, $T = 2\pi/\omega$, and $t_n(\omega)$ is the center group travel time. Other workers refined the filtering to optimize the trade-off between interference from unwanted signals and loss of energy for the signal analyzed (e.g., Cara, 1973; Roult, 1974). At frequencies with strong dispersion, TVF should probably be applied with caution to avoid biased estimates, if $t_n(\omega)$ are the predictions of a model.

The technique has also found application in normal mode studies (e.g., Jobert and Roult, 1976; Roult and Romanowicz, 1984; Roult et al., 1990). Our own experience is that the technique works best for seismograms with epicentral distances far away from 90° (Koptschalitsch, 1988). For epicentral distances near 90°, the close temporal succession of overtones and fundamental modes does not allow an effective suppression of overtones without significantly affecting fundamental mode frequencies by several microhertz and Q by up to 20%. A topic of research still is why mean attenuation estimates for surface waves below 5 mHz often disagree significantly with those obtained from mode studies. Durek and Ekström (1996) suggested that noise contamination in the much longer normal mode seismograms can bias Q estimates high. Roult and Clévédé (2000) improved their time-lapse technique to obtain more accurate mode Q data that are in agreement with those of others though the discrepancy to surface wave Q remains. Our own unpublished experiments lead us to speculate that overtone interference may significantly bias mode Q estimate high, particularly for toroidal modes (Masters and Laske, 1997). Some of this can be removed by TVF. On the other hand, some published surface wave-derived Q values may be biased low as our own surface wave results agree well with the mode Q values. Figures can be found on the REM web page. For a more detailed discussion, see also Chapter 1.01.

1.04.3.3 Other Surface Wave Observables

Surface waves can be deflected significantly from the source–receiver great circle by lateral refraction in a heterogeneous medium. Evernden (1953, 1954) was among the first to observe this phenomenon at long periods. Capon (1970) observed off-great-circle propagation also at short periods (20–40 s) and found that refraction and reflection of wave packets at continental margins were responsible for this. Lateral refraction has also been observed by a large group of other workers and array techniques, such as the tripartite method of Press (1956) or comprehensive modifications thereof (e.g., Stange and Friederich, 1993), have been used to obtain unbiased dispersion estimates. In essence, incoming wavefronts are fitted simultaneously to the phase data of all stations in an array, where phase velocity and angle of approach are free parameters to search for. In regional studies that search for structure within an array, these arrival angles are discarded, but they can serve as additional constraint on structure along the travel path. Woodhouse and Wong (1986) developed the elegant linearized path integral approximation (PIA) to relate arrival angles to lateral heterogeneity. Similar to the integral in eqn [20], we can relate the tangent of the observed arrival angle, $v = \tan\Theta$, to the phase velocity anomalies along the source–receiver great circle

$$v(\Delta) \simeq -\mathrm{cosec}(\Delta)\int_0^{\Delta} \sin\phi \frac{\partial}{\partial\theta}\left[\frac{\delta c(\pi/2,\phi)}{c_0}\right]\mathrm{d}\phi \qquad [23]$$

where the great circle has been rotated onto the equator, the source is at $\phi = 0$, the receiver is at distance Δ, and θ is the colatitude. A similar expression exists for the amplitude

$$\ln A \simeq \frac{1}{2}\mathrm{cosec}(\Delta)\int_0^{\Delta} \sin(\Delta - \phi)\left[\sin\phi\partial_\theta^2 - \cos\phi\partial_\phi\right] \times \left[\frac{\delta c(\pi/2,\phi)}{c_0}\right]\mathrm{d}\phi \qquad [24]$$

where ∂_θ and ∂_ϕ are derivatives with respect to θ and ϕ (e.g., Romanowicz, 1987). Dahlen and Tromp (1998) slightly modified this to include a term with sensitivity to phase velocity at the receiver. Both v and A depend on frequency because phase velocity does.

Both arrival angles and amplitudes depend on gradients of structure rather than structure itself, which gives them sensitivity to shorter wavelengths than the corresponding phase data (see also Romanowicz, 1987). Wong (1989) applied this theory to include amplitude data to obtain frequency-dependent phase velocity maps at very long periods (modes up to angular order $\ell = 59$ at about 6.5 mHz). We developed an interactive technique to measure arrival angles using the multitaper approach of Park et al. (1987a). In the most general case, this method models elliptical particle motion in 3-D space. In a singular value decomposition (SVD) of the three-component

seismogram, we seek the frequency-dependent complex eigenvector that spans the plane of particle motion. From the eigenvectors, we can derive polarization parameters, such as the eccentricity of the ellipse and three angles that define the orientation of the ellipse. The eigenvalues give us an idea of how well-defined the particle motion is, that is, how well it can be explained by a single ellipse. As in the case of phase data, the multitaper approach provides statistical error bars as well as resistance to bias from noise in the time series. Lerner-Lam and Park (1989) first used this technique to investigate lateral refraction and multipathing of long-period surface waves in the Western Pacific.

Other methods to analyze particle motion exist, for example, the method by Jurkevics (1988) that works in real space. In the interactive analysis of Plešinger et al. (1986), one seeks the local coordinate system for which certain component products are zero. These products, as functions of time, can be used to either discriminate between wave types or measure arrival angles. Paulssen et al. (1990) expanded the basic time–frequency analysis for the three-component seismograms and presented the time and frequency-dependent polarization of anomalous surface waves observed at stations on the Iberian Peninsula. They constructed a quality factor that depends on the largest eigenvalue of the SVD to assess the likeness of the signal to a Rayleigh or Love wave. Lilly and Park (1995) applied the time–frequency analysis using a wavelet algorithm and the multitaper technique to investigate the evolution of the frequency-dependent polarization in a time series. The methods described here all involve the analysis of single three-component seismograms. As discussed in the last section, assuming a simple incoming wavefield, arrival angles can also be determined from array analyses (e.g., beamforming). A recent example of this is the study of Cotte et al. (2000) who investigated off-great-circle propagation in southern France caused by lateral refraction of surface waves by the French Alps. Using the beamforming technique, Friedrich et al. (1998) and Essen et al. (2003) observed a strong directivity of ocean-generated microseism noise in Europe. Similar observations exist for Southern California (e.g., Schulte-Pelkum et al., 2004).

Arrival angle data have been included successfully in inversions for global structure (e.g., Laske and Masters, 1996; Yoshizawa et al., 1999). It is interesting to compare the sensitivity of arrival angles and phase to lateral heterogeneity. **Figure 39** shows the integral kernels of eqn [23] in a similar way as those for the phase integral in **Figure 31**. Sensitivity to short-wavelength structure increases with harmonic degree, which is the opposite of the behavior for the phase. This is due to the fact that arrival angles depend on the gradient of structure, not the structure itself as phase does (see eqn [20]). We also notice that sensitivity to high-l structure, relative to low-l structure, increases with travel distance and does not decrease as the sensitivity of phase does. Except for very short paths of $<20°$, sensitivity to even harmonic degrees is always higher than to odd-harmonic degrees. Near the antipodes, sensitivity in the PIA becomes extremely large. At the same time, the antipode is a caustic with severe multipathing effects where asymptotic theories tend to break down (e.g., Romanowicz and Roult, 1986). We therefore discard data for epicentral distances larger than 160°. Relatively speaking, arrival angle data also have larger measurement errors than phase data. In principle, sensitivity to short-wavelength structure can be enhanced by including large data sets of phase data for very short travel paths (i.e., $<30°$) though the separation of the fundamental mode to obtain uncontaminated phase estimates at long periods becomes problematic. The collection of a global data set of arrival angle data, and its subsequent usage in the modeling of global structure, also has a useful by-product. Arrival angle data are sensitive to the misalignment of the horizontal seismometer components from east and north, and such information was not available when we first started our investigation. The joint inversion of arrival angles for structure and component misalignment can be linearized, but the inversion requires several iterations for misalignments of more than 5°. The Harvard group has also observed station misalignment though they use a different approach (Larson

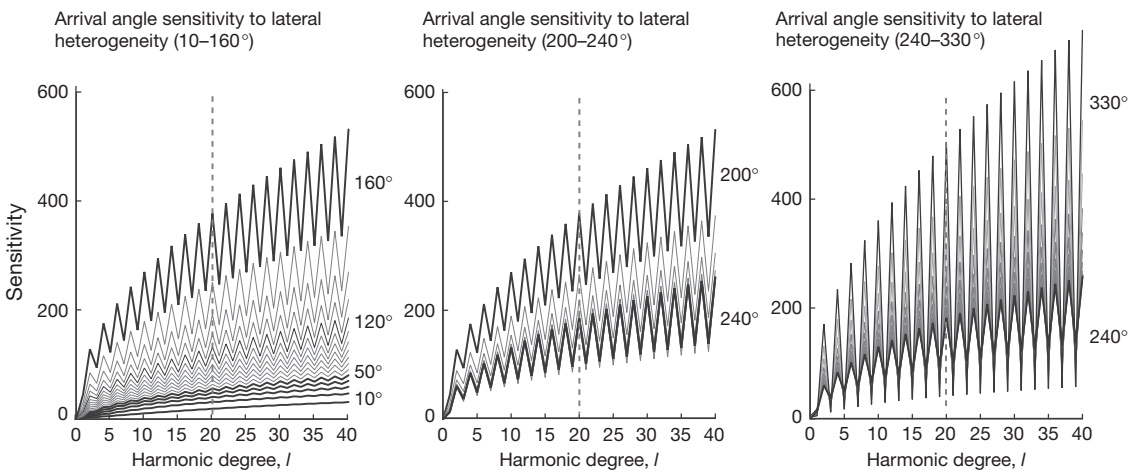

Figure 39 Arrival angle sensitivity to lateral heterogeneity, as function of harmonic degree in structure. Curves are shown for travel distances between 10° and 330°. Paths with distance $<180°$ are for minor arc paths (R_1); larger distances are for major arc paths (R_2). We do not analyze data within 20° of the antipode so the kernels were omitted.

and Ekström, 2002): arrival angle information is extracted from smoothed amplitude estimates using a PMF technique and synthetic seismograms computed with the dispersion measured for each waveform. Their station misalignment data agree quite well with our own. Some of the misalignments that we published (Laske, 1995) have been confirmed by station operators, and this information is now routinely available at the DMCs, together with the instrument responses.

As mentioned in the preceding text, amplitude data are also very useful to constrain lateral heterogeneity. In fact, due to the second derivative in eqn [24], amplitudes are even more sensitive to short-wavelength structure than arrival angles are. Amplitude information has been used as additional constraints to investigate elastic structure. Some of the earliest work is that of Yomogida and Aki (1987) who used the Gaussian beam method to obtain 30–80 s Rayleigh wave phase velocity structure in the Pacific Ocean. Wong (1989) used their linear theory to include amplitudes in the retrieval of elastic structure at very long periods beyond 150 s. Dalton and Ekström (2006) showed that it is possible to retrieve elastic structure using surface wave amplitudes alone, but the primary purpose to study surface wave amplitudes has been to retrieve Earth's attenuation structure (e.g., Billien et al., 2000; Durek et al., 1993). The problem with analyzing surface wave amplitudes is that the effects of lateral elastic heterogeneity may be an order of magnitude larger than those of attenuation. Selby and Woodhouse (2000) found that amplitude variations are dominated by anelastic structure for long wavelengths and by elastic structure at short wavelengths. If the linear approximation of eqn [24] holds, then this would perhaps be expected because the amplitude great-circle integral over anelastic structure is linear and does not involve any gradient as that over elastic structure does. The first to successfully address this problem in the retrieval of anelastic structure was Romanowicz (1994) who took focusing–defocusing effects into account before constructing the first attenuation maps for long-period Rayleigh waves. More recent work to retrieve attenuation includes that of Gung and Romanowicz (2004) who provide a 3-D attenuation model for the upper mantle. Using the nonlinear asymptotic coupling theory (NACT), they first derive an elastic model for V_{SH} and V_{SV} using long-period surface and body wave waveforms. The surface wave waveforms are then aligned using this model and inverted for 3-D attenuation. For further details about modeling attenuation from surface waves, see also **Chapter 1.25**.

Here, we have only discussed the horizontal arrival angles as observables to assess Earth structure, but the particle motion of surface waves is characterized by two additional angles: the sloping angle that describes the deviation of a Rayleigh wave orbit from the vertical and the tilting angle of the elliptical orbit with respect to the horizontal. Vig and Mitchell (1990) attempted to relate arrival angles (which they call inclination) and the sloping angles observed at station HON (Honolulu, Hawaii) of the DWWSSN to the anisotropic mantle around Hawaii. The shape of the Rayleigh wave ellipse, that is, the ratio between major and minor axes of particle motion (HZ ratio), depends on the shallow structure. Tanimoto and Alvizuri (2006) had recently used the HZ ratio of microseisms to infer shallow crustal structure shallower than 5 km in Southern California.

1.04.3.4 Higher Modes

The analysis of overtones, or higher modes, is attractive because it yields independent constraints on structure at depth. Overtones are more sensitive to deep structure than fundamental modes of the same frequency (see **Figure 43** in the next section). At long periods, overtones would significantly enhance resolution in the transition zone and uppermost lower mantle. At shorter periods, overtones carry better constraints on the low-velocity zone in the upper mantle than fundamental modes do. The analysis of overtones, however, faces several problems that are outlined in this section.

1.04.3.4.1 Higher-mode dispersion and waveform modeling

From **Figures 34, 35**, and **37**, we have seen that the fundamental mode is fairly isolated in time and frequency because its group velocities are significantly lower than those of overtones. Overtone velocities, on the other hand, overlap significantly, except at low frequencies. **Figure 37** suggests that we could analyze the first overtone, if we were able to isolate it, for example, using TVF or a phase-matched filtering operation (e.g., Jobert and Roult, 1976). Note, however, that for this particular earthquake, the mode contains relatively little energy. For the other modes, extraction appears very uncertain. To illustrate the problem, **Figure 40** shows the Gabor matrix for a synthetic calculated for isotropic PREM with a 39 km thick crust. For the seismogram in the top panel, all modes were included in the calculations, and we can discern the same body-wave phases, composed of interfering overtones, that we observe in the real seismogram. The other panels show the contribution from each mode, up to the fifth overtone. As just mentioned, the first overtone appears quite isolated in time–frequency space, but its energy is so little that it is not discernible in the composite Gabor matrix. The other overtones overlap significantly though extraction of the second higher mode may be possible at frequencies higher than 10 mHz, because group velocities are relatively low. At lower frequencies, there is significant overlap between the second and third overtones. At frequencies above 12 mHz, the third and fourth overtones overlap. TVF may provide only limited success in this case.

The first convincing observation of overtone dispersion was probably that of Oliver and Ewing (1957) for a path across eastern North America, but utilizing overtone dispersion to study Earth's interior obviously requires a different approach than fundamental modes do. The first breakthrough was achieved by Nolet (1975) and Cara (1978) who used an array stacking technique to separate different overtone branches using a $\omega - k$ transform, for studies of structure in Western Europe and across North America. This approach has also been used in other studies (e.g., Cara et al., 1981 for the Western United States). At fixed frequency, different overtone branches then appear separated in phase-group velocity space. This approach works well to obtain average structure within an array but does not allow us to assess variations within an array. The problem with this approach is also that it needs an array.

Using individual source–receiver data on a global scale, a successful separation of overtones up to order 8 was achieved by van Heijst and Woodhouse (1999). They used their mode branch stripping technique (van Heijst and Woodhouse, 1997)

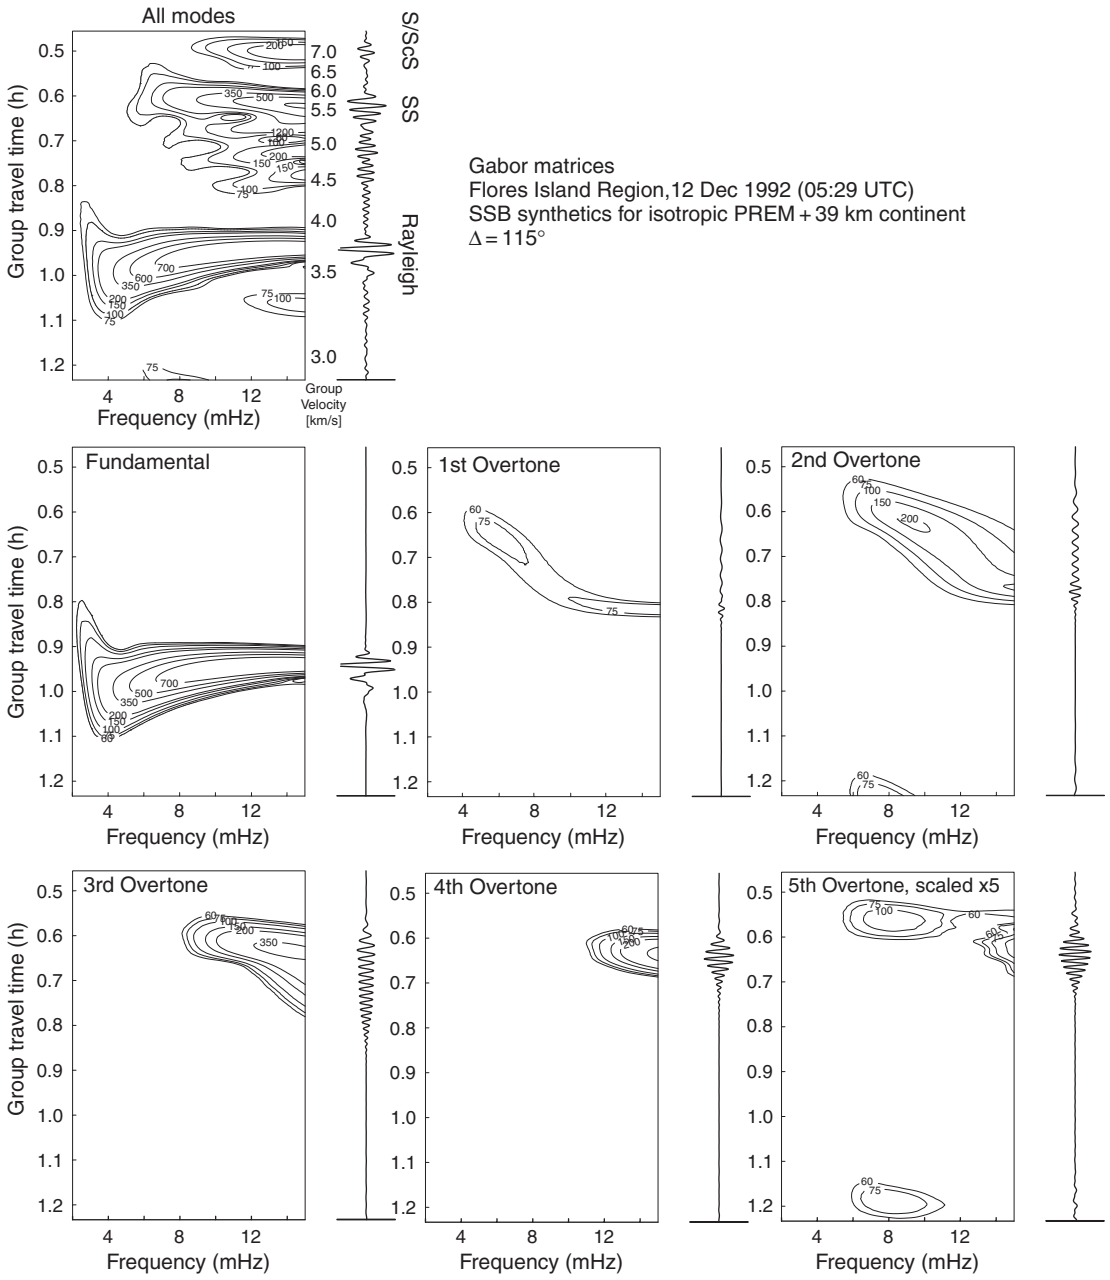

Figure 40 Visualization of a Gabor matrix for the synthetic seismogram in **Figure 37**. The top panel shows the complete synthetic, including all modes computed for isotropic PREM with a 39 km thick continental crust. The bottom panels show the Gabor matrices for the fundamental mode and first five overtones. While the fundamental mode is well isolated, the interference between overtones is rather complex. Note that the amplitudes for the fifth overtone are rather small. Also note that overtones beyond order 7 are required to compose the overlapping body-wave phases S and ScS (see also **Figure 33**).

to isolate the overtone branches and make global phase velocity maps (termed Oxford approach hereafter). This technique makes use of branch cross correlation functions (bccf's) that increase sensitivity to a certain overtone signal. The signal with the most energy is analyzed first and subtracted from the seismogram before successive branches are analyzed in a similar fashion. The technique works well for Rayleigh waves but appears to fail for Love waves due to strong interference effects. This is one of few studies that extract dispersion. The vast majority of publications utilize waveform modeling to retrieve structure at depth directly, without involving the intermediate step of determining dispersion. One may argue about which approach is superior, but a useful by-product of the Oxford approach is the ability to check for consistencies in the data. For example, they were able to compare their fundamental mode Rayleigh wave maps at 40 s with that of the fourth

overtone at 62 s. Since their dependence on structure at depth is quite similar, the phase velocity maps should highly correlate.

The bccf's have been used by others as well who choose the waveform modeling approach (e.g., Cara and Lévêque, 1987; Debayle and Lévêque, 1997). Other advances to study overtone branches include the hybrid technique by Stutzmann and Montagner (1993). This waveform fitting technique retrieves path-averaged overtone phase velocities and path-averaged velocity structure in successive steps. An attempt to determine global structure was discussed by Stutzmann and Montagner (1994) though data coverage was quite sparse. Similar to Nolet's array technique, they utilized several earthquakes along similar paths to retrieve phase velocities. They recently developed the 'roller-coaster technique' (Beucler et al., 2003) that is named after the shape of the misfit function in their method. Their method can be applied to a cluster of events to retrieve structure along a single source–receiver great circle in a nonlinear scheme. Another development is that of Yoshizawa and Kennett (2002, 2004) who used Sambridge's (1999) neighborhood algorithm to efficiently search the model space for multimode dispersion in a nonlinear waveform inversion.

Most of the other techniques involve full waveform modeling and the retrieval of structure at depth directly, without determining dispersion first. The first study on a global scale was that of Woodhouse and Dziewonski (1984) whose global upper-mantle shear velocity models, M84A and M84C, were regarded as reference 3-D model upper-mantle models for the following decade. The technique is still used by the Harvard group and has led to a series of updated whole mantle models such as S12/WM13 (Su et al., 1994) and S362D1 (Gu and Dziewonski, 1999). Though Woodhouse and Dziewonski used normal mode summation to calculate synthetic seismograms, they used a clever trick to account for sensitivity to odd-degree structure by introducing a fictitious epicentral distance shift in the minor and major arc great-circle integrals. This was later justified theoretically by Mochizuki (1986a,b) and Romanowicz (1987). Woodhouse and Dziewonski argued that individual waveforms are probably too noisy for direct inversions for structure so they projected their measurements onto a set of global basis functions in a two-step procedure. Another global waveform modeling approach is that of the Berkeley group called NACT (Li and Romanowicz, 1995). This technique accounts for cross branch coupling that is ignored in conventional path average approximations. While this is less of an issue for fundamental modes surface waves, it becomes relevant for overtones that involve deep-turning body waves. The application of this technique led to the first 'Berkeley model,' SAW12D (Li and Romanowicz, 1996), as well as more recent models (e.g., SAW24B16 by Mégnin and Romanowicz, 2000). In contrast to other mantle models, the Berkeley models have traditionally been V_{SH} models. A recent discussion of asymptotic and nonasymptotic waveform modeling approaches can be found in Clévédé et al. (2000).

With his nonlinear partitioned waveform inversion, Nolet (1990) provided a tool that is widely used in regional-scale studies. The technique is similar to step 1 in the Woodhouse and Dziewonski approach. Publications are too numerous to list here, but examples include work in Western Europe (e.g., Zielhuis and Nolet, 1994), in North America (e.g., van der Lee and Nolet, 1997), and on the Skippy array in Australia (e.g., Simons et al., 2002). Nolet argued that full waveform inversions directly for 3-D structure are computationally expensive and do not allow for a proper assessment of resolution capabilities. Rather, one can 'partition' the process and search for multiparameter, path-averaged structure first, for each source–receiver path, before conducting a computationally efficient inversion of a sparse matrix to retrieve 3-D structure. An advancement of this technique is its automation by Lebedev et al. (2005), which allows the processing of large data sets such as massive global data sets or regional-scale data sets from a dense network such as the USArray.

A few concluding words of caution are in order. We have seen that overtones have the potential to constrain deep Earth structure much better than fundamental modes do, and numerous studies emphasize that resolution is 'significantly' enhanced over fundamental mode only studies. A reader has to bear in mind though that in the parametric approach, due to the massive interference with other overtone branches, errors in the fit to overtone data are probably much larger than to fundamental mode data. Another important point is the relative weight of overtone data in an inversion. We have seen in **Figure 37** that recorded amplitudes of overtones were much smaller than those of the fundamental mode. Overtone experts may argue that the choice of the seismogram to demonstrate this point is poor because this earthquake was shallow. Such earthquakes excite fundamental modes particularly well and usually leave overtones with much reduced amplitudes in the seismogram. A proper choice of earthquakes for overtone studies therefore focuses on deep events. Unfortunately, such events are relatively rare and even more unevenly distributed than shallow events. **Figure 41** shows that earthquakes with source depths >75 km account for only 21% of all earthquakes, while the rest are shallower. Even with source depths of about 150 km, the fundamental modes still dominate the seismogram. Only when source depths become significantly

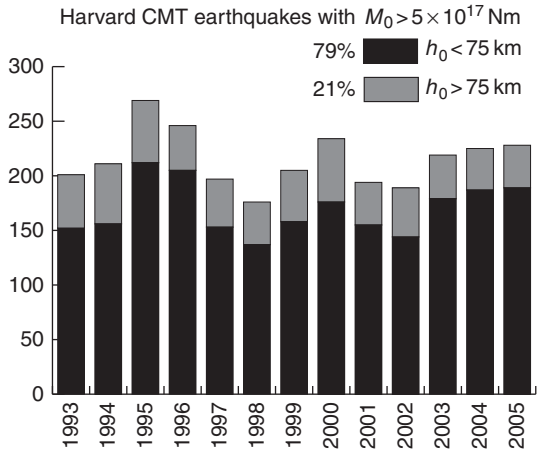

Figure 41 Events from the Harvard CMT catalog, for each year between 1993. Shown are all events with scalar seismic moment $M_0 \geq 5 \times 10^{17}$ Nm. For shallow events, this corresponds approximately to $M_S \geq 5.4$. Shown are 'shallow' events with source depths <75 km, which comprise 79% of all earthquakes. Events deeper than 75 km, which are potentially better earthquakes to study overtones, account for only 21% of all earthquakes.

greater than that, overtones above 4 mHz have larger spectral amplitudes than fundamental modes, which implies further reduction in the number of suitable earthquakes. A careful assessment of the resolution capabilities of a certain data set therefore entails more than just comparing the sensitivity kernels of fundamental modes and overtones. A 3-D surface wave tomographer essentially faces a trade-off problem. One can use all earthquakes to obtain best lateral resolution but bearing in mind that the vertical resolution is dominated by the limitations that fundamental modes dictate. Or one can chose mostly deep events to obtain optimal depth resolution, at the expense of decreased lateral resolution dictated by the sparser source distribution. The Berkeley and Oxford approaches appear to account for this by giving different weights to overtones, but the issue appears somewhat unresolved.

1.04.3.4.2 Love waves and overtones

With increasing amounts of data and the sophistication of measurement techniques, measurement errors have become ever smaller. Systematic biases introduced by unmodeled effects then become significant. We have already pointed out in **Figures 34** and **35** that Love wave overtone group velocity curves are quite close to that of the fundamental mode between 8 and 12 mHz (125–85 s). In a seismogram, short-period Love wave overtones therefore appear at the same times as long-period fundamental modes. Using sophisticated time-frequency analyses, such as the multiple filtering technique, one may be able to separate the different mode branches. However, it appears that even advanced techniques such as the branch stripping technique are not able to properly separate Love wave overtone branches, possibly because cross branch coupling is significant (Mégnin and Romanowicz, 1999). The question now is whether even the fundamental modes can be analyzed without taking interference effects into account. For oceanic paths in particular, overtones and fundamental mode group velocities are nearly the same for similar frequencies and separation is no longer trivial. It was discovered early that Rayleigh and Love waves are often incompatible, that is, that no realistic isotropic model fits the dispersion of both wave types simultaneously (e.g., McEvilly, 1964). Often, such models exhibit low-velocity zones overlain by thin lids with nearly unrealistically high shear velocities.

Some argued that at least some of this discrepancy can be explained by Love wave overtone contamination (e.g., Thatcher and Brune, 1969). Others suggested that no uniform bias can be found in a large data set that includes several earthquakes, for a given path and model (e.g., Boore, 1969). Due to this unsatisfying problem, initial collections of regionalized models resulting from inversions of dispersion curves did not include Love waves (Knopoff, 1972). The vast majority of publications address this problem by allowing transverse isotropy in the model, also called polarization anisotropy or radial anisotropy. More recently, Polet and Kanamori (1997) revisited this problem by studying the biasing effects for an upper-mantle model in Southern California. They found that after correcting for the biasing effect on Love waves from overtone contamination, the models obtained from Love and from Rayleigh waves were much more compatible than before. They also found that after the correction, the isotropic model that fit both wave types was much more realistic than before though the model had an unusually fast thin lid beneath the Moho and a low-velocity zone near 100 km depth, both not obtained when inverting for each wave type alone. On the other hand, Ekström and Dziewonski (1998) argued that anomalies found in V_{SV}, deduced from uncontaminated Rayleigh waves, and not in V_{SH} led to their discovery of anomalous azimuthal anisotropy in the Pacific ocean, while V_{SH} basically follows the lithospheric age progression.

With two-thirds of Earth covered by oceans, a possible contamination of Love wave data by overtones would pose a serious problem to find a proper REM. Our REM website compares the spherical averages of various published Love wave phase velocity maps with toroidal fundamental mode frequencies. Mode frequencies should not be biased by overtone contamination because an entirely different measurement technique is applied. A discrepancy between Love waves and toroidal modes is not apparent, which could indicate that, at least on average, overtone interference does not affect global estimates of Love wave phase velocity. A Rayleigh–Love incompatibility therefore can only be due to transverse isotropy. Nevertheless, a test with synthetic seismograms could help to illuminate how large a possible bias could be. We calculated 1200 mode synthetic seismograms for model 1066A that included the complete set of overtones. Using the same technique that we used in Laske and Masters (1996), we then measured phase relative to 1066A fundamental mode synthetics. **Figure 42** shows the median of our measured phase velocity anomalies. Rayleigh waves are essentially not affected by overtone contamination. Love wave data, on the other hand, show a bias that becomes significant at higher frequencies and can reach 0.06%, a result that could potentially raise concern. However, when comparing these discrepancies with the medians in the real data, we find that this bias is an order of magnitude smaller than what we observe. Potentially, Rayleigh wave overtone contamination could play a role if significant lateral refraction rotates some of the signal from the radial onto the transverse component. We have not tested how much this affects our data set, but we suspect that this effect is much smaller than Love wave overtone contamination. It appears therefore that a possible Rayleigh–Love incompatibility requires a transversely isotropic REM. Note that the medians shown here are averages in the data set and not true spherical averages, which are obtained only after an inversion for phase velocity maps. The small changes this would entail are irrelevant and do not at all affect the discussion here.

1.04.3.5 Surface Waves and Structure at Depth

The first inversion of surface wave dispersion to obtain mantle structure was carried out for the Canadian Shield by Brune and Dorman (1963) along a two-station pair. Forward modeling attempts go back at least 10 years (e.g., Ewing and Press, 1954). A vast amount of modeling attempts has followed since then, and the interested reader finds a detailed description of the quest for structure in the mantle in other contributions in this volume, for example, **Chapter 1.16**, which also discusses azimuthal anisotropy, or that of **Chapter 1.21**, which discusses

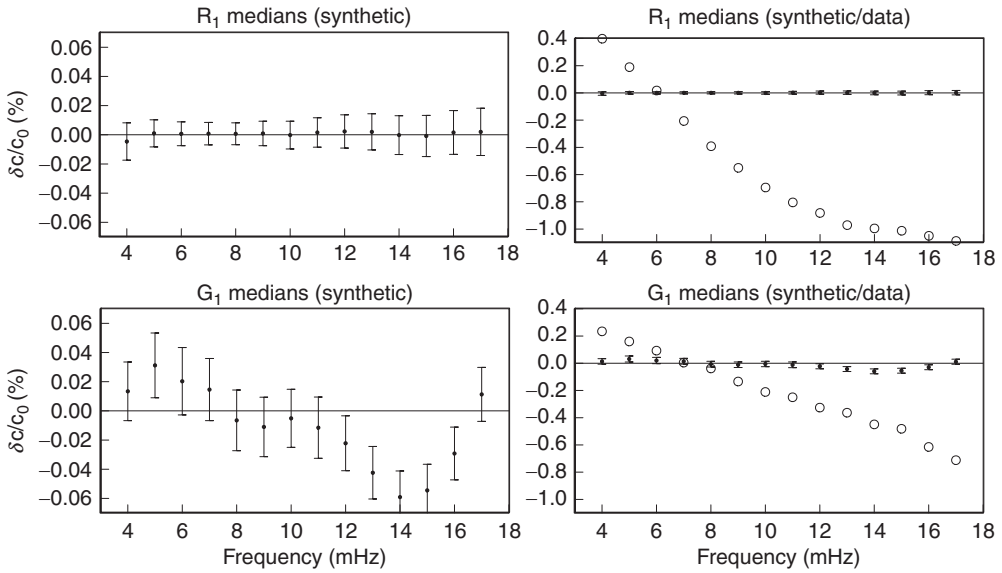

Figure 42 Estimation of the bias on fundamental mode phase velocity estimates introduced by overtone interference. Measurements are with respect to fundamental mode synthetics computed for model 1066A of Gilbert and Dziewonski (1975). The left panels show the bias on about 1200 synthetic waveforms that include the complete set of overtones, for Rayleigh (R_1) and Love (G_1) waves. The right panels show the same synthetic results but now together with the anomalies that we measured in our Laske and Masters (1996) data set (open circles). The synthetic test shows that the bias on Love waves is much greater than on Rayleigh waves, and the bias is significant. On the other hand, the anomalies that we measure on real data are an order of magnitude larger.

attenuation. A comprehensive review on the inversion of surface waves can be found in Romanowicz (2002). Here, we would like to close the discussion on surface wave data and their inversion for structure at depth with just a few remarks. Surface wave phase velocity is sensitive to all three elastic parameters, V_S (or β), V_P (or α), and density ρ:

$$\frac{\delta c}{c} = \int_0^a r^2 \mathrm{d}r \left(\tilde{A} \cdot \delta\alpha + \tilde{B} \cdot \delta\beta + \tilde{R} \cdot \delta\rho \right) \qquad [25]$$

where a is Earth's radius, r is the radius and all other parameters in the integral depend on r. In addition, phase velocity and the integral kernels depend on frequency. For uncoupled modes in transversely isotropic media, phase velocity sensitivity is expressed in terms of even more parameters where the two velocities are replaced by the five elastic parameters A, C, N, L, and F (e.g., Dziewonski and Anderson, 1981; Love, 1927; Takeuchi and Saito, 1972) where

$$V_{PH} = \sqrt{A/\rho}, \quad V_{SH} = \sqrt{N/\rho}$$
$$V_{PV} = \sqrt{C/\rho}, \quad V_{SV} = \sqrt{L/\rho}$$
$$\eta = F/(A - 2L)$$

where $A = C$, $N = L$, and $\eta = 1$ for isotropic media. Note that A here is not to be confused with the integral kernels A-tilde in eqn [25]. Montagner and Nataf (1986) devised an elegant technique to generalize this representation to model azimuthal anisotropy in the so-called vectorial tomography (Montagner and Nataf, 1988). In transversely isotropic media, Rayleigh waves are sensitive to all four velocities: V_{PV}, V_{PH}, V_{SV}, and V_{SH} where sensitivity to the latter is practically negligible. On the other hand, Love waves are sensitive to V_{SH} and V_{SV} where sensitivity to the latter is significantly smaller and usually ignored. We have no space to discuss the effects of anisotropy in greater detail, but the interested reader is referred to **Chapter 1.16**.

As mentioned in the preceding text, investigators strive to include overtones in their modeling because overtones enhance sensitivity to structure at greater depth than fundamental modes do. **Figures 43** and **44** show the sensitivity of Rayleigh and Love wave fundamental modes and their first two overtones to isotropic structure at depth. In the frequency range considered here (4–20 mHz), fundamental modes do not reach much beyond 300 km, though some sensitivity exists down to 500 km for 4 mHz Rayleigh waves. Overtones, on the other hand, reach well into the lower mantle. This fact has been utilized by numerous surface wave studies that concentrate on the transition zone and subducting slabs (e.g., Stutzmann and Montagner, 1994; Trampert and van Heijst, 2002; van der Lee and Nolet, 1997). In the isotropic case, Rayleigh waves are not very sensitive to V_P deeper than 50 km, but sensitivity is significant at shallower depths where sensitivity to V_S is very low. A comprehensive inversion for structure at depth would include the search for all three elastic parameters. In practice, this is usually not feasible, because the frequency range covered by the measurements does not provide enough independent information to make an inversion well constrained. To simplify an inversion, scaling relationships between the kernels for V_S, V_P, and ρ are drawn from mineral physics constraints and used to include the kernels for V_P and ρ in the kernels for V_S. We then invert only for V_S. For mantle structure, we commonly use, for all depths,

$$\tilde{A} \cdot \delta\alpha = (1/1.7)\tilde{B} \cdot \delta\beta$$
$$\tilde{R} \cdot \delta\rho = (1/2.5)\tilde{B} \cdot \delta\beta$$

This assumption is basically valid if observed seismic anomalies are caused by thermal effects. In the crust, above 50 km

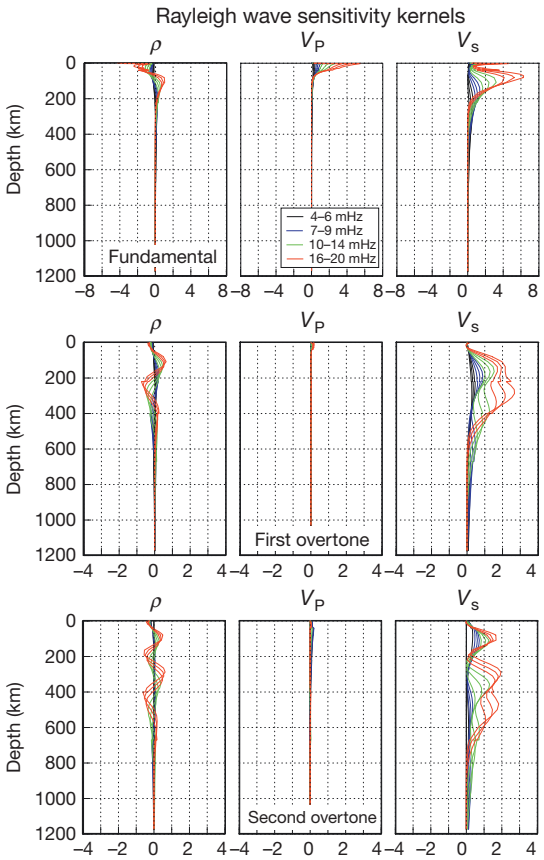

Figure 43 Sensitivity kernels for phase velocity to isotropic structure at depth, for Rayleigh wave fundamental modes and the first two overtones. Rayleigh waves depend on all three parameters, but sensitivity to V_S dominates. Overtone sensitivity to V_P is weak, and fundamental modes are affected only by V_P shallower than 50 km, when sensitivity to V_S decreases. Overtone sensitivity to structure below about 300 km is larger than that of fundamental modes though note that the scale is different by a factor 2. The model used to calculate the kernels is PREM.

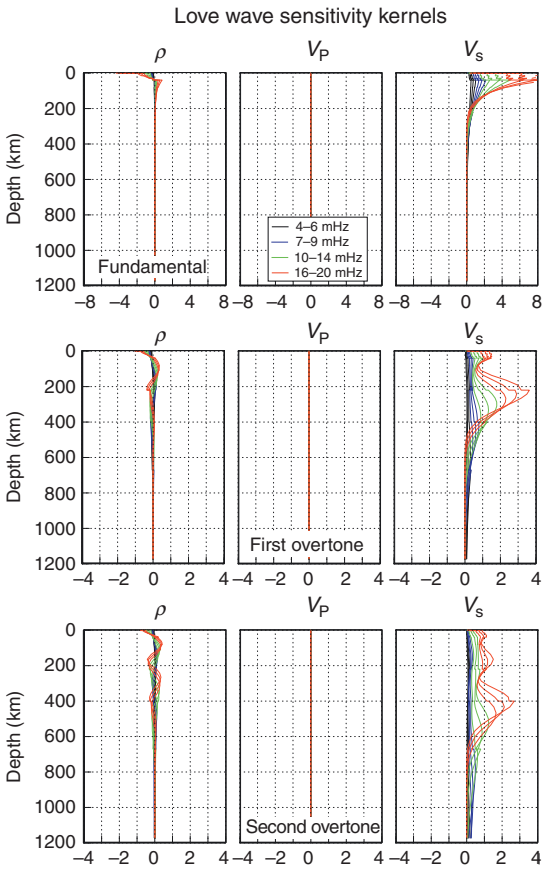

Figure 44 Sensitivity kernels for phase velocity to isotropic structure at depth, for Love wave fundamental modes and the first two overtones. Love wave fundamental modes are primarily sensitive to V_S only, but some sensitivity for density exists, especially for overtones. For details, see **Figure 43**. Second overtones are particularly useful to constrain structure in the transition zone.

depth, compositional variations may dominate and the scaling relationships no longer hold (e.g., in thick sedimentary basins). It is somewhat fortunate that sensitivity to shallow V_S is greatly diminished. Consequently, if we invert for a model, the shallow structure should probably be attributed to variations in V_P, not V_S as is commonly done. Note, however, that sensitivity to shallow density is also significant and a detailed discussion of tectonic implications should take this into account. A point that has not been treated here is that group velocities provide additional independent constraints, not in the physical sense but from a measurement technique point of view. A combination of the two is particularly useful to reduce ambiguities resulting from data uncertainties and to enhance the modeling of crustal structure (e.g., Shapiro and Ritzwoller, 2002).

We should mention that all examples shown in this chapter use a spherical Earth approach. On regional scale, when travel paths are limited to a few 100 km, investigators may choose to use a flat Earth approach. Surface wave applications overlap sufficiently that data or models may be compared that did not use the same approach. In this case, an Earth-flattening transformation has to be applied to facilitate this comparison (e.g., Ben-Menahem and Singh, 1981; Biswas and Knopoff, 1970). In the case of a velocity model comparison, a conversion can be done through

$$v_f(z_f) = \left(\frac{a}{r}\right) v_s(r) \qquad [26]$$

where the subscripts f and s denote 'flat' and 'spherical,' z is the depth, r is the radius, and a is Earth's radius (Shearer, 1999). Near the surface, the differences between v_f and v_s are insignificant, but they become larger with depth. To use Shearer's example, with $v_s = 8.6$ km s^{-1} at 150 km depth, the velocity in the flat Earth model would be 2.4% larger and the impact on velocity becomes relevant when discussing geodynamical implications.

A major issue not covered in this chapter is the model parameterization and the regularization during an inversion. Both influence the outcome of the modeling effort. The two basic classes of parameterizations include 'global' and 'local' ones. In a 'global' parameterization, each contributor to a set of basis functions covers the entire model space but represents different wavelengths (e.g., Chebyshev polynomials or spherical harmonics). In a 'local' parameterization, each contributor

covers only part of the model (e.g., layers or local B-splines). Comprehensive techniques also search for perturbations in boundaries, not only perturbations in elastic parameters. Regularizations or damping tries to account for the fact that some parts of the model space remain poorly constrained by the available data. For example, Rayleigh waves at periods shorter than 50 s have only marginal sensitivity to structure below 150 km. An undamped inversion could falsely place structure at these depths after a least-squares procedure dictated that this is the minimum norm solution. From a data perspective, this solution is not justifiable because there were no data to reliably constrain this. A careful analyst therefore conducts thorough a posteriori hypothesis testing (e.g., spike, checker board, or other tests with hypothetical input structures) on which structures of the model are reliably imaged and which are likely not. Other issues include how the inversion is done. Depending on the inversion algorithm, the modeling can end up in a local minimum of the misfit function in which case the model does not represent the best model consistent with our data. The Monte Carlo technique is used in forward modeling to explore larger areas in the model space (e.g., Shapiro and Ritzwoller, 2002). To make the search computationally more economical, Knopoff (1972) employed a hedgehog algorithm that he and Keilis-Borok developed (see also Keilis-Borok and Yanovskaja, 1967). The search starts out in a Monte Carlo fashion but then refines it once a minimum is found. Neighboring model parameters are tried out but discarded if the predictions move the value in the misfit function outside of a certain boundary around the minimum. Beghein and Trampert (2004) provided a novel approach using the neighborhood algorithm of Sambridge (1999). They define probability density functions to explore the range of possible models. Such forward approaches are attractive, but one should carefully evaluate the coverage of the null space. Last but not least, the Backus and Gilbert (1968) approach is still used today (Masters and Gubbins, 2003) when specific targets are investigated. In the B&G approach, specific linear combinations of data are selected that illuminate a certain model parameter (e.g., density near the core–mantle boundary). This method is attractive in that it provides an elegant way to assess the resolution capabilities of the data.

1.04.3.6 The Validity of the Great-Circle Approximation and Data Accuracy

Much of the discussion presented here is based on the use of Fermat's principle. Anomalies are assumed to accumulate along the great-circle arc between the source and receiver. Concerns about the validity of the great-circle approximation and suggestions to improve the interpretation of observables may go back as far as the great-circle approximation itself, and we need to be aware to which limit approximate theories are applicable. For example, Woodhouse and Girnius (1982) presented surface kernels for normal modes that show a rather broad corridor of sensitivity to structure along the source–receiver great circle. On the other hand, Jordan (1978) made a good argument that, asymptotically, modes are essentially sensitive to structure in the immediate vicinity of the source–receiver great circle. This is true if structure is smooth and the structural wavelength remains much larger than the signal wavelength. This applies not only to normal modes but also to surface waves. Advances in parametric surface wave modeling have been made through Gaussian beam ray-tracing techniques (e.g., Yomogida, 1985), Born single and multiple scattering (e.g., Friederich et al., 1993; Snieder and Nolet, 1987), or diffraction tomography (e.g., Meier et al., 1997; Ritzwoller et al., 2002). More recently, finite-frequency theory (e.g., Yoshizawa and Kennett, 2005; Zhou et al., 2005) has been added to the tools in the quest to resolve ever smaller details in Earth structure using surface waves. While each of these techniques promises vast improvement over simple approximations, they almost always also have their own limitations. Equally if not more importantly, we must not forget that the resulting models can only be as good as the data that the modeling is based on (see, e.g., Trampert and Spetzler, 2006). Measurement uncertainties can be large due to noise in the time series that may often be accepted too readily as being Gaussian because the theory requires it. Often, noise is produced systematically, for example, through coupling or interference effects or by inappropriate measurement techniques or by not accounting for them properly. Noise may simply be introduced by unknown effects such as a failing instrument, a faulty installation, or unknown coupling of the instrument to the ground. It is probably not unheard of that a spurious resonance in an installation (e.g., a process turning on every few minutes) nearly coincides with a normal mode frequency of Earth and the data analyst was not aware of the problem. We hope that this chapter has contributed to raise awareness of how important it is to understand how data are collected and how one's favorite measurement technique works and to judge its strengths and pitfalls objectively. Only then is one able to discuss the validity of small details in a model.

1.04.4 Concluding Remarks

As mentioned in **Section 1.04.1**, the seismograms we analyze are typically collected within the FDSN that includes not only the GSN, GEOSCOPE, and the GEOFON global seismic networks but also regional networks of permanent seismometer installations such as the German GRSN, the Canadian Digital Seismic Network, the Italian MedNet, the Japanese F-net, and the Californian TERRAscope and BDSN. Some of these have been recording continuously for 25 years or longer or have replaced earlier networks, such as the DWWSSN and SRO. The observation of normal modes, with periods up to 54 min, requires a very long-period sensor, and some of the best early digital observations were collected on LaCoste–Romberg gravimeters (e.g., IDA; Agnew et al., 1976) that have been used primarily to observe tides. The disadvantage of recording with gravimeters is that we collect only the vertical ground movement. Also, the first few wave trains in earlier recordings of large earthquakes were typically saturated. More modern equipment therefore includes a very broadband three-component seismometer, such as the Wielandt–Streckeisen STS-1 vault seismometer or the Geotech–Teledyne KS-54000 borehole seismometer. Though some individual installations of the broadband STS-2s deliver spectacular low-frequency spectra, more often, the signals of the gravest modes are buried in the noise. STS-1 and KS-54000 are no longer produced. As

sensors age and start to fail, we are losing some of the best and quietest stations that collected records of memorable quality. For example, at the old IDA/UCLA station SPA at the South Pole, the gravimeter recorded the deep 09 June 1994 Bolivia earthquake, which is, to this day and after the 2011 Tohoku, Japan earthquake, the best digitally recorded deep earthquake to study many overtone modes, including IC-sensitive modes. The station was closed soon after 'Bolivia,' and the site was equipped with seismometers and operated under the GSN umbrella. Though the installation included an STS-1, the 1994 Bolivia spectrum was the last and one of very few noteworthy normal mode spectra collected at SPA. Spectra collected at Earth's poles are invaluable to us because they provide the unique opportunity to study in detail the $m=0$ singlet of a mode. To this day, some $m=0$ singlets, such as that of IC-sensitive mode ${}_3S_2$, have not yet been observed, and we have yet to understand whether this is caused by Earth structure, low excitation by the seismic source, or high noise levels at SPA. The low signal quality at SPA has been known for many years, but such a station is extremely difficult to operate, not lastly for environmental reasons. It is therefore not surprising that it took almost 10 years before new equipment was installed at the new site QSPA, not too far away. The 2004 Sumatra–Andaman earthquake did produce a nice spectrum at QSPA, but this earthquake was exceptionally large. For the more recent, slightly smaller 2011 Tohoku, Japan earthquake, the spectrum of the primary sensor at QSPA, a KS-54000, was so noisy that mode 1S4, that sits between fundamental modes 0S6 and 0S7, was not observable. Note though that the secondary sensor, a Güralp CMG-3T, produced a much cleaner spectrum, with 1S4 clearly visible above the noise, but not 3S2. It still remains to be seen, if the 1994 Bolivia SPA spectrum can be reproduced in the future. The GSN is now a decade past reaching its design goals (Butler et al., 2004). No new stations have come online and the networks are past the transition from a R&D (research and development) to an O&M (operation and maintenance) modus operandi. To guarantee the data flow that we enjoy today requires the continued commitment of network operators to maintain stations at observatory-quality level, preferably at remote, low-noise locations. Amazingly enough, some network operators have run these networks on budgets that have not increased or, at the least, kept up with inflation rates. In today's world of high-resolution tomography and squeezed in between large but temporary projects such as the US EarthScope initiative and other high-visibility endeavors, it is becoming increasingly difficult to make the case for running, and funding, a permanent very long-period global seismic network. There are many yet unresolved problems in the Earth sciences to which normal mode seismology may hold the crucial clues, if not the only ones. Our greatest commitment therefore must be to ensure that we have not yet passed the golden age of normal mode observational seismology. Recent advances in ocean technology now allow year-long temporary deployments of broadband seismometers on the ocean floor that are routinely installed as primary sensors at permanent seismic observatories. Some deep-ocean deployments have produced very promising vertical-component spectra that could fill in crucial gaps in the current global coverage of GSN spectra. During the Hawaiian PLUME ocean bottom seismometer (OBS) deployment (Laske et al., 2009), we gathered several GSN-quality spectra for earthquakes much smaller smaller than the 2011 Tohoku, Japan earthquake. For the M_S=8.3 15 Nov 2006 Kuril Islands earthquake, we observed modes 0S6 and 3S2 – and even 0S5 – routinely on unburied Nanometrics Trillium 240 sensors, and on some Güralp CMG-3T sensors. Burial of the sensor is expected to significantly reduce tilt noise on all three components but particularly so on the horizontal components (Collins et al., 2001). Real-time access to OBS observatories can be provided through communication cables such as station H2O halfway between Hawaii and Oregon or through moored buoys. Innovative wave glider technology could provide real-time access to OBSs that are not serviced by cable or moorings (Laske et al., 2014). Advances in both battery and data acquisition technology nurture realistic hopes that an expansion of the GSN into the remote oceans is within our reach.

Acknowledgments

We wish to thank the network and station operators for their unselfish long-term commitment to continuously and consistently collect high-quality long-period seismic data. Foremost among these are GEOSCOPE (France), IRIS–IDA (UC San Diego, the United States), IRIS–USGS (ASL Albuquerque), GEOFON (GFZ, Potsdam, Germany), TERRAscope/TriNet (Caltech, the United States), BDSN (UC Berkeley, California), GRSN (SZGRF, Erlangen, Germany), BFO (Black Forest Observatory, Germany), and the operators of superconducting gravimeters. Thanks also go to IRIS, FDSN, the global geodynamics project (GGP; Crossley et al., 1999), and all data management centers for freely and readily making the data available to us. This research was funded by grants EAR03-36864 and EAR12-15636 of the US National Science Foundation.

1.05.1 Introduction

Since the first seismic signal (Figure 1) recorded at Potsdam (Germany) from an earthquake in Japan (see Section 1.01.1 of this book as well), accumulation of seismic data (as shown by the stack of thousand of seismic records; Figure 2) (Astiz et al., 1996) illustrates the very special well-structured way waves propagate inside the Earth, which is mainly stratified with depth. Various energy packets can be identified and tracked from one station to another. Where in depth these waves have been scattered is always a difficult question to which seismologists are required to provide more and more precise answers.

Each seismic event generates several wave trains well identified on station records. In those traces, we may distinguish three characteristic timescales associated with different typical length scales. The source duration, related to the duration of each wavelet, comes from extended seismic source from less than 1 km to more than 1000 km in length. Time shifts between wave trains are related not only to the velocity differences between P and S waves but also to distances between interfaces inside the Earth, which may range from tens of meters to thousands of kilometers. Finally, there is recorded time window related to the volume being investigated by the waves, which may range from the whole Earth (Figure 3) to the shallower near-surface layers in applied seismology.

The systematic features of seismograms come from the relatively smooth variations of rheological parameters almost everywhere inside the Earth. This has been an important

Figure 1 The first instrumental recording of seismic waves from a distant earthquake obtained by a horizontal pendulum installed by von Reben Paschwitz in Potsdam (Germany), 15 min after the earthquake occurred in Japan.

discovery and a great motivation for the development of the instrumental seismology on the Earth. For comparison, when considering moonquakes (Latham et al., 1971), no individual wavelets (except the first arriving signal) can be identified (**Figure 4**). If global seismology had been developed on a celestial body like the Moon, it would not have been so successful, and it would certainly not have had such a development as on the Earth. The structure of seismic records is also intensively used at local scales for hydrocarbon reservoir exploration and characterization (**Figure 5**). From a theoretical point of view, the special features of seismograms on the Earth must be associated with the general relevance in the Earth of the high-frequency asymptotic approximations of seismic wave propagation, that is, seismic ray theory (Červený, 2001).

As for geometric optics, seismic ray theory is based on a rather intuitive physical notion but requires a quite sophisticated mathematical framework for a consistent analysis. Behind this powerful interpretation tool are important practical consequences for the exploitation of Earth resources and for the mitigation of seismic risks, making effort for understanding ray approaches worthwhile.

Ray theory has been extensively used for the analysis of seismic signals, for example, Lehmann (1936) discovered the solid core by using straight rays inside the Earth (see also Section 8.01.1 of this book). Most of the present interpretation of body waves for structural analysis has involved essentially picked travel times on traces, although now, we consider curved rays in either a vertically varying Earth (Aki and Richards, 1980; Bullen and Bolt, 1985) or more recently a laterally varying medium as our knowledge of the Earth's interior has increased from core–mantle boundary (Chapman and Orcutt, 1985; Kendall and Nangini, 1996; Lay and Garnero, 2004; Richards, 1973), mantle plumes (Montelli et al., 2004a), the upper mantle (Pavlis et al., 2012; Sigloch et al., 2008; Tian et al., 2009), and slab geometries inside the lower mantle (Bigwaard et al., 1998). Global Earth models are also reconstructed by using phase delays (Section 1.01.4 and **Chapter 1.10** of this book).

Meanwhile, ray theory has been improved theoretically and numerically leading to a great variety of methods and algorithms considering various media (Červený, 2001; Chapman, 2004; Slawinski, 2003). Polarizations and even amplitudes have been estimated in more and more complex structures, and the addition of anisotropic and attenuation effects has led to full waveform interpretations of seismic data (Weber, 1988; Zhu and Chun, 1994b).

This chapter will present an overview of seismic ray theory and its extensions. We will describe basic concepts of high-frequency approximations of seismic waves, as well as limitations and features related to the practical finite-frequency content of seismic waves. Ray theory still appears as a very powerful interpretative tool and will remain a necessary and elegant alternative to brute force tools for numerical wave propagation (Komatitsch et al., 2002; Marfurt, 1984; Virieux, 1986), another necessary tool for seismogram interpretation (see **Chapter 1.05** of this book as well).

1.05.2 Ray Theory

As has been said by Chapman (2004, p. 134), "Ray theory is the cornerstone of high-frequency, body-wave seismology." This theory has also been applied to surface waves by considering evanescent waves along a given direction, which is often a radial or vertical axis in the Earth (Burridge and Weinberg, 1977; Woodhouse, 1974). Excellent descriptions of these approaches of horizontal rays and vertical modes may be found in Keilis-Borok (1989) and Dahlen and Tromp (1998) (see also **Chapter 1.03** of this book). A concise review had been performed by Červený (2001, p. 229). Ray theory has been applied as well for moving media, especially fluids inside a waveguide such as the atmosphere (Abdullaev, 1993; Virieux et al., 2004), giving an illustration of the broad application of this method.

1.05.2.1 Intuitive Approach

Assume an isotropic medium with smooth velocity heterogeneities with respect to the wavelength of the signal we want to propagate. Let us attach a Cartesian reference frame $(0, x, y, z)$ to this medium. Consider at a given time, t, a set of particles, at position $x=(x, y, z)$, vibrating in phase on a smooth surface. We call this surface a wave front. Particles on this wave front

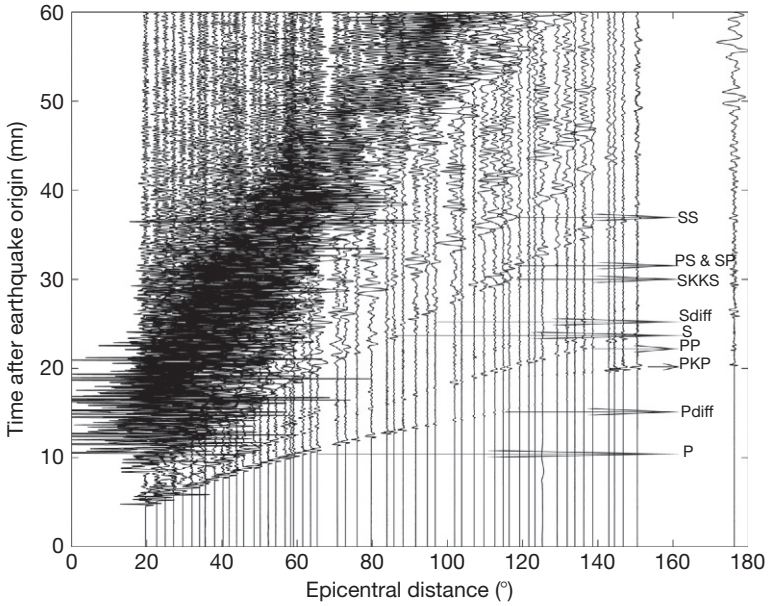

Figure 3 Records of an Indian earthquake (Mm = 7.6, 26 January 2001) on the Worldwide Seismic Network. For displacement, the horizontal scale is 1 mm for each degree. Different phases, for example, P, P_{diff}, PKIK, PP, S, PS, PPS, and SS, are easily seen before the high-amplitude surface wave trains. Courtesy of M. Vallée, IRD.

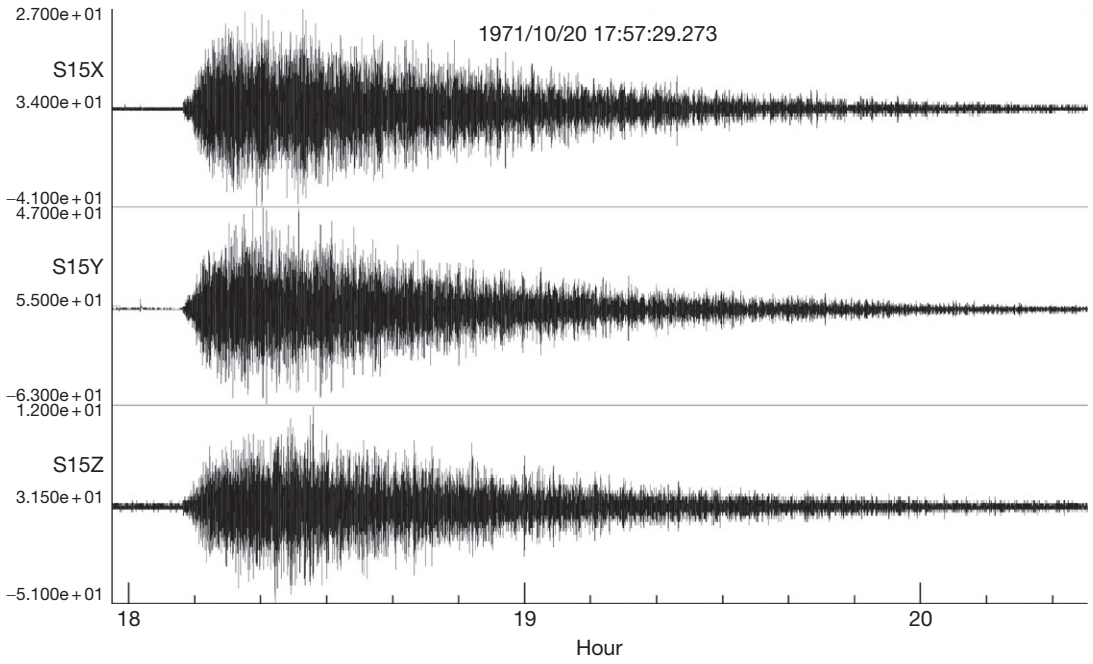

Figure 4 Seismograms produced by the impact of a meteorite on the station S15 of the seismic moon network installed by the Apollo 14 mission. The short-period three-component instrument record ground motion for more than two and one hour half with waves being scattered from the highly heterogeneous region near the Moon's surface. The coda is spindle-shaped, and analysis of the particle motions indicates that the energy is arriving from all directions. Their records differ from typical Earth seismograms for which the coda is weaker than the direct arrivals. Intrinsic seismic attenuation is much smaller on the Moon, while diffraction is stronger, allowing strongly scattered waves to propagate in any direction over a significant time period (Lay and Wallace, 1995, p. 107). Courtesy of J. Gagnepain-Beyneix, IPGP.

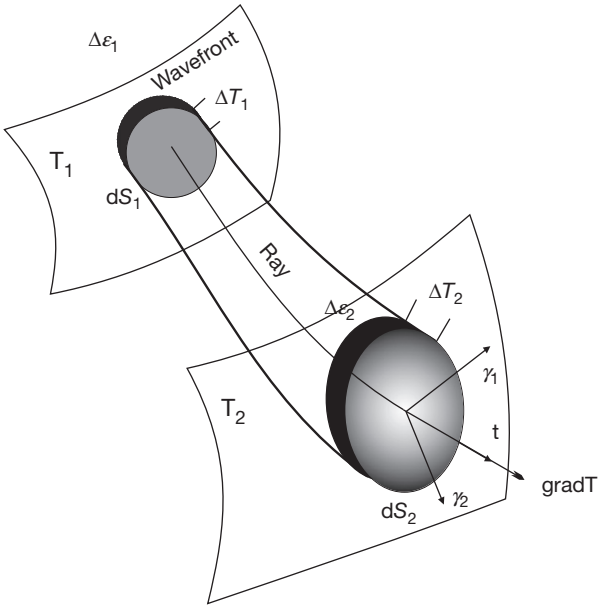

Figure 6 Ray tube geometry: Rays are orthogonal to wave fronts in the isotropic medium. Also, energy flows along rays. The local energy is preserved over an infinitesimal volume controlled by the local velocity (see the text for more details).

have the same travel time, $T(x) = T_0$. As time increases, the wave front moves locally at speed $c(x)$ and the gradient $\nabla T(x)$ is orthogonal to the wave front (Figure 6). Although the wave front moves in one direction, local properties do not allow us to detect what the direction is, which must be known from the previous position of the wave front. Therefore, we must consider the square of the gradient, which gives us the eikonal equation

$$(\nabla T)^2(x, y, z) = \frac{1}{c^2(x)} \quad [1]$$

The gradient is called the slowness vector. In isotropic media, curves orthogonal to the wave fronts, that is, parallel to the slowness vector field, can be defined. We call them rays. Rays are very useful trajectories for calculating travel time but for amplitude variations as well. Indeed, the asymptotic vibration energy moves along the ray tube without any energy leaking (Figure 6). The energy over a small volume of length ΔT_1 crossing the wave front T_1 through the surface dS_1 is related to the square of the amplitude A_1 through the expression $\Delta\varepsilon_1 = A_1^2 dS_1 \Delta T_1$. The energy should be preserved at the wave front T_2, which gives the following conservation of flux as

$$A^2(x_1)\frac{dS(x_1)}{c(x_1)} = A^2(x_2)\frac{dS(x_2)}{c(x_2)} \quad [2]$$

where two different points along the ray tube are denoted by x_1 and x_2 and dS denotes the surface of the elementary orthogonal cross sections of the ray tube. From this equation, and applying the divergence theorem over an infinitesimal volume, we can obtain the local transport equation as the differential expression

$$2\nabla A(x)\cdot\nabla T(x) + A(x)\nabla^2 T(x) = 0 \quad [3]$$

or, under a conservative form, as

$$\nabla\cdot\left(A^2(x)\nabla T(x)\right) = 0 \quad [4]$$

which can be used for a semi-analytic integration along rays. This is one of the reasons we are concerned about the different ray tracing numerical procedures.

As local differential equations, the eikonal and transport equations are fundamental ingredients of ray theory and highlight required properties including smooth wave front spatial continuity and amplitude conservation along ray tubes. Unfortunately, failures of such properties exist quite often in the Earth, for example, interfaces with sharp discontinuity of media properties, shadow zones where no rays are entering, caustics where rays cross each other, strong velocity gradients, and so on. We shall describe efforts to overcome some of these difficulties by introducing a more rigorous framework behind this intuitive ray concept.

1.05.2.2 Elastodynamic Equations and Wave Equations

Let us first consider wave propagation in elastic solid media without attenuation. For the vector displacement field $u(x, t)$ at position x and time t, the linear elastodynamic equation can be expressed as

$$\left(c_{ijkl}(x)u_{k,l}(x, t)\right)_{,j} + f_i(x, t) = \rho(x)u_{i,tt}(x, t) \quad [5]$$

where $f(x, t)$ denotes the vector source field, $c_{ijkl}(x)$ the components of the stiffness tensor, and $\rho(x)$ the density. We use the Einstein convention for summation, boldface symbols for vector and tensor fields, and a comma between subscripts for special derivatives (e.g., $u_{i,j} = \partial u_i/\partial x_j$). For the pressure field $P(x, t)$, the acoustic wave equation can be expressed as

$$\left(\rho^{-1}(x)P_i(x)\right)_i + f^{\mathrm{P}}(x, t) = \kappa(x)P_{tt}(x, t) \quad [6]$$

where $f^{\mathrm{P}}(x, t)$ is the volumetric distribution of pressure source and the compressibility $\kappa(x)$ is the inverse of the bulk modulus $k(x)$. The particle displacement u is deduced from $P = -k\nabla\cdot u$, where the sign $\cdot$ denotes the scalar product. When the density is constant, this so-called acoustic wave equation reduces to the scalar wave equation for the pressure field $w(x, t)$ written as the expression

$$\frac{1}{c^2(x)}w_{tt}(x, t) - w_{ii}(x, t) = f^{\mathrm{w}}(x, t) \quad [7]$$

where the velocity is denoted $c(x)$ and where the specific distribution of pressure source $f^{\mathrm{w}}(x, t)$ is equal to $\rho(x)\, f^{\mathrm{P}}(x, t)$. Some authors introduce first-order hyperbolic systems keeping both displacements and stresses/pressure as variables describing the motion (Chapman, 2004, p. 100).

Solving one of these equations in heterogeneous media cannot be performed analytically and we must rely either on numerical methods or on a specific description of approximate solutions. We shall consider a high-frequency asymptotic solution involving a travel-time function, an amplitude factor, and a source wavelet. Demonstrations can be performed in either the time or the frequency domain, where we select the second domain for easier notation.

The acoustic case is directly connected to our intuitive introduction of the eikonal and transport equations. For the isotropic elastic case, the elastic wave field can be approximately separated into individual elementary waves. These individual waves, P and S waves, propagate independently in a smoothly varying structure, but their travel times are still controlled by eikonal equations, and their amplitudes by transport equations. Because construction of solutions in the elastic case is quite cumbersome, we shall rather consider from now on the scalar wave equation, which captures numerous aspects of the acoustic and elastic cases. We shall mention a few specific considerations for the elastic isotropic and anisotropic cases, and a few words will be said when considering attenuating media (see Chapter 1.06 for further reading).

1.05.2.3 Asymptotic Ray Theory

For specific configurations known as canonical problems, one can get exact solutions of the wave equation. For a homogeneous medium with one speed, canonical solutions can be found as plane waves through separations of variables or as Green functions for a point source (Morse and Feshbach, 1953). The form of these exact solutions should also be valid at high frequency in other media when wavelengths are small compared with the propagation distances and medium heterogeneities. We can then guess probable forms of the solution, known mathematically as an *ansatz*, and then find conditions for them in order to satisfy the wave equations.

Fundamental discussions have been given on *ansatz* structures with very sophisticated arguments for one form or the other depending on the problem to be solved (Babic et al., 1998; Červený, 2001; Kravtsov and Orlov, 1990). The simplest is the ray *ansatz* that we shall introduce. One must be aware that the *ansatz* will only fit the high-frequency components of the solutions. For example, the Green function for a point

source in a 2-D medium exhibits a low-frequency component that the high-frequency approximation will not reproduce (Virieux, 1996).

The ray *ansatz* we shall consider expresses the scalar wave in the frequency domain (Babič, 1956; Chapman, 2004, p. 137; Karal and Keller, 1959) as

$$w(x,\omega) = S(\omega)\mathrm{e}^{\mathrm{i}\omega T(x)}A_0(x) \qquad [8]$$

where the angular frequency is denoted by ω and the source wavelet $S(\omega)$. The subscript zero in the amplitude $A_0(x)$ is related to this so-called zero-order approximation solution. Our convention for the Fourier transforms of a time function $f(t)$ is $f(\omega) = \int_{-\infty}^{+\infty} \mathrm{d}t\, f(t)\, \mathrm{e}^{\mathrm{i}\omega t}$. Smooth functions, travel time $T(x)$ and amplitude coefficient $A_0(x)$, are assumed to be independent of the frequency for the construction of a unique solution. We allow the amplitude coefficients to be complex but the travel time should be real. Specific extensions toward complex values of travel times may lead to new ways of computing seismograms (Felsen, 1984). Let us underline that this estimation should be summed up over the different wave fronts arriving at the position x. The automatic determination of relevant wave fronts at a given receiver has been solved in a combinatorial exercise for multilayered media (Hron, 1972; Hron et al., 1986) but remains a difficult task for an arbitrary inhomogeneous medium as discussed by Clarke (1993a,b).

When introducing this *ansatz* in the scalar wave equation, and also in the frequency domain away from the source zone, we obtain the following equation organized in simple frequency powers as

$$\omega^2 A_0(x)\left[(\nabla T)^2(x) - \frac{1}{c^2(x)}\right] + \mathrm{i}\omega[2\nabla A_0(x)\cdot\nabla T(x) + A_0(x)\nabla^2 T(x)] + \nabla^2 A_0(x) = 0 \qquad [9]$$

Because we are interested in high-frequency solutions, we may neglect the term in ω^0 and set to zero the two other terms in ω^2 and ω^2, leading to the eikonal eqn [1] and to the transport eqn [3].

Further approximations may consider the influence of the neglected term when frequency is finite. Among these alternatives, we must note the definition of the hypereikonal equation (Biondi, 1992; Zhu, 1988; Zhu and Chun, 1994a) where the eikonal is frequency-dependent as are the ray trajectories. A more formal description of the solution in negative power series of $-i\omega$ gives a solution with amplitude terms $A_k(x)$ resulting in new transport equations (Červený, 2001, p. 549). As far as we know, only the A_1 term has been used practically for head waves modeling along interfaces (Červený and Ravindra, 1971; Hill, 1973; Popov and Camerlynch, 1996; Thomson, 1990).

1.05.2.4 Rays and Wave Fronts: A Lagrangian Formulation

The eikonal equation is a nonlinear, partial differential equations (PDEs) of the first order belonging to the Hamilton–Jacobi variety (Kravtsov and Orlov, 1990), usually solved following the method of characteristics (Courant and Hilbert, 1966). The base characteristics are 3-D trajectories $x = x(\tau)$ depending on a sampling parameter τ and satisfying a set of ordinary differential equations (ODEs). If needed, travel time is integrated through quadratures along these trajectories called rays, unless we use it as the sampling parameter. For isotropic media, these rays are orthogonal to wave fronts, sometimes called isochrones. A nice tutorial on characteristics concept has been given by (Bleistein, 1984, **Chapter 1.01**) in relation with differential geometry.

The characteristic system of nonlinear first-order PDEs (eqn [1]) consists of seven ODEs in a 3-D medium connecting the position x, the slowness vector p, and the travel time T, which are very similar to dynamic particle equations of classical mechanics (Goldstein, 1980) and could be expressed as a symplectic Hamiltonian set of equations,

$$\frac{\mathrm{d}x_i}{\mathrm{d}\tau} = \frac{\partial \mathcal{H}}{\partial p_i},$$

$$\frac{\mathrm{d}p_i}{\mathrm{d}\tau} = -\frac{\partial \mathcal{H}}{\partial x_i}, \quad i = 1,2,3$$

$$\frac{\mathrm{d}T}{\mathrm{d}\tau} = p_k \frac{\partial \mathcal{H}}{\partial p_k}, \qquad [10]$$

where the variable τ defined $\mathrm{d}\tau = \mathrm{d}T/(p_k \partial \mathcal{H}/\partial p_k)$ depends on the selected form of the function $H(x, \mathrm{p})$. The independent variables are position x and slowness vector p, defining a 6-D space, called phase space, on which the constant Hamiltonian defines an hypersurface, also called a Lagrangian manifold, on which the value of this Hamiltonian is zero (Lambaré et al., 1996).

The choice of this Hamiltonian $\mathcal{H}_1 = \mathcal{H}(x,\ p) = 1/2\ [p^2 - 1/c^2(x)]$ leads to the simplest differential system to be solved with a sampling variable equal to $\mathrm{d}\tau = \mathrm{d}T/c^2(x)$ for isotropic media, while the Hamiltonian $\mathcal{H}_2 = \mathcal{H}(x,\ p) = 1/2c^2(x)p^2$ has the travel time T for sampling variable along rays, making the third equation of the system [10] automatically verified. Rays are curves in the solution surface, namely, the Lagrangian manifold. One can show that these two choices of sampling provide similar characteristic curves (Slawinski, 2003, p. 179): Hamiltonian choices of sampling provide similar characteristic curves (Slawinski, 2003, p. 180). We may consider as well the Hamiltonian $\mathcal{H}_3 = \mathcal{H}(x,\ p) = 1/2\ [c(x)\ p^2 - 1/c(x)]$ and the related curvilinear sampling along the ray (Červený, 2001, p. 140).

Strategies exist for reducing the number of equation: For example, we may select one spatial coordinate as the sampling variable. Moreover, we may eliminate another variable through the constant value of the Hamiltonian, leading to a so-called reduced Hamiltonian. For example, when considering only rays going downward (or upward), we can select the vertical coordinate z as the sampling parameter. We may also consider the vertical slowness $p_z = \sqrt{1/c^2(x) - p_x^2 - p_y^2}$ as a z-varying reduced Hamiltonian $\mathcal{H}_r(z,\ x,\ y,\ p_x,\ p_y)$ in a 4-D space instead of a 6-D space (Červený, 2001, p. 108). Rays cannot turn as the quantity p_z is always positive, leading to the specific so-called paraxial approximation along z. For arbitrary rays, a possible sampling parameter can be the curvilinear coordinate with two additional orthogonal coordinates leading to the so-called ray-centered coordinate system in a 4-D space as well (Červený, 2001, p. 140). We must be aware now that the quantity $\mathcal{H}_r$ is no longer constant along a ray. The complexity of the related ray equations may increase the number of mathematical operations when performing the ODE integration. One may prefer to consider the system [10] as a

simpler system, although integration is performed in a higher-dimensional space as is often done in field theories.

The method of characteristics is a Lagrangian formulation where we follow the ray point as integrated through the ODEs [10]. This is a very efficient method as it is a 1-D sampling either in a 2-D medium or in a 3-D medium when considering initial condition. Of course, when the number of ray is small, this is the method of choice, namely, ray tracing by directly using rays. More difficult is finding rays between a source and a receiver as we need to guess what the initial conditions are leading to the ray hitting the receiver, the so-called two-point ray tracing problem. For solving this nonlinear problem, we may need to trace a large number of rays. Often, regular ray sampling may be required, leading to a dramatic increase of the number of rays to be traced.

As an alternative, we may consider ray tracing by wave fronts in order to span the entire medium with a regular density of rays. The ray tracing by wave fronts considers an already-evaluated wave front and estimates the new wave front at a later time (**Figure 7**) (Buske and Kästner, 2004; Vinje et al., 1993, 1996a,b). When the ray density becomes too high, we may decimate the number of rays, and when ray density becomes too low, we may increase the number by adding a new ray through judicious interpolation. This adaptative technique, where both ray position and slowness vector are evaluated, had been found to be very efficient when considering 2-D and 3-D smooth media (Lambaré et al., 1996; Lucio et al., 1996) (**Figure 8**). In seismology, Hauser et al. (2008) had recently promoted this ray tracing through wave front using a reduced phase space (Osher et al., 2002), while Rawlinson et al. (2010) presented rather impressive illustrations for complex media at least in 2-D geometries. Various applications have been performed mostly for seismic imaging where later arrivals are required (Operto et al., 2000; Xu and Lambaré, 2004; Xu et al., 2004).

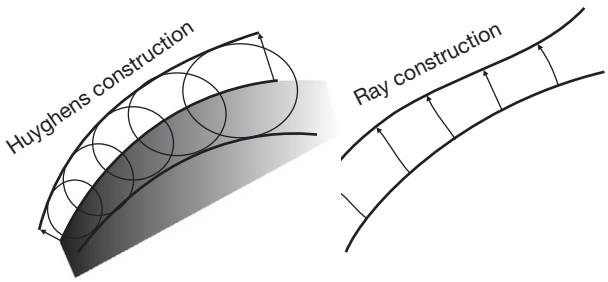

Figure 7 Computation of wave fronts. On the left panel, the construction is based on the Huygens principle, where the new wave front is the envelope of spheres drawn from an initial wave front using a local velocity. The direction is unknown locally. On the right panel, the construction is based on the ray tracing equation, where short ray segments are drawn normal to initial wave front to the new one. The local direction is known by the ray orientation.

Engquist et al. (2002) had promoted an even lower-dimensional space approach, namely, in a 1-D space, by using segment projections, noting that the approach is as fast as by doing ray tracing using rays because it is a 1-D integration. Unfortunately, projections are not so easy to handle from a computational point of view. Tracking the topology of wave fronts is difficult as there is no intrinsic scale to this geometric problem, especially in a 3-D geometry.

Therefore, the methods of characteristics that have been promoted for years may not be the best choice for specific problems when one wants an adaptive more or less uniform sampling of the medium. This is the general drawback of the Lagrangian formulation following either the evolution of rays or the evolution of wave fronts, drawback that has been kept under control in recent computer codes (Hauser et al., 2008; Rawlinson et al., 2010).

1.05.2.5 First Travel Times: An Eulerian Formulation

We may prefer an Eulerian approach for solving the eikonal eqn [1]. The static nonlinear Hamilton–Jacobi PDE

$$\mathcal{H}(x, \nabla_x T(x,t)) = 0 \qquad [11]$$

has received attention by different groups both in seismology and in computational mathematics. The travel-time quantity should be estimated at fixed positions in a given space, while the quantity ∇T might not exist at these points and, therefore, could be discontinuous locally. Crandall and Lions (1983, 1984) had shown that a 'viscous' solution following a minimal entropic criterion exists and is unique. It provides generally the fastest travel time estimated at fixed points of the standard

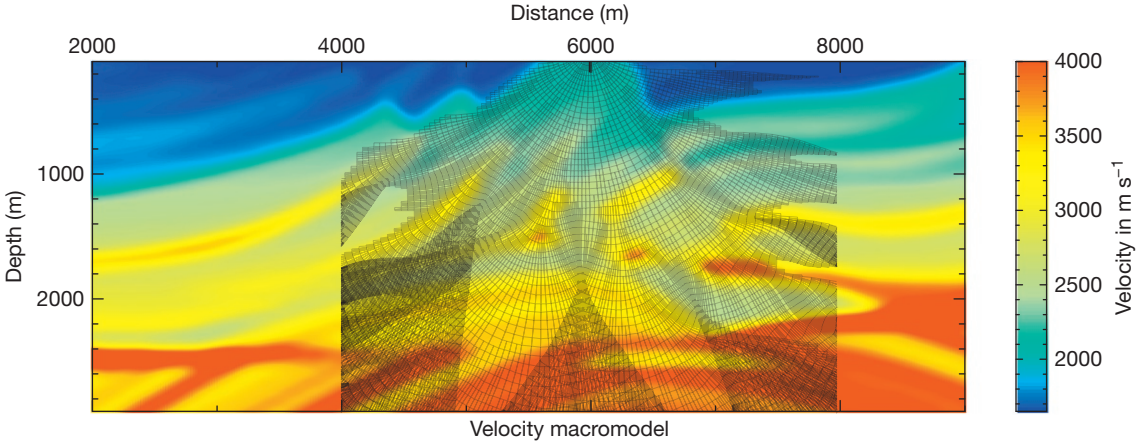

Figure 8 Wave front construction with a uniform ray density criterion in the smooth Marmousi model (Lambaré et al., 1996). Upgoing rays have been eliminated.

space. This Eulerian approach turns out to provide an estimation at all points even when the medium is strongly heterogeneous. As the number of sources and receivers increases, the efficiency of this method increases compared with ray methods.

In seismology, this nonlinear equation has been revisited by Vidale (1988, 1990) where travel times can be computed at fixed points from estimated times at adjacent nodes. A unique value of the travel time is then found at each point. The way at which travel times are updated into the medium has been explored by many authors (Hole and Zelt, 1995; van Trier and Symes, 1991): the update ordering has been called the sweeping technique. Numerous more or less precise algorithms have been designed for both isotropic and anisotropic media (Cao and Greenhalgh, 1994; Eaton, 1993; Lecomte, 1993; Pica, 1997, 1998; Podvin and Lecomte, 1991; Qin and Schuster, 1993; Qin et al., 1992; Zhang et al., 2005).

In numerical mathematics, these nonlinear PDEs have been investigated combining (weighted) essentially nonoscillatory (W-ENO) discrete schemes and Gauss–Seidel iterations with alternating sweeping ordering (Jiang and Peng, 2000; Jiang and Shu, 1996; Liu et al., 1994; Luo and Qian, 2011; Serna and Qian, 2006; Shu and Osher, 1988; Zhao, 2005, 2007). Both 2-D and 3-D geometries have been considered, making the computation more intensive than ray tracing but still quite efficient, leading to the so-called fast sweeping method (FSM). Qian and Symes (2002b) had restricted the sweeping to vertical rays, while Buske and Kästner (2004) had considered polar coordinates.

Another alternative approach, the so-called fast marching method (FMM), is based on techniques related to level set methods (Fatemi et al., 1995; Kimmel and Sethian, 1998; Sethian and Popovici, 1999) concerning interface detection and its evolution on a given hypersurface. This technique has been promoted in seismology by Sethian and Popovici (1999), Sethian (2001), and Popovici and Sethian (2002). Rawlinson and Sambridge (2004a,b), de Kool et al. (2006), and Lelièvre et al. (2011a) had illustrated this approach for strongly heterogeneous media including interfaces. Of course, inside each layer, a unique value of propagation time is estimated.

An excellent review has been given by Rawlinson et al. (2007) on both FSMs and FMMs. Accuracy and computer efficiency have been discussed by Leidenfrost et al. (1999) at least for 2-D geometries.

These techniques have been very attractive in many applications, such as first-arrival travel-time delay seismic tomography (Benz et al., 1996; Le Meur et al., 1997; Zelt et al., 2001) (see also **Chapter 1.08** of this book). Because of the monotonic evolution of the travel time inside the Eulerian frame (time increases always away from the source), one can trace back trajectories from the receiver down to the source. However, a few trajectories, specifically for receivers between nodes with first-arrival travel times from different branches, may not be true rays, especially in the case of sharp discontinuities. When inverting a huge amount of data, a few miscomputed travel times will not affect the overall tomographic inversion. Partial derivatives used for velocity tomography, as well as for improved travel-time estimation, can be computed along the ray trajectory during this back ray tracing. For FSM, Taillandier et al. (2009) had used the adjoint formulation for the computation of the velocity model gradient used in seismic tomography, avoiding the back ray tracing Lelièvre et al. (2011b) had taken benefits of the fast marching algorithm for constructing full sensitivity kernels for a given source and for linking some elements of this kernel to the partial derivatives for a specific receiver, once the forward problem has been performed for the selected source.

1.05.2.6 Multivalued Travel Times and Phases: An Eulerian Formulation

Dealing with multiple arrivals increases the complexity of the problem. One way to address this issue is by reducing the travel-time estimation problem to branches where the travel-time branches are unique as suggested by the so-called big ray tracing approach (Abgrall and Benamou, 1999; Benamou, 1996) or the segment projection method (Engquist et al., 2002). We are then back to finding the 'viscous' solution in an Eulerian frame for each branch or each segment as long as we are able to identify them. But this is a difficult detection problem in relation to the Lagrangian analysis of these branches/segments.

Eulerian approaches may be more stable as the information about the wave front is sampled on fixed grids. In these approaches, the spatial resolution of the wave front is controlled by the local discretization size (Osher et al., 2002). However, Hamilton–Jacobi equations have difficulties when wave fronts become folded with multiple travel times. We shall follow a similar strategy as the ray tracing by wave fronts. We may extend the domain of investigation from the physical space to a phase space combining the physical position, as well as the slowness vector, as we have done for rays. The solution for the travel times turns out to be unique at each point of this space, thanks to Liouville theorem.

Hamilton–Jacobi equations have attracted a lot of attention in mathematics for obtaining multivalued solutions. Among the different strategies, let us mention briefly the dynamic surface extension approach (Steinhoff et al., 2000), the slowness matching method (Symes and Qian, 2003), the segment projection method previously mentioned as a Lagrangian method (Engquist et al., 2002), the phase space method (Fomel and Sethian, 2002), the moment-based method (Engquist and Runborg, 1996), and the level set method (Osher and Sethian, 1988). Nice overviews are provided by Benamou (2003) and Engquist and Runborg (2003). A review more oriented toward the seismological community has been provided by Rawlinson et al. (2007).

Instead of artificially extending the eikonal equation as a static Hamilton–Jacobi equation [11] into a dynamic Hamilton–Jacobi equation, let us first illustrate that the ray theory is directly connected to a dynamic system by considering the time formulation instead of a frequency formulation. Let us introduce the phase function $\phi(x,t)$, which can be defined using the following ray *ansatz*:

$$w(x,t) = S(t)e^{iw\phi(x,t)}A_0(x,t) \qquad [12]$$

as a high-frequency solution specified by the quantity ω. Sometimes, the quantity ω is omitted and replaced by its inverse ϵ. However, we keep it as frequency that allows us to

consider the slowness vector and not the wave number vector as is usually done in seismology. The phase ϕ now depends on time as well as the amplitude A_0. Following Engquist et al. (2002), we may deduce the related eikonal equation considering power of the quantity ω as the expression

$$\left(\frac{\partial\phi(x,t)}{\partial t}\right)^2 - c^2(x)(\nabla\phi(x,t))^2 = 0 \qquad [13]$$

which can be recast as

$$\frac{\partial\phi(x,t)}{\partial t} \pm c(x)\nabla|\nabla\phi(x,t)| = 0 \qquad [14]$$

where we need to select which direction the waves go. The transport equation is given as

$$\frac{\partial A_0(x,t)}{\partial t} + c(x)\frac{\nabla\phi(x,t)\cdot\nabla A_0(x,t)}{|\nabla\phi(x,t)|} + \frac{c^2(x)\nabla^2\phi(x,t) - \partial^2\phi(x,t)/\partial^2 t}{2c(x)|\nabla\phi(x,t)|}A_0(x,t) = 0 \qquad [15]$$

This equation, which defines the amplitude evolution, can be recast as

$$\frac{\partial A_0^2(x,t)}{\partial t} + c^2(x)\nabla_x\cdot\left(A_0^2(x,t)\frac{\nabla_x\phi(x,t)}{c(x)|\nabla_x\phi(x,t)|}\right) = 0 \qquad [16]$$

Following Jin et al. (2005), this leads to the conservative transport equation for the amplitude density $\rho = A_0^2/c^2$ expressed as

$$\frac{\partial\rho(x,t)}{\partial t} + \nabla_x\cdot\left(\rho(x,t)\nabla_p\mathcal{H}_2(x,p)_{p=\nabla_x\phi(x,t)}\right) = 0 \qquad [17]$$

Following Ryzhik et al. (1996), one can define the scaled Winger distribution of the high-frequency solution as

$$W_0(x,p,t) = A_0^2(x,t)\delta(p - \nabla_x\phi(x,t)) \qquad [18]$$

such that the so-called energy density W_0 follows the Liouville equation in phase space

$$\partial_t W_0(x,p,t) + \nabla_p\mathcal{H}_2\cdot\nabla_x W_0(x,p,t) - \nabla_x\mathcal{H}_2\cdot\nabla W_0(x,p,t) = 0 \qquad [19]$$

stating that the density W_0 does not vary in time along rays following the symplectic ray equations $dx/dt = \nabla_p\mathcal{H}$, $dp/dt = -\nabla_x\mathcal{H}$. Because the slowness vector p has a known modulus equal to the slowness, the inverse of the velocity, the energy density has only five independent spatial variables plus time for a 3-D geometry (and three independent variables plus time for a 2-D geometry), defined as the reduced phase space. Using the Hamiltonian $\mathcal{H}_2$, this PDE is a Vlasov-type PDE written as

$$\frac{\partial W_0(x,p,t)}{\partial t} + c^2(x)p\cdot\nabla_x W_0(x,p,t) - \frac{\nabla_x c(x)}{c(x)}\cdot\nabla_p W_0(x,p,t) = 0 \qquad [20]$$

A similar expression exists for other Hamiltonian definitions with the corresponding sampling parameter. Let us again underline that the Hamiltonian $\mathcal{H}_1$ provides the simplest expression of the Liouville equation (Engquist and Runborg, 2003).

Let us now describe briefly one of the Eulerian methods for solving these PDEs. At an initial time, the function $W_0(x, p, 0)$ is zero for each component of the phase gradient and, therefore, should stay zero for all time. The method of level set functions developed in other fields (Liu et al., 2006; Osher and Sethian, 1988; Osher et al., 2002; Sethian, 1999) can be used for tracking these functions and their zero level sets. We must add an additional component as we need to evaluate the phase in addition to the phase gradient. The phase remains constant along the bicharacteristic strip, that is, the wave front in our terminology, and, therefore, follows the Liouville equation (this is true for any Hamiltonian, which is homogeneous of degree one in $\nabla\phi$). This results in a 4-D level set function $\Phi(t, x, p)$ for which each component follows the Liouville PDE. In a 6-D phase space, the intersection of the zero level sets of these four functions, once projected into physical space, provides the 2-D wave front at the selected time t.

Initial values $\Phi(0,x,p) = (p_x - \nabla_x\phi_0, p_y - \nabla_y\phi_0, p_z - \nabla_z\phi_0, \phi_0 - C) = (0,0,0,0)$ are obtained from the phase $\phi(x, 0)$ and its gradient. The phase space quantity Φ is obtained at later times using integration of the linear Liouville equation for each component. We may extract the hypersurface as common zeroes of these components and project it down into physical space to define the wave front at that travel time. Because of the high dimensionality of the phase space, we may benefit from the slowness vector having a specified modulus for reducing by one the dimension leading to the so-called 5-D reduced phase space. The level set function Φ has now only three components (instead of four) to be integrated in the 5-D space. The Eulerian approach in this reduced phase space is still a challenging problem, and different techniques have been deployed for reducing the cost of such Eulerian PDE integration.

If we consider only vertical propagation, we may use the z coordinate as the evolution parameter instead of time variable, a typical paraxial approximation (among other paraxial ones). This restriction leads to a 2-D phase space $(x, p_x/|p|)$ for a 2-D (x, z) geometry with a source at the position x_s, z_{depth} for upgoing rays with a negative z increment. Following Qian and Leung (2004, 2006), we may solve the evolution of two functions $\Phi(z, x, p_x/|p| = \xi) = (\Phi_1, \Phi_2)$ where the Liouville equations are

$$\partial_z\Phi_1 + u\partial_x\Phi_1 + v\partial_\xi\Phi_1 = 0$$
$$\partial_z\Phi_2 + u\partial_x\Phi_2 + v\partial_\xi\Phi_2 = 0 \qquad [21]$$

with initial condition $\Phi_1(z_{depth}, x, \xi) = x - x_s$ and $\Phi_2(z_{depth}, x, \xi) = 0$ and the initial travel-time value set to zero everywhere in the 2-D phase space. The initial value $\Phi_1 = 0$ gives the solution for the source at position x_s. By a simple constant shift of the level set, we may consider other source positions at the same depth. The advection velocity field $v = (u, v) = (dx/dz, d\xi/dz)$ governing the motion of the function Φ is just the ray equations in the reduced phase space. The implicit initial curve (x, ξ) defined as $\Phi_1(z_{depth}, x, \xi) = 0$ is multivalued and will stay at the zero value when the evolution parameter z is decreasing, giving us a multivalued wave front. Figure 9 is an illustration of the zero level of $\Phi_1(0, x, \xi) = 0$ at the free surface $z = 0$ for the Marmousi model leading different $p_x/|p|$ values at the same x position (Qian and Leung, 2004, 2006). One may see that solutions between two different grids are identical where the solution is expected to be smooth, while small details are only captured by the finer grid. The definition of the grid sets the

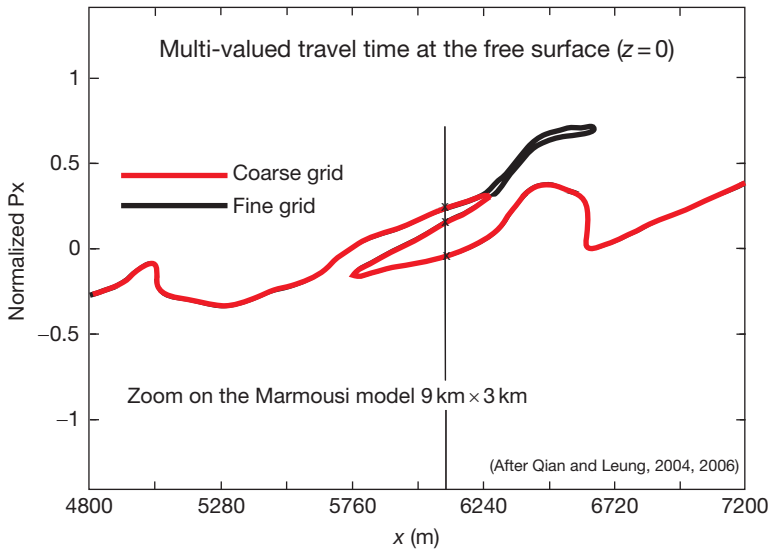

Figure 9 A level set line of the surface $\Phi_1(0, x\, p_x/|p|) = 0$ following the level set method multivalues are found at a fixed x position as noted by the black vertical line. Note that the solution is identical for the coarse grid (red line) and for the fine grid (black line) away from the small branch. The grid selection provides a simple resolution level for the number of multivalues one is looking for.

expected level of resolution. Similarly, zeroes of the $\Phi^2(0, x, \xi)$ will provide travel times. Intersecting the two surface $\Phi_1(0, x, \xi) = 0$ and $\Phi_2(0, x, \xi) = 0$ and projecting it on to physical space provide the multivalued travel times $T(x, z = 0)$ at the free surface. Different ingredients such as reinitialization and orthogonalization will guarantee that the Eulerian sampling is adequately fulfilled. Applications to 2-D anisotropic media have been performed using this paraxial approximation (Qian and Symes, 2002b), and 3-D extension was performed by Leung et al. (2004) using an efficient local level set method. Multi-grid strategy has been proposed by Bokanowski (2013) for even higher dimensions. Although still quite intensive from a computational point of view, solution can be obtained readily for multiple sources, a nice feature when we need to consider problems with many sources. Nice illustrations in seismology have been provided by Hauser et al. (2006, 2008) and reviewed by Rawlinson et al. (2007).

Many other techniques for solving these Hamilton–Jacobi PDEs have also been used. These include finite elements methods, especially the discontinuous Galerkin methods (Cheng and Shu, 2007; Li et al., 2008; Yan and Osher, 2011) on a reduced phase space, which could include discontinuities of the velocity fields as well. Fomel and Sethian (2002), Liu et al. (2006), and Cheng (2007) had also purposed alternative efficient methods for these multivalued estimations of the travel time. Jin et al. (2005) had also investigated similar approaches for other physical observables, such as the amplitudes.

We expect that some of these different methods for estimating phases, as well as the amplitudes, of rays will reach a mature enough level for applications in seismology and seismic exploration in the near future, in spite of difficulties related to the high-dimensional space we must consider.

One may wonder why we have switched to complex nonlinear PDEs for the more familiar linear wave PDE we started with. Several reasons might be advocated including long-range simulations as well as the need for specific quantities within tomographic applications such as the slowness vector. Because the Earth attenuates seismic waves, we may consider that large time integrations or thousands of wavelengths of propagation are not an issue in seismology as it is in geometric optics. However, the Earth is translucid to seismic waves and not transparent. Extracting quantities such as the travel time, the slowness vector, and the amplitude from observed or synthetic seismograms is not an easy task as we shall see, and therefore, ray theory can provide an adequate approach if we need these quantities.

1.05.2.7 Variational Approaches for Ray Tracing

The ray equations can also be considered on the framework of variational approaches where Lagrangian and Hamiltonian formulations can reveal their fruitfulness.

The choice of the Hamiltonians $\mathcal{H}_1$ and $\mathcal{H}_2$ seems to be quite natural ones (especially for anisotropic media) for variational investigations because, only if the Hamiltonian is of second degree is slowness, Lagrangian and Hamiltonian may be related by the Legendre transform defined as

$$L(x, \dot{x}) = p \cdot \dot{x} - H(x, p) \qquad [22]$$

where $\dot{x}$ denoted $\mathrm{d}x/\mathrm{d}\tau$. The Lagrangian, defined in a 3-D space of position x, verifies the Euler–Lagrange equations of second order expressed as

$$\frac{\mathrm{d}}{\mathrm{d}T}\left(\frac{\partial L}{\partial \dot{x}_i}\right) - \frac{L}{\partial x_i} = 0 \qquad [23]$$

Its integral over the ray path is stationary (Hamilton's principle). The travel time is given by the integral

$$T - T_0 = \int_{\tau_0}^{\tau} (L(x, \dot{x}) + H(x, p))\, \mathrm{d}\tau = \int_{x_0}^{x} p \cdot \mathrm{d}x = \int_{x_0}^{x} \frac{1}{c(x)} \mathrm{d}s \qquad [24]$$

where s denotes the curvilinear abscissa. This last integral is stationary for fixed x_0 and x trajectories, which is the reduced least action principle of mechanics, often called

Maupertuis–Euler–Lagrange–Jacobi principle (Arnold, 1976; Goldstein, 1980), or equivalently Fermat's principle in optics.

When the Hamiltonian depends explicitly on the sampling parameter, we may consider the least action principle related to the Poincaré–Cartan invariant. This is the case for the atmosphere where the speed is time-dependent (Abdullaev, 1993). The augmented time-phase space $2n+1$ where the space dimension is denoted by n is always odd-dimensional and has been investigated by many mathematicians as Poincaré and Cartan using differential geometry techniques. When the Hamiltonian $H(x, p)$ does not depend explicitly on time, the dimension of the chosen phase space may be reduced by two (Arnold, 1976, p. 240): as an example, only four ODEs have to be solved in a 3-D medium (Červený, 2001, p. 107).

Although one might not find these identifications between different theoretical formulations necessary, we shall borrow from mechanics and optics well-designed tools for performing ray tracing! As an example, mechanics of small vibrations or equivalently Gaussian optics open a road for performing efficient ray tracing in the vicinity of an already-traced ray, a topic we shall focus in **Section 1.05.2.10**.

Fermat's principle, its minimum time aspect, plays an important role for the computation of travel times when considering first-arrival times only. Finding the shortest path between a source and a receiver leads to network ray tracing. It can be based on graph theory applied to a grid of points with connection between them making a network and related to the well-known traveling salesman problem. The connection between two grid points is the ray and the related travel time between these two points is the fastest one. A very efficient algorithm has been proposed by Dijkstra (1959) and various implementation and modifications have been proposed in seismology (Bai et al., 2007; Klimeš and Kvaskička, 1994; Moser et al., 1992a; Nakanishi and Yamaguchi, 1986). One must be aware that this technique leads to rays, while solving first-arrival times through eikonal approaches leads to travel times. Klimeš and Kvaskička (1994) and Leidenfrost et al. (1999) had shown that these algorithms give smaller errors in travel-time estimation for the network approach than for eikonal discrete solver previously considered (see **Section 1.05.2.11**). Impressive algorithms have been developed by Bai et al. (2009, 2010) considering the shortest path inside each layer, while multiple arrivals are included through the interface discontinuities where transmitted, reflected (or refracted), and converted phases should obey Snell law and Huygens principle. This leads to the same richness of estimated phases as for eikonal solver (Rawlinson and Sambridge, 2004a). The review by Rawlinson et al. (2007) is worthwhile for comparison of methods, while the shortest path algorithm is fully described by Bai et al. (2010).

Drawing rays from the time grid in the eikonal approach is possible and will certainly allow for an accurate recomputation of travel times (Latorre et al., 2004) as bending rays between source and receiver will improve precision for the network approach. Very active algorithmic development may replace, in the near future, fast but less precise tools for locating earthquakes (Bai and Greenhalgh, 2006; Font et al., 2004; Lomax et al., 2000; Moser et al., 1992b), for seismic travel-time tomography (Bai et al., 2008; Benz et al., 1996; Le Meur et al., 1997; Toomey et al., 1994), and for high-definition tomography (Guillaume et al., 2011) as long as the picking of travel times or residual travel times is possible and efficient (Gentili and Michelini, 2006; Rowe et al., 2002; Satriano et al., 2008; Siliqi and Talaalout, 2009; Traonmilin et al., 2009; Zhang et al., 2003). See also **Chapter 1.08** of this book for applications.

1.05.2.8 Transport Equation

When we consider the transport eqn [3], we see that the amplitude estimation is linked to the travel-time field. Multiplying the transport eqn [3] by the complex conjugate of the assumed nonzero amplitude $A_0^*(x)$, we obtain the local property $\nabla\cdot(A_0^*(x)A_0(x)\nabla T(x))=0$. This equation can be deduced as well from eqn [16] when considering a time variation. By following our intuitive presentation backward, we end up with the description of the amplitude evolution expressed as

$$A_0(x_2)=A_0(x_1)\sqrt{\frac{c^2(x_2)J_T(x_1)}{c^2(x_1)J_T(x_2)}} \qquad [25]$$

where the position x_1 (resp. x_2) is implicitly defined by the sampling parameter time T_1 (resp. T_2) and where the elementary surface ds is estimated through the geometric spreading J_T. This geometric spreading factor is obtained by looking at the wave front evolving inside a ray tube defined by neighboring rays with slightly different initial conditions. By noting two variables γ_1 and γ_2 related to the ray position at time T_1 parameterizing the wave front and orthogonal to the wave front normal (**Figure 6**), the geometric spreading can be defined as the Jacobian,

$$J_T=\left|\frac{\partial(x,y,z)}{\partial(T,\gamma_1,\gamma_2)}\right| \qquad [26]$$

from which one can see the dependence of the geometric spreading on the sampling parameter (Červený, 2001, p. 215).

The scalar wave field $w(x, \omega)$ may then be written as

$$w(x,\omega)\approx S(\omega)\phi_w(\gamma_1,\gamma_2)\sqrt{\frac{c^2(x)}{J_T(x)}}e^{i\omega T(x)} \qquad [27]$$

where the expression $S(\omega)$ denotes the signature of the source. The Jacobian might change sign and we must be careful of this as we shall see in the next paragraph. The radiation pattern $\phi_w(\gamma_1, \gamma_2)$ must be found by matching this asymptotic solution and a canonical solution of the exact solution for a local homogeneous medium around the source (coordinates γ_1 and γ_2 evolve with the ray position x). As the source acts as a singularity itself, improved asymptotic solutions have been investigated around the source (Yedlin, 1987). We shall postpone this estimation of the Jacobian when considering the evaluation of seismograms.

Points along the ray where the Jacobian vanishes are called caustic points. Caustic points of the first order, when the rank of the Jacobian matrix [26] is equal to two, make the ray tube shrink into a line. These points create caustic surfaces, which are envelopes of rays classified into folds, cusps, and swallowtails using a terminology related to catastrophic theory (Brown and Tappert, 1987; Gilmore, 1981). Caustic points of the second order, when the rank is equal to one, are often called focus points (**Figure 10**). As the ray crosses a caustic, the Jacobian changes its sign and the phase suffers a negative

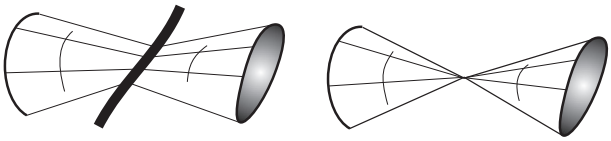

Figure 10 Points along the ray where the Jacobian [26] vanishes are called caustic points. For caustic points of the first order (left), the rank of the Jacobian matrix [26] is two and the ray tube shrinks into a line. For caustic points of the second order (right), the rank of the Jacobian matrix [26] is one and the point is called a focus point.

shift $-\pi/2$ for a first-order caustic and $-\pi$ for a second-order caustic. This shift is estimated through matching different asymptotic solutions (Ludwig, 1966). The phase shift is cumulative along the ray as we cross caustics. The associated index, called the KMAH index as proposed by Ziolkowski and Deschamps (1984) for acknowledging the contributions of J.B. Keller, V.P. Maslov, V. Arnold, and L. Hörmonder, may jump by one or by two depending on the change of rank of the Jacobian. The asymptotic solution for the scalar wave field is then

$$w(x,\omega) \approx S(\omega)\phi_w(\gamma_1,\gamma_2)\sqrt{\frac{c^2(x)}{|J_T(x)|}}e^{i\omega T(x)\mathrm{sign}(\omega)}e^{-i\frac{\pi}{2}\mathrm{KMAH}(x)} \quad [28]$$

1.05.2.9 Acoustic and Elastic Ray Theory

When considering isotropic acoustic and elastic cases, very similar eikonal and transport equations can be derived. Let us first consider the acoustic equation where the density may vary. The eikonal equation is the same as for the scalar wave equation, while the transport equation is

$$2\nabla T\cdot\nabla\left(\frac{A_0^{\mathrm{acous}}}{\sqrt{\rho}}\right)+\frac{A_0^{\mathrm{acous}}}{\sqrt{\rho}}\nabla^2 T=0 \quad [29]$$

which is essentially the same equation as for the scalar wave equation when considering $A_0^{\mathrm{acous}}(x)/\sqrt{\rho(x)}$. Therefore, we can write the pressure

$$P_0(x,\omega) \approx S(\omega)\phi_P(\gamma_1,\gamma_2)\sqrt{\frac{\rho(x)c^2(x)}{|J_T(x)|}}e^{i\omega T(x)} e^{-i\frac{\pi}{2}\mathrm{KMAH}(x)\mathrm{sign}(\omega)} \quad [30]$$

from which one can deduce the asymptotic form of the particle displacement in the acoustic case

$$u_0(x,\omega) \approx S_u(\omega)e(x)\phi_P(\gamma_1,\gamma_2) \sqrt{\frac{1}{\rho(x)|J_T(x)|}}e^{i\omega T(x)}e^{-i\frac{\pi}{2}\mathrm{KMAH}(x)\mathrm{sign}(\omega)} \quad [31]$$

where the vector e denotes the normalized polarization of the wave (orthogonal to wave front) and where S_u is the displacement signature, which can be directly obtained from the pressure signature S.

Without increasing the complexity of notation, we may consider the general anisotropic case for elastic wave propagation. The wave field is now a vector field and the polarization has to be considered (Červený, 2001). The eikonal equation is defined by

$$G_m(x,p)=1, \quad m=1,2,3 \quad [32]$$

where G_m are the eigenvalues of the 3×3 Christoffel matrix defined by

$$\Gamma_{ik}(x,p)=\frac{c_{ijkl}}{\rho}(x)p_j p_l \quad [33]$$

The polarization vectors are the corresponding eigenvectors, and it can be shown that associated amplitudes still satisfy a scalar transport equation involving the geometric spreading along the ray (Červený, 2001, p. 60).

For the isotropic case, two identical eigenvalues $G_1(x,p)=G_2(x,p)=\beta^2(x)p^2$ give two polarizations for the shear wave speed $\beta(x)$ of S waves, while the third eigenvalue $G_3(x,p)=\alpha^2(x)p^2$ is related to the compressional wave speed $\alpha(x)$ of P waves. The corresponding eigenvector $g_3(x,p)$ is simply orthogonal to the wave front. Orthogonal eigenvectors $g_1(x,p)$ and $g_2(x,p)$, corresponding to shear waves, may be estimated through the differential equation

$$\frac{\mathrm{d}g_i}{\mathrm{d}t}=(g_i(x,p)\cdot\nabla\beta(x))g_3(x,p) \quad [34]$$

where $i=1, 2$ (Chapman, 2004, p. 181).

For the anisotropic case, we must consider qS_1 and qS_2 on the one hand and qP on the other hand. We are often unable to obtain explicitly eigenvalues for the anisotropic case, while we can achieve that for the elastic case (Červený, 2001, p. 62). Moreover, the propagation of qS_1 and qS_2 must be considered together because of possible shear wave singularities (Červený, 2001, p. 512). The anisotropic elastic case not only follows the same general scheme as the elastic one but also exhibits some important particularities. For example, the rays are not orthogonal to isochrones in the anisotropic case. The amplitude still satisfies a scalar transport equation involving the estimation of geometric spreading along rays (Červený, 2001).

1.05.2.10 Paraxial Ray Theory

The ray tube can be estimated by tracing neighboring rays, which must be kept nearby the studied ray. Therefore, a small perturbation approach known as paraxial ray tracing should be considered where the paraxial ray is only sensitive to velocity/slowness variations (as well as spatial derivatives) on the central ray. However, the paraxial ray may deviate from a neighboring ray, which samples velocity variations differently (**Figure 11**). Around a given central ray, the perturbation $\delta\gamma^t=(\delta x,\delta p)$ of both the position and the slowness vector follows, to the first order, the linear ordinary differential system

$$\frac{\mathrm{d}\delta\gamma}{\mathrm{d}T}=\begin{pmatrix}\nabla_p\nabla_x\mathcal{H}_0 & \nabla_p\nabla_p\mathcal{H}_0\\ -\nabla_x\nabla_x\mathcal{H}_0 & -\nabla_x\nabla_p\mathcal{H}_0\end{pmatrix}\delta\gamma \quad [35]$$

where the Hamiltonian $\mathcal{H}_0$ has a subscript zero because it is evaluated on the central ray regardless of the perturbation vector $\delta\gamma$ (**Figure 11**). This linear system can be solved following the standard propagator formulation introduced by Gilbert and Backus (1966) in seismology, while Farra and Madariaga (1987) emphasized the Hamiltonian formulation initially introduced by Backus (1964) and Burridge (1976). In this

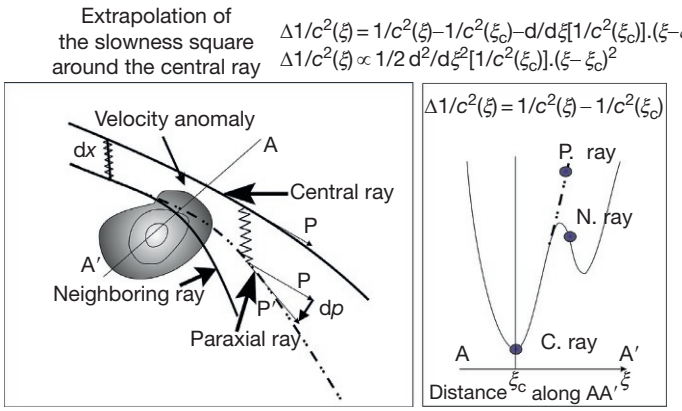

Figure 11 Paraxial ray tracing. The left panel shows the central ray as well as the paraxial ray derived from the velocity anomaly felt by the central ray as symbolized by a spring, Therefore, the paraxial ray is different from a neighboring ray. The right panel shows the difference between the square of the slowness $1/c^2$ in the medium and the parabolic extrapolation of the square of the slowness form the central ray across section AA′. The true velocity profile shown by a continuous line is felt by the neighboring ray, while the approximate parabolic profile, expanded from the central ray and shown by a dash-dotted line when away from the true profile, controls the paraxial ray.

approach, the propagator $P(T, T_0)$ links $\delta\gamma$ at times T and T_0 through

$$\delta\gamma(T) = P(T, T_0)\delta\gamma(T_0) = \begin{pmatrix} P_{xx} & P_{xp} \\ P_{px} & P_{pp} \end{pmatrix} \delta\gamma(T_0) \qquad [36]$$

For example, the submatrix P_{xp} contains partial derivatives of the position x with respect to the slowness vector $p_0 = p(T_0)$, which describes the geometric spreading [26] from a point source and will give us an easy way for computing the cross-sectional area or for caustics detection. In practice, the 6×6 propagator could be reduced to a 4×4 propagator depending on the problem at hand (Červený, 2001; Farra and Madariaga, 1987; Virieux and Farra, 1991). Symplectic symmetries are very important both from a theoretical point of view and from a practical point of view because rays can be traced in either direction without the need for inverting a 6×6 matrix (Červený, 2001; Chapman, 2004; Luneberg, 1964). We have the following relation:

$$P^{-1}(T, T_0) = P(T_0, T) \qquad [37]$$

from which one can deduce the so-called Luneberg relations in optics or Poisson and Lagrange brackets of classical mechanics (Goldstein, 1980). Initial values are defined by

$$P(T_0, T_0) = I_d \qquad [38]$$

where I_d is the identity matrix. For further discussion, Červený (2001) and Chapman (2004) are good references. One must remember that the travel-time function is expanded to the second-order terms when considering paraxial theory. In the configuration space, around a given ray position (x_0, p_0), this leads to the general expression

$$T(x, p_0) = T(x_0, p_0) + \frac{\partial T}{\partial x}(x_0, p_0)\delta x + \frac{1}{2}\delta x^t \mathcal{M}(x_0, p_0)\delta x \qquad [39]$$

where the curvature matrix $\mathcal{M}$, a real matrix in classical ray theory, can be constructed from paraxial quantities, since we have

$$\mathcal{M}(x_0, p_0) = \left(P_{xx}\frac{\partial x}{\partial(\gamma_1\gamma_2 T)} + P_{xp}\frac{\partial p}{\partial(\gamma_1\gamma_2 T)}\right) \times \left(P_{px}\frac{\partial x}{\partial(\gamma_1\gamma_2 T)} + P_{pp}\frac{\partial p}{\partial(\gamma_1\gamma_2 T)}\right)^{-1} \qquad [40]$$

where we have considered point source initial conditions with the two parameters γ_1 and γ_2 describing a two-parametric orthonormal system of rays, that is, a fan of rays (Červený, 2001, p. 235). This expansion may be carried out on a subset of perturbations and in different coordinate systems as we shall see later. The ray-centered system is often used in practice. We must emphasize that solutions to the paraxial equations are coordinate-dependent, while solutions of the ray equations are coordinate-independent, but as we move toward the central ray, paraxial quantities have similar infinitesimal behavior. Let us also remark that the curvature matrix stays invariant through changes in coordinates. Finally, ray coordinates and paraxial ray quantities must satisfy the eikonal equations and perturbed eikonal equations if we want to consider them as rays or paraxial rays (Farra and Madariaga, 1987).

In seismology, we have not yet tackled theories beyond the paraxial one as already performed in optics as the geometric theory of aberrations (Born and Wolf, 1980, **Chapter 1.06**) where the third-order terms around a given ray are considered. These approaches were often developed for homogeneous media and have strong relations with finite-frequency effects and diffraction phenomena we shall consider later on. Note that paraxial ray theory is also very useful for introducing perturbations of the velocity field. Applications of paraxial theory for fast ray tracing (Farra, 1990, 2005; Pšenčik and Farra, 2005; Virieux, 1991) and Fréchet derivatives estimations in tomographic applications (Billette and Lambaré, 1998; Lambaré, 2008) have been proposed.

1.05.2.11 Tools for Ray Tracing

Both ray and paraxial ray equations, which are ODEs, can be solved by numerical tools using Runge–Kutta (RK) of specified order or predictor–corrector (PC) schemes (Press et al., 1994,

Chapter 1.19). Initial boundary problems, where both initial position and initial slowness (i.e., six initial values) are specified, can be efficiently solved. Because we have a first integral of these equations, which is the Hamiltonian/eikonal value, we may efficiently avoid gear-like methods (Press et al., 1994, p. 739) and check accuracy at each integration step by estimating the eikonal constant (Virieux and Farra, 1991). Of course, if we use the reduced Hamiltonian system, we lose this first integral at the benefit of fewer variables to be integrated. Although PC schemes are more superior than RK schemes (only one spatial derivative to be estimated at each integration step whatever the order of precision), we rely essentially on the latter in seismology because it is easy to implement considering its self-starting property. Paraxial equations are linear equations and could be solved with quite significantly coarser integration steps than ray equations. They may be solved in a second step once rays have been found and may well complete with integral formulations of propagator matrices. Other strategies based on analytic solutions inside each cell of a mesh have been considered, although the improved efficiency is effective only when a simple coarse discretization is performed (Červený, 1985; Chapman, 1985; Farra, 1990; Körnig, 1995; Virieux, 1991).

An order of magnitude more difficult is the two-point ray tracing problem where rays between a source and a receiver have to be estimated (Červený, 2001; Červený et al., 1977; Sambridge and Kennett, 1990; Virieux and Farra, 1991). In the frame of ray tracing by rays, we may consider three kinds of local methods for making the ray converge to the receiver. The shooting method corrects an initial value problem until the ray hits the receiver. How to estimate the new initial slowness relies on many different numerical strategies linked to root solver (Press et al., 1994). The paraxial ray turns out to be useful for an efficient Newton procedure (Virieux et al., 1988). The bending method deforms an already-specified curve connecting the source and the receiver. The search is essentially performed in the spatial domain (Farra, 1992; Pereyra, 1992; Pereyra et al., 1980; Um and Thurber, 1987) where each node along the trajectory is perturbed until we may consider it as a ray. The continuation method is based on rays connecting the source and the receiver for very simple velocity structures for which one may find easily the connecting ray. The velocity field is then deformed until it matches the true velocity field (Keller and Perozzi, 1983; Snieder and Spencer, 1993). Fully nonlinear methods of finding initial conditions at the source in order to reach the receiver have also been explored (Sadeghi et al., 1999) at the expense of an exhaustive exploration without any guarantee that all initial conditions have been found. We may find these two-point ray tracing techniques quite inefficient if one has to span the entire medium with many receivers.

Another strategy is the ray tracing by wave fronts presented in a previous section. Paraxial information may help in designing adaptative techniques for fixing ray density according to ray curvature in the phase space (Lambaré et al., 1996; Lucio et al., 1996) (**Figure 8**). Of course, the entire medium is sampled, which may be a quite intensive task compared with the 1-D sampling performed by a single ray. Moreover, these techniques are quite sensitive to strong variations of the velocity.

For multivalued estimations of travel time and amplitude, we may rely on the approaches based on the Lagrangian formulation, but we could also consider Eulerian formulations, which control the complexity of the wave front evolution or, in other words, the number of travel times at a given position through the discretization of the medium we consider. This is a new perspective spreading into the seismological community (Hauser et al., 2008).

1.05.2.12 Eikonal Solver Tools

Three strategies have emerged for computing the fastest travel times following the eikonal equation including the FMM, the FSM, and the short path method. In each case, a discretization of the medium is required in association with a consistent and accurate numerical scheme for verifying the eikonal equation. These numerical schemes should include the causality of the equation (an earlier time is always better than an estimation with a higher value) and should deal with singularities at intersections of characteristics. Variations in the construction of these numerical schemes lead to different performances and, therefore, explain the wide range of related publications. On this topic, once the discretization is done, a large nonlinear system has to be solved.

In the first method, the solution is updated one grid point at a time in such a way that the travel-time estimation is always increasing as we move away from the source. Therefore, an upwind difference scheme following the Godunov scheme (Godunov, 1959) in connection with the Roe solver (Roe, 1981) should be selected, as well as a heapsort algorithm, which will describe the accepted nodes where the time has been computed, the narrow band nodes where the scheme will be applied, and the far nodes where the time is not estimated. Inside the band, the time could be updated if smaller than previous value at the node. Far nodes nearby the edges of the band are integrated for the next iteration. The efficiency of the method relies on the sorting procedure and this leads a complexity O(N ln N) when we consider N nodes. Improved sorting techniques dedicated to the eikonal equation have reduced the complexity to O(N) (Kim, 2001), while the buffered FMM with an additional zone of buffered nodes should be used for anisotropic media (Cristiani, 2009).

In the second method, we also use an upwind scheme in order to get a nonlinear system to be solved, and we shall use Gauss–Seidel iterations with alternating direction sweeping in such a way that characteristics are covered by a group of sweeps. No heapsorting is used and, therefore, the complexity is O(N). For the eikonal equation, strict causality guarantees convergence in a finite number of alternating sweepings (Luo and Qian, 2011; Qian et al., 2007; Zhao, 2005). Moreover, the algorithm is extremely simple to implement and has no difficulties with anisotropy (Qian and Symes, 2002b). Higher-order upwind schemes, especially W-ENO stencils, are often preferred to reduce the number of iterations. Higher-order upwind schemes, especially W-ENO stencils, are often preferred to reduce the number of iterations. Improved accuracy has been obtained using the factorized eikonal equation (Fomel et al., 2009; Luo and Qian, 2012). The travel time is decomposed into two terms as $T = T_0 + \tau$ or $T = T_0\,\tau$ where the solution T_0 is known analytically and captures features of the solution nearby the source. The FSM is only applied to the correction τ term.

The third method is based on the Dijkstra algorithm (Dijkstra, 1959) where the shortest path is found between

one very vertices of a graph and every other vertex with a nonnegative distance between them. The complexity is of order O(N ln N) when using the Fibonacci heap ordering.

Solving the dynamic Hamilton–Jacobi PDE for multivalued travel times follows rules of numerical techniques for these PDEs. Discretization of the (reduced) phase space is required. ENO (Osher and Sethian, 1988; Shu and Osher, 1988) and W-ENO (Jiang and Peng, 2000; Liu et al., 1994; Qiu and Shu, 2005) schemes are designed to adapt stencils for high accuracy and a nonoscillatory property near discontinuities for the estimation of derivatives. These could be applied on structured and unstructured grids. Time integration is performed using total variation diminishing Runge–Kutta methods, which avoid oscillations of the solution during the time evolution by introducing fractional time stepping (Shu and Osher, 1988). A discussion in the geophysical literature is given by Qian and Symes (2002a). Various approaches such as level set methods and discontinuous Galerkin methods are based on such discretizations (Bokanowski et al., 2011; Min, 2004).

1.05.3 Rays at Interfaces

Up to now, we have considered media without any abrupt changes of properties. If there is a sharp contrast, ray theory fails. All that we have seen until now was described for media without discontinuities. "If the medium contains interfaces, that is, discontinuities in the material properties, density or elastic parameters, then the ray theory solution breaks down due to discontinuities in the solution or its derivatives. It is then necessary to impose the boundary conditions on the solution at the interface before continuing the ray solution" (Chapman, 2004, p. 198).

In the context of high-frequency approximation wave trains arriving at an interface can be viewed locally as plane waves hitting a flat interface. Only amplitude variations should require curvature estimations from wave fronts and interfaces. Consequently, many features of plane waves can be generalized to ray theory when dealing with interfaces. Because many textbooks (Aki and Richards, 1980; Červený, 2001; Červený et al., 1977; Chapman, 2004; Kennett, 1983) have described these features in great details, we shall only outline specific features important for rays.

1.05.3.1 Boundary Conditions, Continuity, and Reflection/Transmission Coefficients

As soon as the ray hits an interface, we must estimate quantities such as times, slowness vectors, and amplitudes and consider possible converted rays such as reflected or transmitted rays. Continuity of travel times leads to the Snell–Descartes law, which states that the tangent slowness component is preserved at the interface. This means that the transmitted wave front is moving locally at the same speed as the incident and reflected wave fronts along the interface.

Energy conservation requires continuity of stresses and displacement at the contact point on the interface. "In the seismic ray method, the reflection/transmission coefficients can be locally applied even to a nonplanar wave, incident at a curved interface separating two inhomogeneous anisotropic media" (Červený, 2001). Although these coefficients, called Zoeppritz coefficients, are quite well known (Aki and Richards, 1980; Červený, 2001), let us mention recent results for viscoelastic anisotropic media (Červený and Pšenčík, 2005a,b).

Whatever the formulas to be used, we must stress that slowness components play a key role and that one should avoid any headaches related to multivalued trigonometric functions when implementing numerical tools related to interface conversions.

A very complementary point of view has been proposed for single-valued travel times. As the wave front computed by any eikonal solver hits the interface, one may evaluate travel times along the interface and restart the eikonal solver for either reflection or transmission with these values (Rawlinson and Sambridge, 2004b). Of course, only single-valued travel-time computations may be considered inside each layer, but multiple arrivals coming from interfaces could be considered (Rawlinson and Sambridge, 2004a). A similar procedure is performed by Bai et al. (2010) for the shortest path approach inside each layer but still with multiple arrivals at receivers. We may note as well that discontinuous Galerkin methods for Eulerian multivalued estimation of travel times could be considered as well for discontinuities in the velocity field (Cheng and Shu, 2007; Li et al., 2008; Yan and Osher, 2011).

1.05.3.2 Paraxial Conditions

When dealing with paraxial rays at interfaces, one must consider continuity of travel times up to second order. This continuity is necessary for starting the transmitted or reflected paraxial rays. This second-order continuity requires estimation of curvature of the incident wave, of the interface, and of the converted wave. Pure differential geometry tools have been used by Popov and Pšenčík (1978), while Farra et al. (1989) had developed a more tractable approach for this second-order continuity, thanks to the Hamiltonian formulation.

1.05.4 Ray Seismograms

When properties of the medium vary smoothly with respect to the characteristic wavelengths of the propagating wave train, the source signature $S(t)$ is transported everywhere with a time shift related to the travel time. It is scaled by an amplitude factor and, eventually for the elastic case, polarized toward a specific direction through a polarization vector. Hilbert transformation of the source signature is expected when crossing a caustic. Therefore, the source signature (with a negative sign) is recovered after a second caustic is crossed. The Hilbert transform $S(t)$ of the $S(t)$ function is defined as

$$S(t) = \frac{1}{\pi}\int \frac{S(\xi)}{(t-\xi)}\mathrm{d}\xi \qquad [41]$$

and has as Fourier transform $-\mathrm{sign}(\omega)\, S(\omega)$, which introduces the $-\mathrm{i} = \exp(-\mathrm{i}\pi/2)$ phase shift required by the caustic crossing (Chapman, 1978).

For such computation of seismograms, we need all the rays connecting a source and a receiver. By summing over these rays, we may estimate seismograms as long as receivers are located away from caustic zones. Unfortunately, we may find the computation of these seismograms with contributions

close to caustics difficult. However, techniques have been developed for addressing the problem based on different integral wave decompositions (plane waves, Snell waves, beams, and so on), which are used to smooth out very locally unstable variations of the amplitude.

1.05.4.1 Classical Ray Seismograms

Following Chapman (1978), we may rewrite, in a very compact form, ray seismograms, at a receiver x for an elastic wave emitted by a source x_0 using the frequency domain expression [31]. We end up with a sum over rays, which gives the following asymptotic result:

$$u(x,t) \approx \sum_{\text{rays}} \text{Real}\left[\phi P(\gamma_1,\gamma_2)(x,x_0) \sqrt{\frac{1}{\rho(x)|J_T(x,x_0)|}} e^{-i\frac{\pi}{2}\text{KMAH}(x,x_0)} e(x,x_0)\tilde{S}(t-T(x,x_0))\right] \quad [42]$$

where $\tilde{S}$ is the analytic function associated with the source signature S, which is simply a complex function for the real part and its Hilbert transform for the imaginary part.

There is a priori no difficulty in using this asymptotic formula, except for a few situations. There is a failure of the expression when the receiver is exactly located at a position where the geometric spreading is equal to zero. From eqn [42], we see that amplitude then grows to infinity providing an erroneous expression for the seismogram amplitude. This failure of asymptotic ray theory at caustics is a well-known artifact of the method. Other pathological cases exist within shadow zones where no rays enter, while vibrations still exist (Chapman, 1985). Several solutions have been proposed for solving this problem, where high-frequency singular wave fields are expressed as summations of regular high-frequency asymptotic elementary solutions. Several types of waves can be used like plane waves or Gaussian beams as we shall see.

1.05.4.2 Seismograms by Summation on the Ray Field

1.05.4.2.1 The WKBJ summation

This approach is based on the introduction of high-frequency asymptotics into the wave equation resulting from the spatial horizontal Fourier transform of the scalar wave equation (eqn [7]) in a laterally invariant velocity model, $c(z)$. In the temporal frequency domain, we obtain an ODE for $w(z) = w(\omega p_x, \omega p_y, z, \omega) = w(k_x, k_y, z, \omega)$ as

$$-\omega^2 p_z^2(z) w(z) \frac{d^2}{dz^2} w(z) = f^w(z) \quad [43]$$

with $p_z^2(z) = \frac{1}{c^2(z)} - p_x^2 - p_y^2$ and $f^w(z) = f^w\left(\omega p_x, \omega p_y, z, \omega\right)$ where we introduce slowness vector $\mathbf{p}$ rather than wave number $\mathbf{k}$ where $k = \omega p$. As in the case of ray theory, we can introduce a WKBJ *ansatz* (Chapman, 2004, p. 278)

$$w(z) = S(\omega)\left(\sum_{n=0}^{\infty} \frac{W_n(z)}{(-i\omega)}\right) e^{i\omega\tau(z)} \quad [44]$$

where the expansion is done at constant p_x and p_y. We find, equivalent to the eikonal and transport equation, two equations

$$\frac{d\tau(z)}{dz} = \pm p_z(z) \quad [45]$$

and

$$\frac{d^2\tau}{dz^2}(z) W_0(z) + 2\frac{d\tau}{dz}(z)\frac{dW_0}{dz}(z) = 0 \quad [46]$$

These equations are ODEs that can be easily integrated using analytic or numerical approaches. The sign in eqn [45] determines the up- or downgoing behavior of the wave. Asymptotic WKBJ solutions appear as an extension of plane waves in homogeneous media to heterogeneous 1-D models. These solutions agree with when the velocity model does not depend on depth. Equations [45] and [46] are only valid when the velocity model is continuous in z up to the second order. When there are interfaces, similar to ray solution, high-frequency asymptotic continuity conditions need to be introduced. This reduces to the application of Snell–Descartes law and to the introduction of standard reflection/transmission coefficients.

The WKBJ expansion [44] breaks down when a turning point exists, that is, when the vertical slowness component is zero (Chapman, 2004, p. 286). Another asymptotic expansion can then be applied: the Langer asymptotic expansion (Chapman, 1974; Langer, 1937; Wasow, 1965; Woodhouse, 1974) involving Airy functions (Abramowitz and Stegun, 1972) with finite amplitudes on caustics.

An alternative to the WKBJ expansion [44] has also been the use of WKBJ solution or Bremmer series. This approach allows one to solve the so-called WKBJ paradox (Gray, 1982), that is, whatever the vertical gradient of the velocity, it will never generate a reflected wave. We would expect to observe such a phenomenon at low frequency, but since up- and downgoing waves are fully decoupled in the WKBJ expansion, it will never happen using this approximation. In the iterative WKBJ formulation, we assume that the wave field can be represented as a combination of up- and downgoing first-order WKBJ solutions. This coupling function satisfies an ordinary differential in z called the *coupling equation*, which can be solved iteratively leading to a solution series (de Hoop, 1990; Gray, 1983; Richards and Frasier, 1976; Scholte, 1962; Verweij and de Hoop, 1990).

Once the 1-D wave eqn [43] has been integrated using some high-frequency approximation, it will be necessary to perform the inverse Fourier transform in order to come back to the (x, t) domain. Several methods can be used including the exact technique of the *Cagniard–de Hoop–Pekeris method* (Cagniard, 1939; de Hoop, 1960; Pekeris, 1955a,b), the *WKBJ approach* where the slowness summation is truncated to real values of the travel times (Chapman, 1978), spectral methods such as the *reflectivity method* (Fuchs and Müller, 1971), and *full wave theory* (Aki and Richards, 1980, **Chapter 1.10**). A complete review has been performed by Chapman and Orcutt (1985) using both WKBJ and Langer approximations with applications to realistic profiles in the global Earth.

Truncation errors in the solution (Yedlin et al., 1990) especially in the presence of strong velocity gradients as well as numerical effects coming from smoothing boxcar windows or from convolution operators (Dey-Sarkar and Chapman, 1978) require specific attention when one wants to reconstruct the velocity structure. Reverberations from a stack of layered structures, which can be observed in the *reflecting method*, are well

separated as WKBJ contributions (Shaw, 1986) (see also **Section 1.05.4** of this book).

Finally, if WKBJ approximation is limited to 1-D media and exhibits interesting properties when compared with classical ray theory, WKBJ provides high-frequency asymptotic solutions in the (x, t) domain as summations of high-frequency asymptotic plane waves. Indeed, it appears that these summations may be regular at caustics, providing an interesting opportunity for computing high-frequency asymptotic solutions in those locations where classical ray theory fails. Moreover, as we will see now, extensions of WKBJ summations exist, which allow one to consider fully heterogeneous velocity models.

1.05.4.2.2 Maslov summation

The WKBJ approach is limited to 1-D layered media. Extension to laterally varying media is not straightforward. Approximate solutions assuming only small lateral variations of velocity have been introduced recently by Ni et al. (2003), but a more systematic formation can be based on the Maslov approach using the Legendre transformation (Kravtsov, 1968; Maslov and Fedoriuk, 1981). Maslov summation has been introduced by Chapman and Drummond (1982) in seismology and by Ziolkowski and Deschamps (1984) in electromagnetics. The Maslov approach, which reduces to the WKBJ approach for laterally homogeneous media, involves summation of high-frequency asymptotic local plane waves. In fact, high-frequency asymptotic solutions can be obtained in any of the 3-D subspaces of the phase space, that is, (x, y, p_z), (x, p_y, z), (p_x, y, z), ... or even (p_x, p_y, p_z). These solutions can be obtained by applying the stationary phase approximation (Chapman, 2004) to some Fourier transforms of the high-frequency asymptotic approximations in the (x, y, z) space. For example, we obtain from expression [27]

$$\omega(p_x, y, z, \omega) \approx \sqrt{i\pi \ \mathrm{sign}\left(\frac{\partial^2 T}{\partial x^2}\right)(x_{\mathrm{spec}}, y, z)}\, S(\omega)\phi_\omega(\gamma_1, \gamma_2) \sqrt{\frac{c^2(x_{\mathrm{spec}}, y, z)}{G_T(x_{\mathrm{spec}}, y, z)}}\, e^{i\omega T(x_{\mathrm{spec}}, y, z) - ip_x x_{\mathrm{spec}}} \quad [47]$$

where x_{spec} (p_x, y, z) denotes the specular position (we assume a single specular point), for which $\partial T/\partial x = p_x$, that is, where the Fourier parameter $p_x = k_x/\omega$ fits with the ray field parameter $p_x^{\mathrm{spec}} = \partial T/\partial x$ and the Jacobian G_T is defined by

$$G_T = \left|\frac{\partial(p_x, y, z)}{\partial(T, \gamma_1, \gamma_2)}\right| \quad [48]$$

Once we have these high-frequency asymptotic approximations, we can express the solution in the configuration space as an inverse Fourier transform or equivalently as a p_x slowness integral as in a WKBJ summation. This expression is called the Maslov summation. At high frequencies, this integral expression agrees with the classical ray solution, when it exists. When the classical ray solution is singular (a caustic point), it can be shown from the Liouville theorem (Goldstein, 1980) that there exists at least one alternate projection where the Maslov summation involves regular asymptotic plane waves. Regular high-frequency asymptotic solutions of the wave equation can then be found by blending both the ray solution and the Maslov summations using weighting functions (Chapman, 2004; Chapman and Drummond, 1982; Huang and West, 1997). For nice illustration of the Maslov summation, see also **Section 1.05.4.3** of this book.

Note that equivalent to caustics in classical ray theory, singularities may appear in the elementary high-frequency solution obtained in the other subspaces. They are called pseudocaustics and correspond to zeros of the Jacobian [48] (we follow the terminology of Klauder (1987a) as suggested by Kendall and Thomson (1993)).

A more general approach known as phase partitioning (Kendall and Thomson, 1993) may be used in practical situations where caustics and pseudocaustics cannot be separated. Semantically speaking, the frequency needs to be considered high enough to make them separable. These strategies could be avoided from the theoretical point of view but they are very useful in practice.

1.05.4.2.3 Gaussian beam summation

Another technique of summation will be through local Gaussian beams, which are used in the boundary-layer approach and which originally were applied to the computation of seismograms (see Popov, 1982 for original references in Russian). It has been popularized by Červený and coworkers (1982). One advantage is that individual Gaussian beams have no singularities either at caustics or at pseudocaustics. Moreover, two-point ray tracing is unnecessary and the summation is less sensitive to model parameterizations. A nice review had been given by Nowack (2003). Section of this book will present the formulation in the ray-centered coordinate system.

A Gaussian beam can be defined around a central ray (x_0, p_0) from the paraxial approximation [39],

$$W_{\mathrm{GB}}(x_0 + \delta x, p_0, \omega) = W_{\mathrm{GB}}(x_0, p_0, \omega) e^{i\omega\left(T(x_0, p_0) + p_0\delta x + \frac{1}{2}\delta x^t \mathcal{M}(x_0, p_0)\delta x\right)} \quad [49]$$

where $\mathcal{M}$ is now complex with $\mathrm{Im}(\mathcal{M}(x_0))$ being positive-definite. Note that, although this method has been presented mainly in the ray-centered system of coordinates, it can be constructed in any global coordinate system, such as here by using general Cartesian coordinates. The value of the Gaussian beam along the central ray is given from paraxial quantities [11] and initial curvature matrix [40] by the relation

$$W_{\mathrm{GB}}(T, \omega) = \frac{W_{\mathrm{GB}}(T_0, \omega) e^{i\omega(T - T_0)}}{\sqrt{\det\left(\mathcal{P}_{xx}(T, T_0) + \mathcal{P}_{xp}(T, T_0)\mathcal{M}(T_0)\right)}} \quad [50]$$

The expression remains finite as long as the term $\mathcal{M}(T_0)$ is symmetrical; since the $\mathrm{Im}(\mathcal{M}(T_0))$ is positive-definite, the term $\partial x/\partial(\gamma_1, \gamma_2 T)(T_0)$ is regular. The width of the Gaussian beam depends on the imaginary part of $\mathcal{M}$, which ensures a Gaussian decay of amplitude away from the central ray. The width of the beam varies according to variations of $\mathcal{M}$ and may be chosen according to various strategies. For example, Hill (1990) had proposed to choose an initial complex $\mathcal{M}$ related to an initial beam width w_l at frequency w_l. This has been applied efficiently in prestack depth migration (Gray, 2005; Gray and Bleistein, 2009; Hill, 2001) using Gaussian beam summation (GBS) with a ray sampling compatible with the beam width. Numerical comparisons have been investigated by many authors (Madariaga, 1984; Nowack and Stacy, 2002; Weber, 1988; White et al., 1987) in seismology (**Figure 12**).

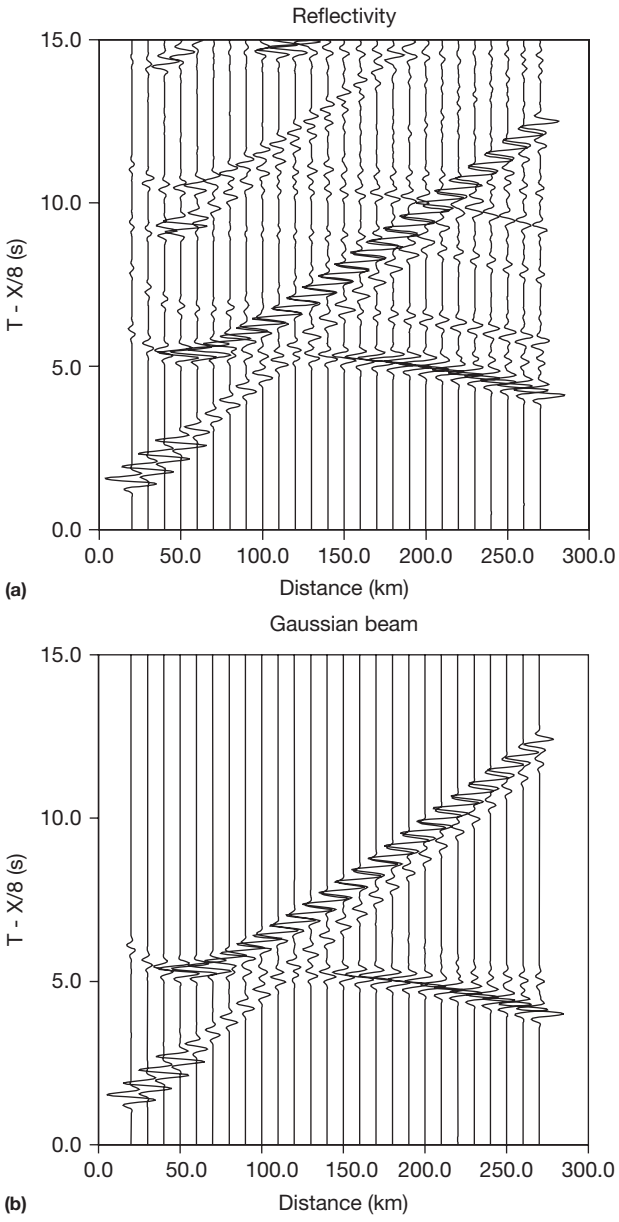

Figure 12 Comparison between Gaussian beam summation (bottom panel) and reflectivity method (top panel). Note that for this comparison, some of the later arrivals shown in the reflectivity modeling were not simulated in the GBS, but could have been included (Courtesy of R. Nowack).

The Gaussian beam solution represents an approximate solution of the wave equation, and their superposition integral represents an asymptotic approximation of the wave field. In practice, once the complex curvature matrix has been chosen at some T_0, the weighting of the various Gaussian beams in the superposition integral has to be defined in such a way as to fit with asymptotic ray theory, where it is regular. By construction, Gaussian beams are always regular and they consequently provide regular high-frequency solutions. GBS may be shown to be equivalent to Maslov summation under the hypothesis of plane wave with infinitely wide Gaussian decay (Madariaga, 1984). This equivalence shows the larger possibilities offered by GBS, with, for example, the advantage of limited truncation artifacts.

1.05.4.2.4 Coherent-state transformation technique

Formulations based on the coherent-state transformation technique (Klauder, 1987a,b) fills the gap between local plane wave decomposition of WKBJ/Maslov approaches and overcomplete beam decompositions with a simple parabolic approximation of the phase function (Thomson, 2001, 2004). This allows us to preserve many tracing tools for real rays. A comparison between the Maslov approach, the Gaussian approach, and the Coherent-state approach has been performed by Albertin et al. (2001).

Attempts have been made to move toward complex rays where both amplitudes and travel times are complex functions because analytic continuation of velocity variation is easily possible for simple analytic function (Deschamps, 1971; Felsen, 1976, 1984; Keller, 1971; Wu, 1985; Zhu and Chun, 1994b). However, extension to arbitrary numerical velocity variations is still a challenging problem, although recent work (Amodei et al., 2006) seems to solve the analytic continuation for numerical velocity variations, opening the road to more applications of complex ray theory for heterogeneous media.

1.05.4.3 The Geometric Theory of Diffraction

In addition to previous strategies, which can be used to avoid caustic singularities or to estimate fields inside shadow zones in smooth media, other uniform ray expansions are also possible when considering caustics (Kravtsov, 1964; Ludwig, 1966) using Airy functions or at discontinuities, where the wave field creates a shadow zone. Although rather sophisticated tools of Riemannian geometry are required, we may adopt a more phenomenological point of view and illustrate the geometric theory of diffraction introduced by Keller (1962). Justification of Keller's formulation from a mathematical point of view, especially when media have variable velocity, has generated an impressive list of references, and they are fruitful monographs by Babič and Kirpičnikova (1979), Babič and Buldyrev (1991), and Klem-Musatov (1995). Nice reviews by Kravtsov (1968), Babič (1986), and Hron and Chan (1995) will help the reader in understanding the various methods for the construction of asymptotic solutions.

The method of canonical problems transforms the problem at hand into a simpler problem. By matching asymptotically field expansions for a simpler problem, expansion coefficients can be estimated (Keller, 1962). The best example is the diffraction of an arbitrary wave field from a body with a rib, which can be transformed into the diffraction of a plane wave by a wedge. A boundary-layer formulation can be used and express the solution in the transition zone, the width of which goes to zero when the frequency goes to infinity (Babič, 1975; Buchal and Keller, 1960). This approach related to the method of parabolic equations (see reference works in Fock, 1965) does not require any analytic solutions as for the canonical matching approach.

On a linear edge, an incident plane wave is reflected creating illuminated and shadow zones for the reflection wave front (**Figure 13**). Energy will flow into the shadow zone, and

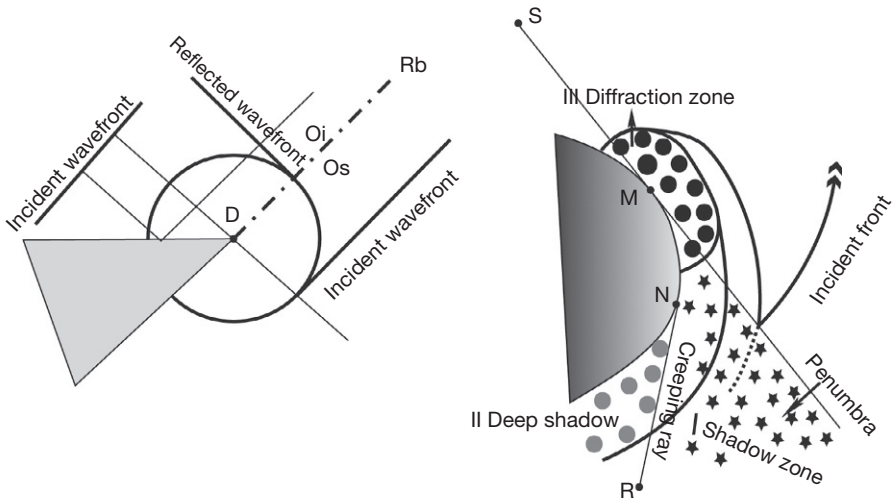

Figure 13 Geometric interpretation of diffraction. On the left panel, the gray diffracting object does not allow wave penetration. The reflection wave front is connected to the diffraction front emitting from point D. This wave front is connected to the incident wave front. Ray *Rb* separates the reflection zone and the diffraction zone. On the right panel, waves may penetrate the diffracting body. The line SM separates the penumbra zone and the lighted zone. Because a creeping ray leaves the obstacle at the point N (which is defined both by the front and the interface curvatures for a specific ray), we shall distinguish the deep shadow zone (II) from the standard shadow zone. The diffraction zone (III) will move into the lighted zone behind the converted front related to the first diffraction at the point M (I). These limits will be very sensitive to the frequency content of the wave and ad hoc corrections are necessary to keep the ray approximation as a useful interpretation tool.

asymptotically, this diffraction may be well modeled by diffraction rays, which follow an eikonal equation with a source at point D. Therefore, we must consider both reflected waves and edge waves. Their wave fronts must coincide along the shadow boundary. The boundary ray separating illuminated and shadow zones does not follow the usual transport equation and a dedicated theory is required. Comprehensive analysis based on earlier work has been given by Klem-Musatov (1995) to compute scalar diffraction amplitudes (see the review by Hron and Chan, 1995).

The surface limiting the illuminated and shadow zones may have a complex geometry (Borovikov and Kinber, 1974). For a convex body limited by a discontinuous surface, three zones in the shadow may be distinguished: the neighborhood of the shadow zone (I), the neighborhood of the body surface (II), and the intersection of these two zones (III), related to the point M of the surface hit by the grazing ray (see **Figure 13**).

In seismology, diffractions by the core–mantle or inner core boundaries of the Earth require a deep understanding of these approaches (see the interesting presentation by Thomson, 1989). Because seismology deals with elastic propagation, Thomson (1989) stressed that the boundary-layer method can be applied when considering P and S wave fields as long as P and S grazing rays do not hit the boundary at the same point. A canonical solution with detailed elastic diffraction coefficient estimates has been constructed in 3-D for crack diffraction by Achenbach and Gautesen (1977). Further improvements can be performed in this direction for elastic diffraction in the future.

1.05.5 Finite-Frequency Effects

The ray path connecting a source S and a receiver R is a trajectory along which the high-frequency part of the energy is propagating. Because the frequency we consider is always finite, the wave field at the receiver is also modified by the velocity distribution in the vicinity of the ray. This volume, called the Fresnel volume, may be defined in a very simple way for a wave frequency content f. Any point F of this volume should satisfy the inequality (Kravtsov and Orlov, 1990)

$$|T(\mathrm{S},\mathrm{F}) + T(\mathrm{F},\mathrm{R}) - T(\mathrm{S},\mathrm{R})| \leq \frac{1}{2} f^{-1} \qquad [51]$$

Basically, this means that only points that satisfied inequality [51] will contribute significantly to the seismogram at the receiver around time T(S, R). Often, we call the Fresnel volume a physical ray (Červený, 2001, p. 115). This volume plays a key role for resolution estimation of seismic imaging methods in relation with the validity domain of ray theory (Kvasnička and Janský, 1999). We will now consider a procedure linking model perturbations and seismogram perturbations, which allows us to introduce the contributions of this volume to seismogram computation.

Before going into these linearized approximations, we must emphasize the path integral approach where any trajectory connecting the source and the receiver may contribute to seismogram estimation (Lomax, 1999; Schlottmann, 1999; Thomson, 2001). Although we have not yet found a practical way of assessing convergence toward the true solution of these integrals, these methods exhibit nonlocal behaviors, which make them completely different from approaches we gave consider up to now.

We can see that the travel time, a very robust observable from seismograms, has an implicit frequency context, which one should be aware of for different applications in seismology. Therefore, we need to be concerned about procedures for extracting travel times as was recognized a long time ago through the International Seismological Centre (ISC, www.isc.ac.uk) as promoted by John Milne at the beginning of the twentieth century.

1.05.5.1 Travel-Time Estimation, A Data Mining Issue

A manual picking strategy is still used for identifying seismic phases, but more and more automatic picking approaches are routinely performed as the number of seismograms has increased exponentially in recent years. Nolet (1987) discussed the statistics of picking travel times in seismology when their probability distribution is away from Gaussian one. It is still an active research area where objective analysis of seismogram structure needs to be performed. We may consider data-driven strategies where only observed seismograms are analyzed (Chevrot, 2002; Gentili and Michelini, 2006; Rowe et al., 2002; Zhang et al., 2003) and model-driven strategies where observed seismograms are compared with synthetic ones computed in a reference model. Using a data-driven strategy, Maggi et al. (2009) had performed time window detection either on observed seismograms or on synthetic seismograms while Lee and Chen (2013) have developed a frequency-time window detection. Sigloch and Nolet (2006) had used cross correlation between observed and synthetic data computed with ray theory for picking travel times, while Satriano et al. (2008) had underlined the interest of performing the picking by cross correlation iteratively as models are updated during tomographic reconstruction. Other ways of picking travel times as well as curvatures, especially once wave propagation effects have been removed by time migration, have been performed by a dense systematic extraction over a 5-D seismic cube (x_s, x_r, t) (Hardy, 2003; Jones, 2013; Siliqi et al., 2007). Zaroli et al. (2010) had combined both time windowing and cross correlation for increasing the number of travel-time picks to hundreds of thousands, but still far below the millions of handpicked arrivals. They argued that the distribution of their automatic *S*, *ScS*, and *SS* picked times shows finite-frequency effects including wave front healing the frequency dependence of *ScS* times and the average dispersion for *S* and *SS* travel times favors a frequency-dependent attenuation model.

The extraction of seismic observables is linked with comparisons of seismograms through the definition of misfit criteria (Kristeková et al., 2006, 2009). These criteria are widely used not only for intercomparisons of numerical methods but also for various full waveform inversions. Amplitude can also be extracted from seismograms, as well as instantaneous phases and envelopes (Bozdağ et al., 2011; Fichtner et al., 2008; Tape et al., 2007).

One can see that data mining is a crucial step in seismic analysis and in ray approach that is widely used for the extraction of observables from seismograms.

1.05.5.2 Ray + Born/Rytov Formulation

This resolution of the seismic inverse problem (recovering the elastic parameter field from the seismic data) is one of the major challenges of seismology. The problem is huge ill-constrained and nonlinear inverse (Tarantola, 1987), which has to be addressed in some appropriate ways. For example, as soon as we have some reasonable initial model for the elastic parameters, one may build a linearization of the relation connecting the data perturbation to the model perturbation. This is the Born approximation, which has been widely used as a basis for linearized seismic inversion (Beylkin, 1985; Beylkin and Burridge, 1990; Tarantola, 1984b, 1986). In fact, the Born approximation is only the first-order term of a recursive relation connecting a seismic wave field perturbation $\delta w(\mathrm{r}, \omega)$ to a model perturbation $\delta m(\mathrm{x})$ (Hudson and Heritage, 1981). We may write for the squared slowness perturbation $\delta m(\mathrm{x}) = 1/c^2(\mathrm{x}) - 1/c_0^2(\mathrm{x})$ (where $c_0(\mathrm{x})$ denotes the velocity in the reference model) a set of relations

$$\delta w_{n+1}(\mathrm{r}, \omega) = \omega^2 \int_V \mathrm{d}x\ \delta m(\mathrm{x})\ G_0(\mathrm{r}, \omega; \mathrm{x})(\delta w_n(\mathrm{x}, \omega) + w_0(\mathrm{x}, \omega)) \quad [52]$$

where n denotes the order of the Born approximation, V denotes the full space volume, and $G_0(\mathrm{r}, \omega; \mathrm{x})$ denotes the Green function for a point source at position x and a receiver at position r in the reference velocity model. We have for the first-order perturbation $\delta w_0(\mathrm{x}, \omega) = 0$, which provides the classical Born approximation, that is, a linearized approximation for $\delta \mathrm{w}$, (r, ω); the Born approximation can be extended to acoustic and elastic media (Ben Menahem and Gibson, 1990; Gibson and Ben Menahem, 1991).

The reference model can be chosen to be homogeneous in order to take advantage of exact and explicit expression of reference Green function. For realistic problems, inhomogeneous reference models are necessary and lead to the distorted Born approximation (Chapman, 2004). In this case, it is possible to use an approximate expression of the Green function as it can be obtained by ray theory, for example. We obtain then the WKBJ + Born (Clayton and Stolt, 1981; Ikelle et al., 1988) or ray + Born approximations (Bleistein, 1984, 1987; Beylkin, 1985; Beydoun and Mendes, 1989; Beylkin and Burridge, 1990; Cohen et al., 1986; Jin et al., 1992; Thierry et al., 1999a,b; Operto et al., 2000; Xu and Lambaré, 2004; Xu et al., 2001, 2004) widely used for seismic imaging. From the expression [52], the ray + Born approximation can be expressed for the perturbation of the Green function as

$$\delta G(\mathrm{r}, \omega; \mathrm{s}) = \omega^2 \int_V \mathrm{d}x \delta m(\mathrm{x}) \mathcal{A}(\mathrm{r}, \mathrm{x}, \mathrm{s}) \mathrm{e}^{\mathrm{i}\omega T(\mathrm{r}, \mathrm{x}, \mathrm{s})} \quad [53]$$

where $A\ (\mathrm{r}, \mathrm{x}, \mathrm{s}) = A\ (\mathrm{s}, \mathrm{x})$ is the product of the amplitude of asymptotic Green functions for the rays $\mathrm{x} \rightarrow \mathrm{s}$ and $\mathrm{x} \rightarrow \mathrm{r}$ in the reference velocity model and $T\ (\mathrm{r}, \mathrm{x}, \mathrm{s}) = T\ (\mathrm{r}, \mathrm{x}) + T\ (\mathrm{s}, \mathrm{x})$ is the sum of the corresponding travel times. **Figure 14** shows common offset traces obtained using the ray + Born approximation. See also Section 1.07.4 of this book for the application to regional and global scales.

Since we use, in the ray + Born approximation, high-frequency approximation of the Green function in eqn [52], there may be difficulties iterating these equations even if generally smooth reference velocity models are used. For remedying this, Coates and Chapman (1990) and Chapman and Coates (1994) proposed a generalization of the Born approximation, which takes into account approximate Green function. This generalization emphasizes a difficult aspect of the use of the ray + Born approximation, the definition of limits for the perturbation approach related to the reference velocity model selection. These limits are related to limitations of ray theory and to first-order Born approximation. Practically, the reference velocity model should be valid for ray theory but should also be sufficiently heterogeneous for

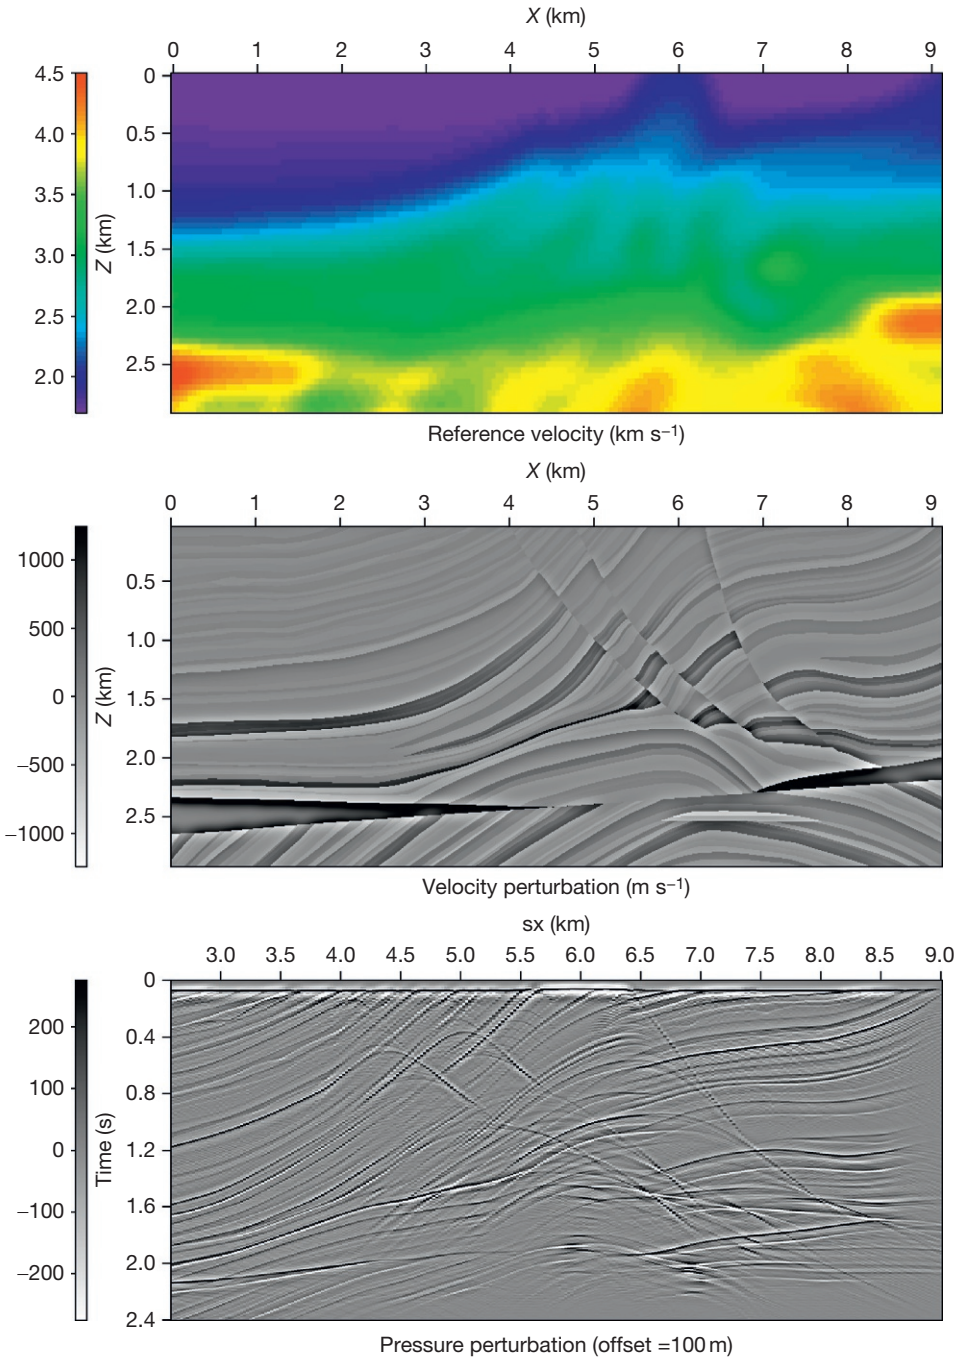

Figure 14 The ray + Born approximation. The Marmousoft model and dataset (Billette et al., 2003). On the top panel, the smooth reference velocity model; the middle panel, the velocity perturbation; and the bottom panel, the common offset section (offset is 100 m) profile.

reproducing the main features of the forward seismic wave propagation in the perturbed velocity model. In terms of ray tracing, it means that the reference velocity model should preserve, within the precision of the propagated wavelengths, the travel time of the forward propagation.

In practice, the ray + Born approximation essentially works for small-sized heterogeneities and for small angles of reflection or diffraction (Beydoun and Tarantola, 1988; Keller, 1969; Wu, 1989). This is the context of reflection seismic exploration, where linearization has been proposed (Lailly, 1983; Tarantola, 1984a,b), and even nonlinear seismic inversions (Pica et al., 1990; Tarantola, 1986) based on local iterative optimization schemes. In fact, the limitations of the standard local optimization methods have been recognized (Gauthier et al., 1986; Jannane et al., 1989; Kolb et al., 1986) and credited to the strong nonlinearity of the problem where the long-wavelength components of the velocity model expressed through the asymptotic Green function in eqn [53] are decoupled from the short-wavelength components expressed through the model perturbation δm in eqn [53].

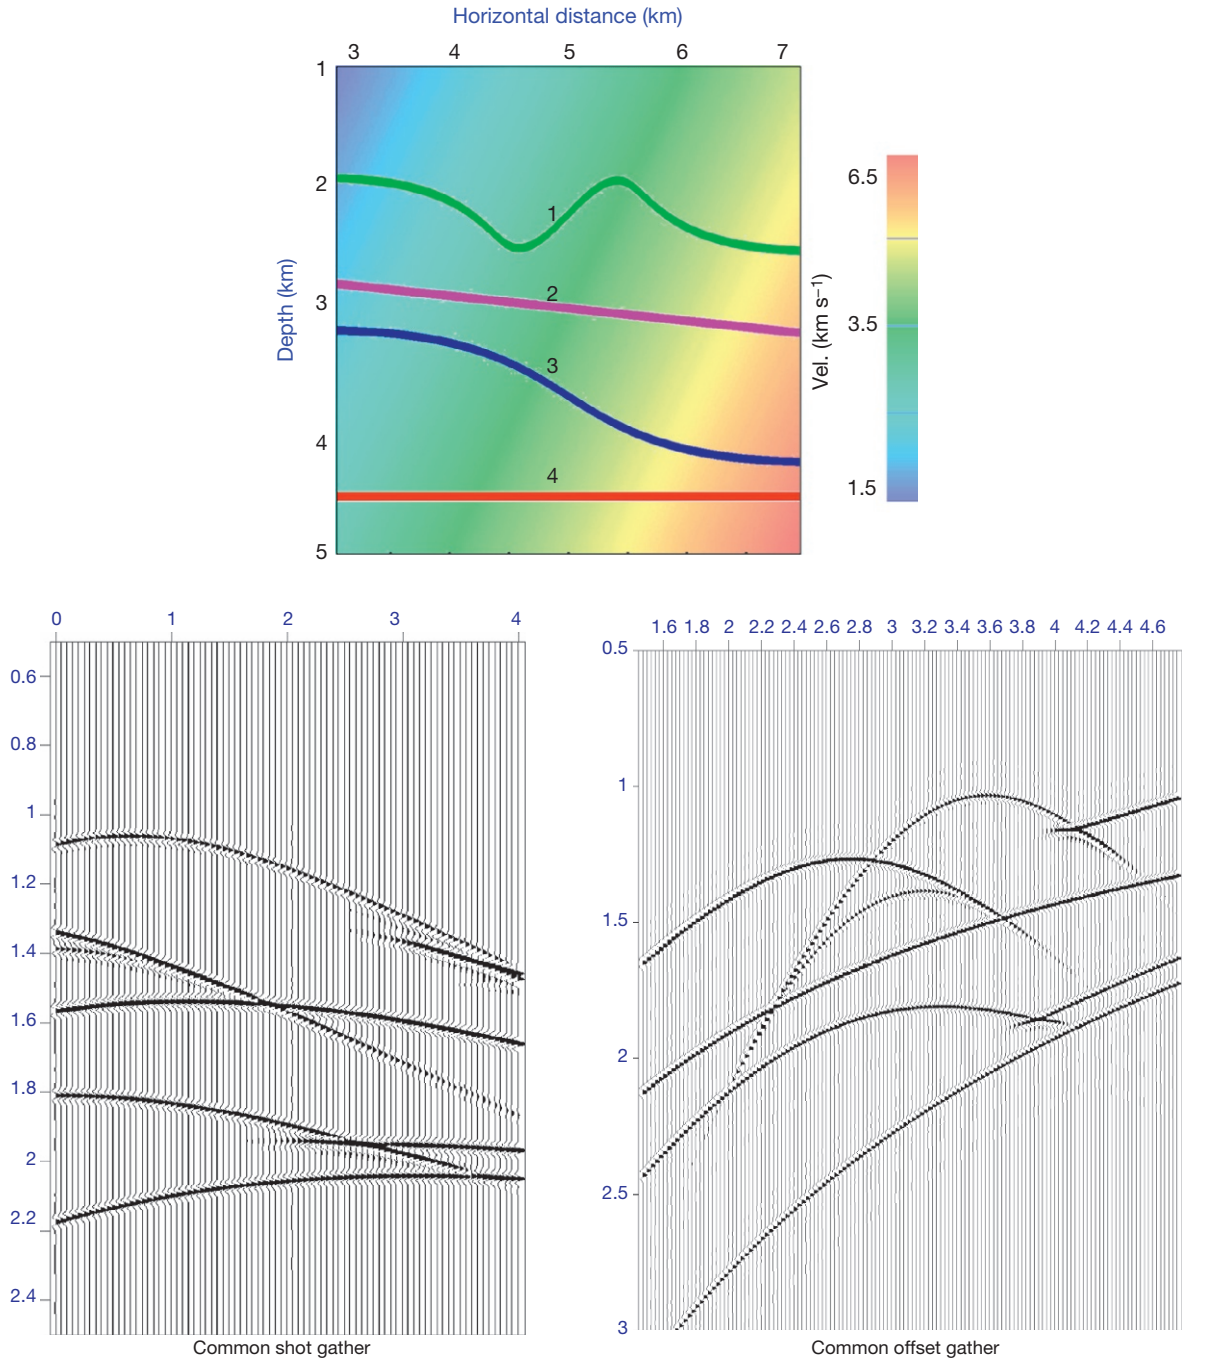

Figure 15 Synthetic seismograms using the Kirchhoff summation. On the top panel, the smooth velocity model (tilted gradient of the velocity). Along with four superimposed reflectors. On the bottom panel, the left plot shows a common shot gather modeled by ray + Kirchhoff summation, while the right plot shows a common offset gather modeled by ray + Kirchhoff summation. Courtesy of R. Baina (OPERA, France).

Changing the dataset from traces to phases could allow a better coupling between the spectral contents of the velocity model (Billette and Lambaré, 1998; Bishop et al., 1985; Farra and Madariaga, 1988). The quantity $\delta\phi = \mathrm{In}(\omega/\omega_0)$, the phase of the wave field, could be expressed to first order as

$$\delta\Phi(\mathrm{r},\omega) \approx \omega^2 \int_V \mathrm{d}x\,\delta\mathrm{m}(\mathrm{x}) \frac{\mathcal{A}(\mathrm{r},\mathrm{x},\mathrm{s})}{\mathcal{A}(\mathrm{r},\mathrm{s})} \mathrm{e}^{\mathrm{i}\omega(\mathcal{T}(\mathrm{r},\mathrm{x},\mathrm{s})-\mathcal{T}(\mathrm{r},\mathrm{s}))} \qquad [54]$$

which has similar terms as the Born eqn [53] except for the phase term, which has a travel-time delay and, therefore, a short-wavelength contribution to the model perturbation. This Rytov approximation is expected to fit the perturbed transmitted wave field better than the Born approximation (Beydoun and Tarantola, 1988; Keller, 1969; Rytov et al., 1987; Samuelides, 1998). Until now, it has not been applied much to seismic inversion (Devaney, 1981; Nahamoo et al., 1984) in spite of recent work (Gélis et al., 2007).

1.05.5.3 Ray + Kirchhoff Approximation

The Born approximation is not the only linearized approximation used for seismic modeling and inversion. In the context of reflection seismic exploration, the first-order Kirchhoff approximation is so far the most preferred. This approximation provides a relationship between the primary reflected wave field and the distribution of reflectivity in the model. This approximation is derived from the representation theorem (Aki and Richards, 1980), which allows one to express any causal wave field, $w(\mathrm{x}, \omega)$ associated with the source distribution, $f(\mathrm{x}, \omega)$, as a volume integral over the volume V of source distribution and a surface integral over the volume boundary δV

$$w(\mathrm{r}, \omega) = \iiint_V \mathrm{d}x\, \mathrm{G}(r, \omega; \mathrm{x}) f(\mathrm{x}, \omega) + \iint_{\delta V} \mathrm{d}x \left(\frac{\partial G}{\partial n}(\mathrm{r}, \omega; \mathrm{x}) w(\mathrm{x}, \omega) - \mathrm{G}(\mathrm{r}, \omega; \mathrm{x}) \frac{\partial w}{\partial n}(\mathrm{x}, \omega) \right) \quad [55]$$

where $\delta/\delta n$ denotes the spatial derivative along the outer normal to the surface. Let us assume now that we consider Green function, that is, $\omega(\mathrm{x}, \omega) = \mathrm{G}(\mathrm{x}, \omega; \mathrm{s})$ or equivalently $f(\mathrm{x}, \omega) = \delta(\mathrm{x} - \mathrm{s})$, and that the volume V is bounded by a reflecting surface. We can then express the reflected wave field as

$$G_{\mathrm{refl.}}(\mathrm{r}, \omega; \mathrm{s}) = \iint_{\delta V} \mathrm{d}x \left(\frac{\partial G}{\partial n}(\mathrm{r}, \omega; \mathrm{x}) G_{\mathrm{refl.}}(\mathrm{x}, \omega; \mathrm{s}) - \mathrm{G}(\mathrm{r}, \omega; \mathrm{x}) \frac{\partial G_{\mathrm{refl.}}}{\partial n}(\mathrm{x}, \omega; \mathrm{s}) \right) \quad [56]$$

where G is the free-space Green function (Bleistein, 1984; Chapman, 2004) (i.e., the direct wave from the source that does not interact with the scatterer). The reflected field is expressed as a summation over the unknown reflected wave field. In the framework of high-frequency asymptotics, it is possible to approximate the reflected wave field on the reflecting interface from the incident wave field and the reflection coefficient. This result is in the Kirchhoff approximation (Bleistein, 1984; Frazer and Sen, 1985) in 3-D geometries as

$$G_{\mathrm{refl.}}(\mathrm{r}, \omega; \mathrm{s}) = i\omega \iint_{\delta V} \mathrm{d}x \mathcal{R}(\mathrm{r}, \mathrm{x}, \mathrm{s}) \mathcal{A}(\mathrm{r}, \mathrm{x}, \mathrm{s}) \mathrm{e}^{\mathrm{i}\omega T(\mathrm{r}, \mathrm{x}, \mathrm{s})} \quad [57]$$

where

$$\mathcal{R}(\mathrm{r}, \mathrm{x}, \mathrm{s}) = q(\mathrm{x}, \theta(\mathrm{r}, \mathrm{x}, \mathrm{s})) R(\mathrm{x}, \theta(\mathrm{r}, \mathrm{x}, \mathrm{s})) \quad [58]$$

denotes the product of the reflection coefficient $\mathrm{R}(\mathrm{x}, \theta)$ and of the stretching factor, $q(\mathrm{x}, \theta) = |\nabla_{\mathrm{x}} \mathcal{T}| = 2\cos\theta / c(\mathrm{x})$, where θ denotes the half aperture angle between ray $\mathrm{x} \to \mathrm{s}$ and $\mathrm{x} \to \mathrm{r}$. Expression [58] is reciprocal for the source and receiver positions (Ursin and Tygel, 1997). The Kirchhoff approximation can be easily extended to the acoustic and elastic cases (Chapman, 2004; Ursin and Tygel, 1997), where a summation is done for any interface and any mode conversion. See an example of Kirchhoff summation in **Figure 15**.

We see when comparing expressions [53] and [57] that the ray + Born and ray + Kirchhoff expressions are very similar. This similarity can be enhanced further if we extend the summation from a surface to a volume, assuming that the whole reflected wave field can be built by stacking contributions of individual reflectors. In this case, we consider a volumetric distribution of specular reflectivity $R(\mathrm{x}, \theta(\mathrm{r}, \mathrm{x}, \mathrm{s}))$

$$G_{\mathrm{refl.}}(\mathrm{r}, \omega; \mathrm{s}) = i\omega \iiint \mathrm{d}x\, q(\mathrm{x}, \theta(\mathrm{r}, \mathrm{x}, \mathrm{s})) R(\mathrm{x}, \theta(\mathrm{r}, \mathrm{x}, \mathrm{s})) G(\mathrm{s}, \omega, \mathrm{x}) G(\mathrm{r}, \omega, \mathrm{x}) \quad [59]$$

where the 3-D Green functions, $G(\mathrm{s}, \omega, \mathrm{x}) = A(\mathrm{s}, \mathrm{x}) \mathrm{e}^{\mathrm{i}\omega T(\mathrm{s}, \mathrm{x})}$ and $G(\mathrm{r}, \omega, \mathrm{x}) = A(\mathrm{r}, \mathrm{x}) \mathrm{e}^{i\omega T(\mathrm{r}, \mathrm{x})}$, have to be calculated in some reference velocity model.

The Born and Kirchhoff approximations are in widespread use and are the basis of numerous seismic imaging methods. In practice, even if the derivation of the formulas relies on high-frequency asymptotics, the asymptotic Green functions in expression [59] are sometimes replaced by other types of numerical Green functions like one-way paraxial approximation of the wave equation (Claerbout, 1970), two-way extrapolation approaches (Kosloff and Baysal, 1983; Sandberg and Beylkin, 2009), or reverse-time migration (Baysal et al., 1983; McMechan, 1983). Most depth migration methods consider these Green functions in order to recover the reflectivity function at any point of the medium, knowing some reference velocity model. When ray-based Green functions are used, this type of migration is called Kirchhoff migration (Bleistein, 1987; French, 1974, 1975). It is widely used in the petroleum industry for 3-D depth migration (Xu and Lambaré, 2004; Xu et al., 2004), while applications at crustal and mantle scales may also be possible (see Section 1.7).

1.05.5.4 Finite-Frequency Effects on Ray Functions

Away from waveform estimation and fitting, can we introduce finite-frequency features for travel-time and/or amplitude analysis? Filling the gap between, on the one hand, travel-time inversion and, on the other hand, full waveform inversion has gained the attention of many workers since the pioneering work of Luo and Schuster (1991) and Woodward (1992). The concept of wavepath (Woodward, 1992) as the product of the incident wave field from the source and the back-propagated wave field from the receiver displays well the Fresnel volume (**Figure 16**). Points moving away from the first Fresnel zone bring higher-frequency content into the image reconstruction, especially for waveform fitting (Operto et al., 2004; Pratt et al., 1996).

Linear kernels, often called Fréchet kernels, have been introduced for travel time. A recent and impressive literature on surface waves (Marquering et al., 1998, 1999; Zhou et al., 2004), normal modes (Katzman et al., 1998; Li and Romanowicz, 1995; Li and Tanimoto, 1993; Tanimoto, 1995; Zhao et al., 2000), and rays (Dahlen et al., 2000; Hung et al., 2000; Montelli et al., 2004a,b) shows the vitality of such a concept. Discontinuities such as internal boundaries and interfaces have been introduced as well (Dahlen, 2005; Xie and Yang, 2008). The range of sensitivity kernels have increased rapidly for various model perturbations and propagation configurations. All of them are related to Fresnel optics as they are confined to a point-to-point geometry. Correspondence with the Fraunhofer optics could also be done using plane wave decomposition (Iturben et al., 2009). A nice review had been performed by Nolet (2008). For example, the time delay δT at a

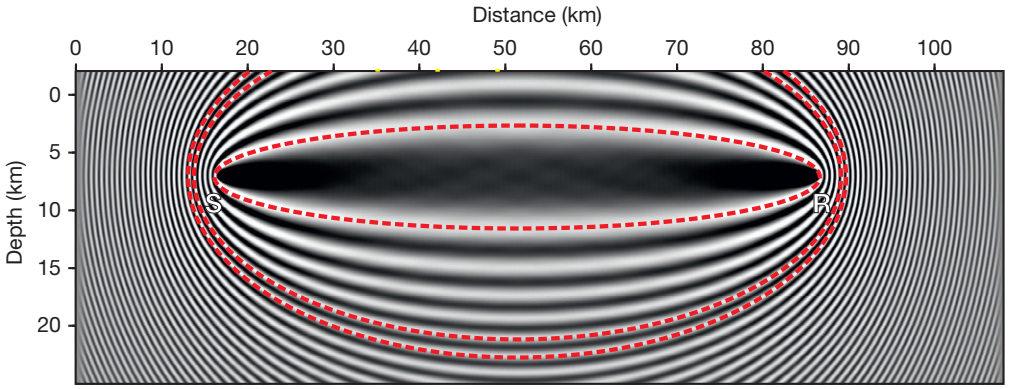

Figure 16 A simple description of wavepath. The first Fresnel zone (the red dashed line) is the zone of main contribution for diffraction when considering finite-frequency effects. As we introduce other Fresnel zones, smaller-scale features are (included in) both the medium description and the seismogram estimation. Courtesy of S. Operto, CNRS.

given receiver r coming from a scattering point x for a given source s is associated with the time difference $\Delta T(s,r,x,\omega) = T_{sr} - T_{sx} - T_{xr}$ through the equation

$$\delta T(s,r) = \int_D K_t(\mathrm{x},\omega)\frac{\delta_c(\mathrm{x})}{c(\mathrm{x})}\mathrm{d}V \qquad [60]$$

where the integration domain D is over diffracting points x. This domain must be defined carefully. The Fréchet kernel or sensitivity kernel $K_t(x, \omega)$ has an expression depending on frequency ω, time difference ΔT (s, r, x, ω) for a path to the scattering point, and three synthetic amplitudes or geometric spreadings between the pairs (source and receiver, source and diffracting point, and receiver and diffracting point) (Nolet, 2008, p. 127). Dahlen et al. (2000) had developed a systematic use of paraxial theory, which speeds up significantly the estimation of the sensitivity kernel especially for mantle tomography; however, one may need to consider true rays between source/receiver and diffracting points in the crust (Gautier et al., 2008). Applications to amplitudes (Dahlen and Baig, 2002) and to anisotropy (Favier and Chevrot, 2003) (with the splitting intensity related to polarization of the incoming wave; Chevrot, 2000) introduce new sensitivity kernels and will extend applicability in the near future.

A interesting reconstruction of mantle plumes had been performed by Montelli et al. (2004a,b, 2006b) and, more recently, by Sigloch et al. (2008), Tian et al. (2009, 2011), Sigloch (2011), and Pavlis et al. (2012) under the North American Plate among other reconstructions based on such travel times.

The contribution of diffracting points increases when we move away from the ray making the so-called banana-doughnut shape for travel times, the usefulness of which has been questioned by de Hoop and van der Hilst (2005). For the amplitudes, the maximal contribution is found on the ray (**Figure 17**). The near-field influence has been discussed by Favier et al. (2004).

Aside from the theoretical questions of the shape of the sensitivity kernel, the claimed improvement of the resolution when considering finite-frequency tomography compared with standard ray tomography has been questioned by different authors (Boschi et al., 2006; Montelli et al., 2006a; van der Hilst and de Hoop, 2005). Trampert and Spetzler (2006) had mentioned that regularization required for making a stable inversion of the phase delays prevents the appearance of the improved resolution form finite-frequency tomography. Moreover, often, the discretization of the velocity model is coarser than the Fresnel zone size of related finite-frequency data. Finally, the database of delay times used for finite-frequency tomography needs to be increased for a better estimation of the effects of finite-frequency effects. This is the motivation behind the work done by Zaroli et al. (2010), and one may expect a dramatic increase of the size of these databases.

1.05.6 Discussion

Velocity perturbations are rather weak in the Earth's mantle, making estimation of synthetic travel times quite reliable although one could not guarantee that a false association between an observed time and a synthetic time may exist. Amplitudes based on ray theory have so far not been used for such reconstructions because of a strong trade-off with source frequency content and attenuation effects. Further improvements will certainly close this gap and will bring us back to waveform fitting, an important challenge for global seismology in the next 10 years.

Numerical methods such as the spectral element method (Komatitsch et al., 2002) and the finite difference method (Levander, 1988; Moczo et al., 2006) have been integrated in many seismic inversion procedures (Bozdağ et al., 2011; Fichtner et al., 2008; Plessix, 2006; Pratt et al., 1996, 1998; Tape et al., 2007; Tromp et al., 2005) using filtered or transformed seismograms based on time-frequency analysis, such as the instantaneous phase and envelope measurements. These transformations emphasize the importance of phase delays before amplitude misfits. Impressive results have been shown at local scales (Kamei et al., 2012; Operto et al., 2004, 2006) and at regional scales (Fichtner et al., 2009; Tape et al., 2010; Zhu et al., 2012), while the seismological community is still waiting for results at the global scale.

What is the best approach we may consider? Should one perform extraction of observables such as travel times from seismograms and incorporate with these data a finite-frequency tomography for reconstruction or should we move to full waveform inversion based on comparison of observed

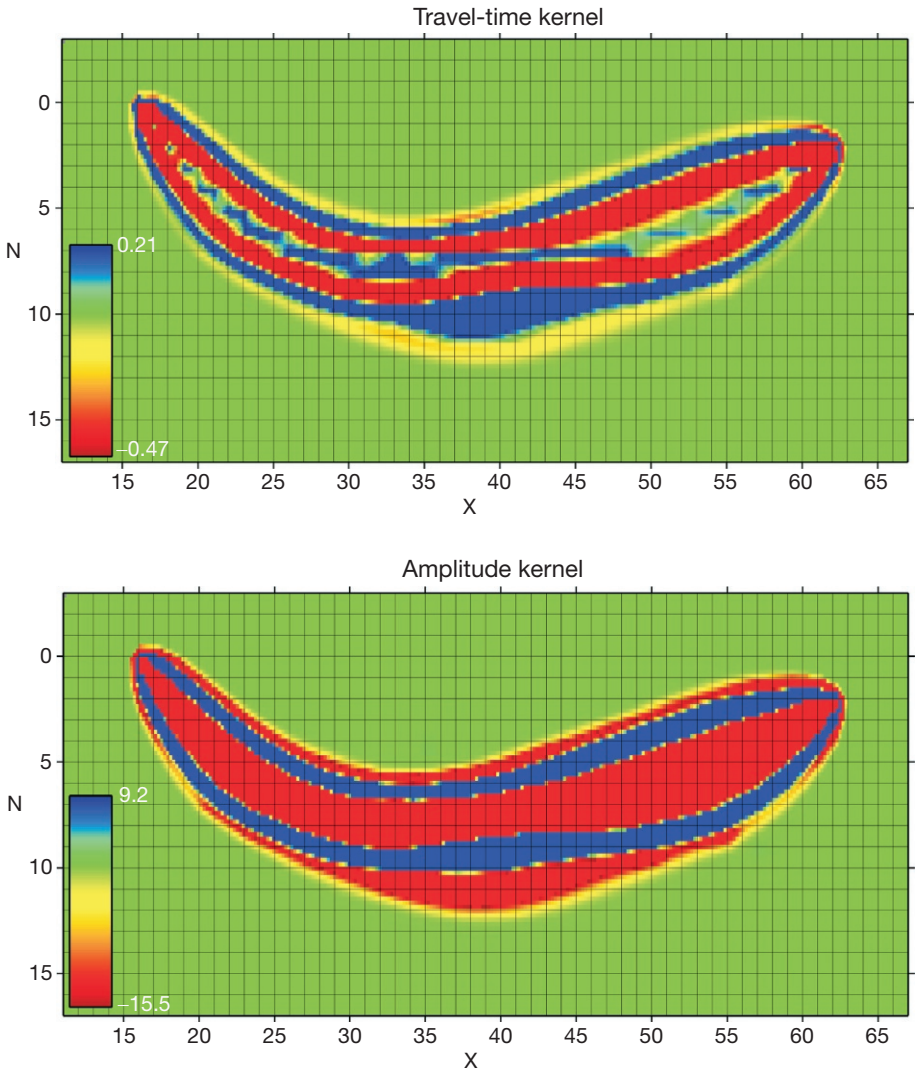

Figure 17 Travel-time and amplitude sensitivity kernels in a local heterogeneous medium. Note the weak contribution in the central part of the kernel for travel times associated with the central ray of Fermat's principle (top panel), while the contribution in the central part of kernel is maximal for amplitude (bottom panel). Courtesy of S. Gautier and G. Nolet.

and synthetic seismograms using linear elastodynamic equations with and adapted misfit criteria strongly based on phase information? The first approach is quite efficient compared with the second one because the modeling stays simple. In case of multiple arrivals inside the same phase window, it may not be the case as we rely on nonlinear Hamilton–Jacobi equations.

Since the pioneering work of Lailly (1983). Tarantola (1984a) and the connection between tomography and inversion made by Luo and Schuster (1991), upper crust investigations have favored the second approach. As promoted by Jin et al. (1992) and Lambaré et al. (1992, 2003), full waveform inversion might use ray theory or extended approaches as long as one can find an efficient and stable way of computing ray seismograms in updated velocity models and not only just the smooth initial model, which has been the case for the so-called ray+born approach. For the core–mantle boundary, it might be quite difficult to propagate using numerical method waves down to this zone, and therefore, ray methods play a central role if we should master the problem of multiple arrivals inside a time window since we might expect quite complex triplications coming from velocity variations over undulations of this interface (Kendall and Nangini, 1996; Wang et al., 2008).

1.05.7 Conclusion

Until now, the growth of seismology as an investigation tool for the Earth's interior has essentially relied on the use of ray theory. During this time, significant progress has been made in ray theory, which is definitely not a 'discipline from the nineteenth century.' This constant progress (not only in terms of numerical developments) has, for example, considerably extended the application domain of these techniques, which still remain essential for the analysis of seismic traces.

Although numerical methods for solving wave equations (finite difference methods, e.g., Moczo et al., 2006; Virieux, 1986, and finite element methods with fast

convergence such as spectral element methods, e.g., Chaljub et al., 2003; Komatitsch et al., 2002) may open new strategies for both forward and inverse modelings because of the increasing performance of computers, understanding of seismograms will still require interpretation in terms of high-frequency asymptotic approximations. Many observables, which can be deduced from ray theory, are still not strongly investigated. For example, differential information, such as the travel-time slope (Billette and Lambaré, 1998; Yanovskaya, 1996) or the polarization of the arrival (Le Bégat and Farra, 1997), are rapidly developing. Even the use of amplitudes is starting to be exploited using the asymptotic approaches. In this context, the present development of dense data acquisition will be a real challenge, where the assets of ray theory will certainly open roads to interesting opportunities for describing complex media.

The efforts for the adaptation of ray theory to more complex rheologies involving complex geometries, anisotropy, viscoelasticity (Ribodetti et al., 2000), or multiphase media have to be pursued. These new developments will certainly also offer important opportunities for the analysis of seismograms in the future.

Improvements on resolution of the seismic velocity model will be a key ingredient for the discrimination of different methods of forward modeling and inversion techniques (de Wit et al., 2012; Fichtner and Trampert, 2011).

Acknowledgments

We thank discussions with Bob Nowack, David Simpson, Colin Thomson, and Stéphane Operto. We gratefully thank Reda Baina, Jeannine Gagnepain-Beyneix, Stéphanie Gautier, David Le Meur, Guust Nolet, Bob Nowack, Stéphane Operto, Peter Shearer, and Martin Vallée for kindly providing us with figures. A careful review by Barbara Romanowicz improved the first edition. Authors would like to thank Bob Nowack for important suggestions in the elaboration of this second edition.

1.06.1 Introduction

Body waves are solutions of the elastic equation of motion that propagate outward from a seismic source in expanding, quasi-spherical wave fronts, much like the rings seen when a rock is thrown in a pond. The trajectory along which the elastic energy propagates is called a ray. Rays are normal to the wave front in materials that are elastically isotropic, in which the stress–strain relation at any point is independent of the choice of the coordinate system. The normals to the wave fronts, called rays, are useful in illustrating body waves' interactions with gradients and discontinuities in elastic velocities as well as their sense of polarization of particle motion. Except for the special cases of grazing incidence to discontinuities, body wave solutions to the equations of motion are nearly nondispersive. All frequencies propagate at nearly the same phase and group velocities. Hence, the body wave excited by an impulsive, delta-like, seismic source-time function will retain its delta-like shape with propagation to great distances (Figure 1).

Surface waves are solutions of the elastic equations of motion that exponentially decay with depth beneath the surface of the Earth for a boundary condition of vanishing stress at the surface. Unlike body waves, surface waves are strongly dispersed in the Earth, having phase and group velocities that depend on frequency. Observations of surface waves in the 0.001–0.1 Hz band of frequencies can constrain structure of the crust and upper mantle of the Earth, but only body waves provide information on the elastic velocities of the deeper interior of the Earth, all the way to its center. Summing modes of free oscillation of the Earth can represent both body and surface waves. The most efficient representation of the highest-frequency content body waves, however, is given by propagating wave front or ray-type solutions of the elastic equations.

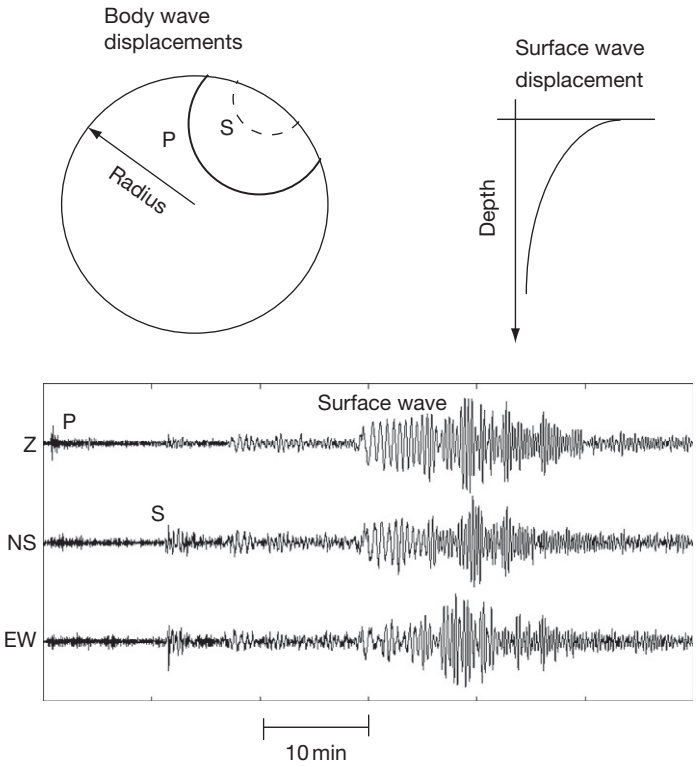

Figure 1 Top left: Displacement of body waves is concentrated in propagating quasi-spherical wave fronts. Top right: The displacement of surface waves exponentially decays away from the surface of the Earth. Bottom: Example seismogram showing impulsive, pulse-like, body waves and dispersive surface waves.

In a homogeneous Earth, the wave fronts of body waves excited by a point source are spherical, with radii equal to the distance from the source to an observation point on the wave front. Since the density of kinetic energy at a point in time is proportional to the surface area of the wave front, the particle velocity of a body wave is inversely proportional to the distance to the source. This inverse scaling of amplitude with increasing distance is termed the geometric spreading factor, R. Even in an inhomogeneous Earth, the inverse-distance scaling of body wave amplitude can be used to make a rough estimate of the behavior of amplitude versus distance.

Rays (energy trajectories) follow paths of least or extremal time, representing a stationary-phase approximation to a solution of a wave equation, Fourier transformed in space and time. The least-time principle is expressed by Snell's law in a material in which velocity is a function of one coordinate (often depth or radius in the Earth). In spherical geometry, Snell's law is equivalent to the constancy of a ray parameter, or horizontal slowness, p. The ray parameter is defined by $p = r \sin(i)/v(r)$, where i is the acute angle between the intersection of a ray path and a surface of radius r and v is the body wave velocity at r. Snell's law is obeyed by ray paths in regions of continuously varying velocity as well as by the ray paths of reflected and transmitted/converted waves excited at discontinuities. Since velocities usually increase with depth (decrease with radius) in the Earth, ray paths of body waves are usually concave upward (Figure 2). The least-time principle can also be exploited in linearized tomography to find perturbations to reference Earth models by assuming that ray paths are

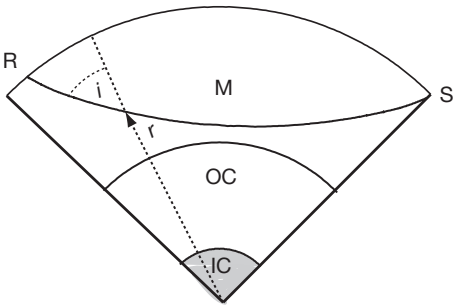

Figure 2 Following Snell's law in spherical geometry ($r \sin(i)/v = \text{constant}$), the ray paths of body waves in the Earth are mostly concave upward because elastic velocities mostly increase with depth.

stationary with respect to small perturbations in velocities. In models having three-dimensional (3D) variation in elastic velocity, the least-time principle can be used to develop a system of linear equations for ray trajectory.

Complementing the information contained in travel times are the shapes (waveforms) of the body waves. Complexities and subtle shape changes observed in waveforms can be used to image elastic properties of the Earth at spatial scales down to a quarter wavelength from its surface to its center. The velocities of body waves in the Earth range from 1.5 to >13 km s^{-1}. Since waves that penetrate the deep interior of the Earth are commonly observed at frequencies at least up to 2 Hz, structures having spatial scales as small as 1 km can be potentially imaged from a densely sampled wave field. Body waveforms also

contain information about the spatial and temporal history of earthquake, explosion, or impact seismic sources.

This chapter reviews algorithms for modeling the effects of structure and source on teleseismic waveforms. It will point to references for the theoretical background of each algorithm and currently existing software. It will also make suggestions for the model parameterization appropriate to each algorithm and the treatment of source-time functions, instrument responses, attenuation, and scattering. Mathematical development of each algorithm can be found in textbooks in advanced and computational seismology (Aki and Richards, 2002; Cerveny, 2001; Chapman, 2004; Dahlen and Tromp, 1998; Kennett, 1983, 2001). A thorough understanding of the derivation of each algorithm requires a background that includes solution of partial differential equations by separation of variables, special functions, integral transforms, complex variables and contour integration, and linear algebra. Practical use of each algorithm, however, often requires no more than a background in simple calculus and an intuitive understanding how a wave field can be represented by superposing either wave fronts or modes at different frequencies.

1.06.2 Plane Wave Modeling

1.06.2.1 Elastic Velocities and Polarizations

Two types of body waves were identified in early observational seismology, P, or primary, for the first arriving impulsive wave and S, or secondary, for a second slower impulsive wave (Bullen and Bolt, 1985). These are the elastic wave types that propagate in an isotropic solid. In most regions of the Earth, elastic isotropy can be assumed, in which only two elastic constants are required to describe a stress–strain relation that is independent of the choice of the coordinate system. In the case of anisotropy, additional elastic constants are required to describe the stress–strain relation. In a general anisotropic solid, there are three possible body wave types, P and two quasi-S waves, each having a different velocity.

The velocities of propagation and polarizations of motion of P and S waves can be derived from elastic equation of motion for an infinitesimal volume in a continuum:

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \sigma_{ij,j} + f_i \qquad [1]$$

where ρ is the density, u_i is the ith component of the particle displacement vector $\mathbf{U}$, σ_{ij} is the stress tensor, and f_i is the ith component of body force that excites elastic motion. Summing over the repeated index j, the total elastic force in the ith direction is represented by the jth spatial derivative of the stress tensor, $\sigma_{ij,j}$. The stress tensor elements are related to spatial derivatives of displacement components (strains) by a generalized Hooke's law, which for general anisotropy takes the form

$$\sigma_{ij} = c_{ijkl} u_{kl} \qquad [2]$$

and for isotropy the form

$$\sigma_{ij} = \lambda \frac{\partial u_i}{\partial x_i} + \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \qquad [3]$$

where c_{ijkl}, λ, and μ are elastic constants. The summation convention is assumed in eqns [1]–[3], that is, quantities are summed over repeated indices.

Elastic wave equations for P and S waves in an homogeneous isotropic solid can be derived by, taking the divergence and curl of the equation of motion [1], demonstrating that volumetric strain, $\nabla \cdot U$, propagates with a P wave velocity

$$V_P = \sqrt{\frac{\lambda + 2\mu}{\rho}} = \sqrt{\frac{K + 4/3\mu}{\rho}} \qquad [4a]$$

and rotational strain, $\nabla \times U$, propagates with the S wave velocity

$$V_S = \sqrt{\frac{\mu}{\rho}} \qquad [4b]$$

(Note: the P wave velocity can be represented in terms of either the Lame parameter λ and shear modulus μ or the bulk modulus K and shear modulus μ.)

Alternatively, the phase velocities and polarizations of body waves can be derived by assuming propagation of a harmonic plane wave having frequency ω and a wave front normal $\mathbf{k}$ of the form

$$u(\mathbf{x}, t) = \mathbf{A} e^{(i\omega t - \mathbf{k}\cdot\mathbf{x})} \qquad [5]$$

and substituting this form into [1]. This substitution leads to an eigenvalue/eigenvector problem, in which the eigenvalues represent the magnitudes of the wave number vector $\mathbf{k}$ and hence phase velocities from $v = \omega/|\mathbf{k}|$. The associated eigenvectors represent the possible orientations of particle motion (e.g., Keith and Crampin, 1977). There are three possible eigenvalues/eigenvectors, two eigenvalues (phase velocities) of which are equal in an isotropic medium. The eigenvalue associated with the fastest phase velocity is the P wave. Its eigenvector specifies a P wave polarization normal to the wave front. In an isotropic medium, the two equal eigenvalues and their two orthogonal eigenvectors are associated with the S wave. Their eigenvectors specify an S wave polarization tangent to the wave front. Thus, S wave polarization, perpendicular to the direction of S wave propagation, is analogous to the polarization of electromagnetic waves. P polarization, parallel to the direction of propagation, has no analog to electromagnetic wave polarization.

To facilitate the solution and understanding of the interactions of the P and S wave types with discontinuities in elastic moduli and/or density, it is convenient in a radially or vertically varying Earth to define a ray (sagittal) plane containing the source, receiver, and center of the Earth. In an isotropic medium, the polarization of the S wave, which depends on the details of source excitation and receiver azimuth, is most conveniently decomposed in a vector basis consisting of an SV component, lying in the sagittal plane, and an SH component, perpendicular to the sagittal plane (**Figure 3**). At a discontinuity in elastic velocity, SV waves can excite reflected and transmitted and SV waves as well as reflected and transmitted P waves, but SH waves can only excite reflected and transmitted SH waves. The effects of body wave-type conversions on polarizations have contributed to fundamental discoveries in deep Earth structure. The most famous example of these discoveries is the SV polarization of the SKS wave, which confirms that the outer core of the Earth is liquid. In this example, the SV component of an S wave incident on the boundary of the solid mantle excites a transmitted P wave in the liquid outer

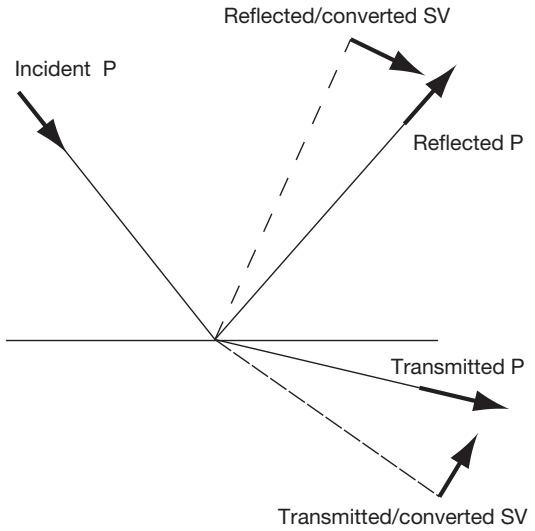

Figure 3 The interaction of a P wave incident on a discontinuity in P and S velocity, showing reflected and converted P and SV waves and their polarizations (arrows).

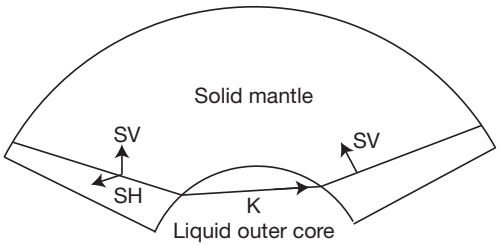

Figure 4 The SV component of the S wave on the core–mantle boundary excites a compressional (K) wave in the outer core, which has its particle motion along its ray. The K wave exits the outer core as a transmitted SV wave in the mantle, which has its particle motion perpendicular to its ray, lying in the sagittal plane.

core (K wave), which can convert back to an SV wave in the solid mantle. The SH component of the incident S wave cannot excite a K wave in the liquid outer core, and the K wave cannot excite a transmitted SH wave in the mantle. Hence, the received SKS wave is purely SV-polarized in an isotropic Earth (Figure 4).

Solutions of the elastic equations of motions can also be developed in terms of potentials, showing that the existence of fully decoupled P and S wave equations exist only in homogeneous regions where elastic moduli and density are constant in space (e.g., Aki and Richards, 2002). The use of potentials, however, leads to needless mathematical complexity when the quantities of modeling interest are displacements and stresses. This is especially true when solutions are continued across discontinuities in elastic moduli and density. At discontinuities, boundary conditions must be imposed on components u_i of the particle displacement vector **U** and stress tensor elements σ_{ij}. Three fundamental types of boundary conditions occur in seismic wave propagation in the Earth: (1) the surface of the Earth, where all elements σ_{ij} vanish; (2) welded, slip-free, discontinuities between two solid discontinuities, where both particle displacements and stress tensor elements are continuous; and (3) liquid–solid discontinuities such as the ocean/ocean crust, mantle/outer core, and outer core/inner core, where only the displacements and stresses perpendicular to the discontinuity are continuous. These boundary conditions and the associated changes in the eigenvectors and eigenvalues of plane wave solutions can be compactly handled by a fundamental matrix and propagator formalism in a layered radially or vertically varying medium (Gilbert and Backus, 1966). In this approach, the vertically separated component for the solution to the equations of motion is written as a linear system of the type

$$\frac{\mathrm{d}\mathbf{f}}{\mathrm{d}z} = \mathbf{A}\mathbf{f} \qquad [6]$$

where **f** is a 2-vector for the components of displacement and stress associated with SH waves or a 4-vector for the components of stress and displacement associated with P and SV waves; **A** is either a 2×2 matrix for SH waves or a 4×4 matrix for P and SV waves; and derivative d/dz is with respect to depth or radius. The possibility of both up- and down-going waves allows the most general solution of the linear system in eqn [6] to be written as a solution for a fundamental matrix **F**, where the rows of **F** are the components of displacement and stress and the columns correspond to up- and down-going P and S waves. For P and SV waves, **F** is a 4×4 matrix; for SH waves, **F** is a 2×2 matrix. An example of the fundamental matrix for SH waves in a homogeneous layer is

$$\mathbf{F} = \begin{pmatrix} e^{i\omega k_z(z-z_o)} & e^{-i\omega k_z(z-z_o)} \\ ik_z\mu e^{i\omega k_z(z-z_o)} & -ik_z\mu e^{-i\omega k_z(z-z_o)} \end{pmatrix} \qquad [7]$$

where z_o is a reference depth and the sign of the complex phasors represents propagation with or against the z-axis to describe down- or up-going waves. The first row in eqn [7] represents displacement and the second row stress.

The solution of eqn [6] can be continued across discontinuities, with all boundary conditions satisfied, by use of a propagator matrix **P**, where **P** also satisfies [6]. The fundamental matrix in layer 0 at depth z_1,, $\mathbf{F}_o(z_1)$, is related to the fundamental matrix in layer N at z_N, $\mathbf{F}_N(z_N)$, through a propagator matrix $\mathbf{P}(z_1,z_N)$ such that

$$\mathbf{F}_o(z_1) = \mathbf{P}(z_1, z_N)\mathbf{F}_N(z_N) \qquad [8a]$$

where

$$\mathbf{P}(z_1, z_N) = \left(\mathbf{F}_1(z_1)\mathbf{F}_1^{-1}(z_2)\right)\left(\mathbf{F}_2(\mathbf{z}_2)\mathbf{F}_2^{-1}(\mathbf{z}_3)\right) \ldots \left(\mathbf{F}_{N-1}(z_{N-1})\mathbf{F}_{N-1}^{-1}(z_N)\right) \qquad [8b]$$

In an isotropic Earth model, once the relative source excitation of S waves has been resolved into separate SH and SV components of polarization, the treatment of boundary conditions on P and SV waves can be separated from that needed for SH waves by the use of either the 4×4 fundamental matrices for P and SV waves or the 2×2 fundamental matrices for SH waves.

1.06.2.2 Superposition of Plane Waves

Superposition of plane waves of the form in eqn [5] along with techniques of satisfying boundary conditions at discontinuities using fundamental and propagator matrix solutions of eqns

[8a] and [8b] allows calculation of all possible body wave solutions of the elastic equations of motion as well as the dispersive wave interactions with the free surface (surface waves) and deeper discontinuities (diffractions and head waves) in radially or vertically varying media. This process of superposition in space and frequency is equivalent to solution of the equations of motion by the integral transform methods of Fourier, Laplace, Bessel or spherical harmonics. Fourier and Laplace transforms can always be applied in a Cartesian coordinate system, but analytic solutions of the equation of motion in terms of Bessel/Hankel functions and spherical harmonics are limited to Earth models whose layers and discontinuities are either spherically symmetrical or plane-layered, having cylindrical symmetry about the source point. Some well-tested extensions and perturbation methods, however, allow their application to models in which the symmetry is broken by lateral heterogeneity, aspheric or nonplanar boundaries, and anisotropy.

Transform-based methods, ray-based methods, and their extensions are reviewed in Section 1.06.4. Before beginning this section, however, it is important to have an intuitive feel for the effects of Earth structure on the propagation of body waves, how structure can induce complexity in body waveforms, and what outstanding problems can be investigated by the synthesis of waveforms.

1.06.3 Structural Effects

1.06.3.1 Common Structural Effects on Waveforms

Body waves are commonly synthesized to study the effects of waveform complexity or multipathing due to rapid or discontinuous changes in elastic velocity. Two common structures inducing waveform complexity are a rapid or discontinuous velocity decrease and increase with depth (Figure 5). A rapid or discontinuous decrease is characterized by a shadow zone, followed by a caustic and two multipaths in the lit zone, each having opposite signs of curvature in their associated travel time curves. A caustic is a surface, line, or point where body waves are strongly focused, frequency-independent ray theory breaks down, and geometric spreading vanishes. A rapid or discontinuous velocity increase produces a triplication of the travel time curve, with a region of distances with three different ray paths and associated travel time curves, one of which has an opposite sign of curvature in its travel time curve compared to those of the other two paths. The two points where the curvature of travel time versus distance changes denote the distance at which the caustics intersect the Earth's surface.

P waves interacting with the Earth's inner and outer core boundaries provide an example of the waveform complexity induced by both a discontinuous velocity increase and a discontinuous velocity decrease. A shadow zone and caustic are induced by a discontinuous velocity decrease at the core–mantle boundary, and a triplication is induced by a discontinuous velocity increase at the inner core boundary (Figure 6). The velocity decrease at the core–mantle boundary generates a reversal of the travel time–distance curve and strong focusing of waves at the caustic distance B. The discontinuous increase in velocity at the outer core–inner core boundary generates the triplication C–D–F. Frequency-dependent diffraction occurs along the extension of BC to longer distances. A lower amplitude partial reflection along the dashed segment extends from D to shorter distances. In addition to the effects induced by radially symmetrical structure, lateral heterogeneity near the core–mantle boundary can scatter higher-frequency body waves in all directions. The curved dashed line extended to shorter distances from point B in Figure 6 represents the minimum arrival time of high-frequency energy scattered from

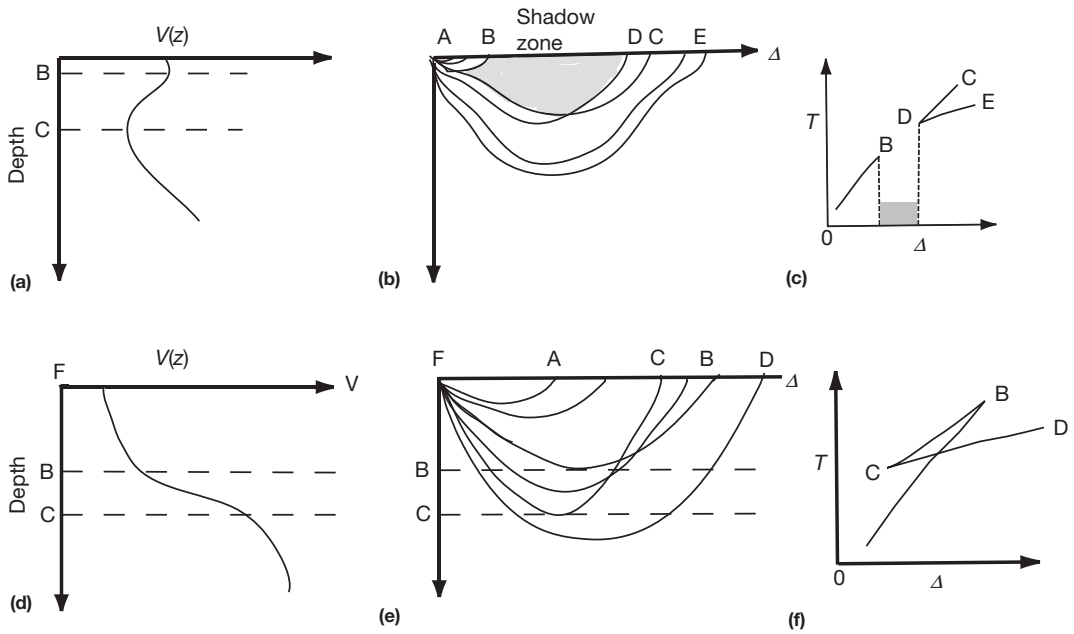

Figure 5 Ray multipathing and travel time complexity induced by a regions of either rapid velocity decrease with depth (a–c) or rapid increase (d–f) with depth.

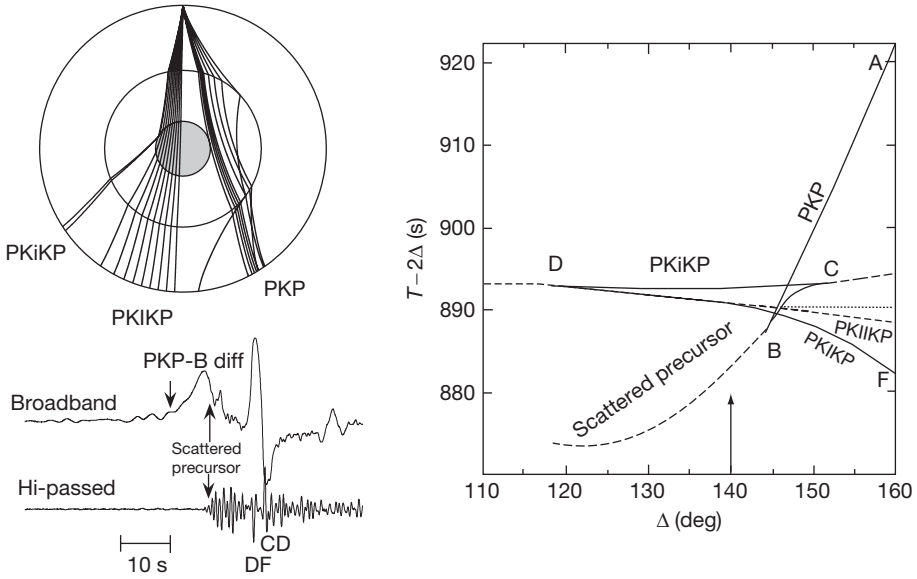

Figure 6 Rays and travel time curves of P waves interacting with the Earth's inner and outer cores. Bottom left: Observed broadband displacement and high-pass-filtered seismograms from a deep earthquake recorded near 140°.

either heterogeneity near or topography on the core–mantle boundary.

Changes in the curvature of travel time curves for waves also induce changes in the shapes of the waves associated with each multipath. These waveform distortions can be understood from geometric spreading effects. In an inhomogeneous medium, geometric spreading R is proportional to the square root of the product of the principal radii of curvature of the wave front

$$R \propto \sqrt{r_1 r_2} \qquad [9]$$

In a homogeneous medium, where wave fronts are spherical, $r_1 = r_2$, and geometric spreading reduces simply to the distance to the source. A wave front is described by a 3D surface $\tau(\mathbf{x})$ over which travel time is constant. Hence, the principal radii of curvature of the wave front are determined by the second spatial derivatives of the travel time surface τ. From [9], a change in the sign of either of the two principal wave front curvatures (r_1 or r_2) produces a change in the sign of the argument of the square root in eqn [9] and hence a $\pi/2$ phase change in the waveform associated with that wave front. A consequence of this relation is that any two waveforms having travel time branches with a difference in the sign of the second derivative with respect to great circle distance will differ by $\pi/2$ in phase. This $\pi/2$ phase change is called a Hilbert transform (Bracewell, 1986). A Hilbert transform of a delta function has a gradual positive onset, sharp downswing to negative values, and a gradual negative return to zero (Figure 7). The travel time curve of the PKP waves along the AB branch in Figure 6 has a concave upward curvature, while travel time curvatures of the PKP waves along the BC branch and the PKIKP waves along the DF branch are concave downward. Hence, waveforms along PKP-AB travel time branch are Hilbert-transformed ($\pi/2$ phase-shifted) with respect the waveforms along of the PKP-BC and PKP-DF branches (Figure 8).

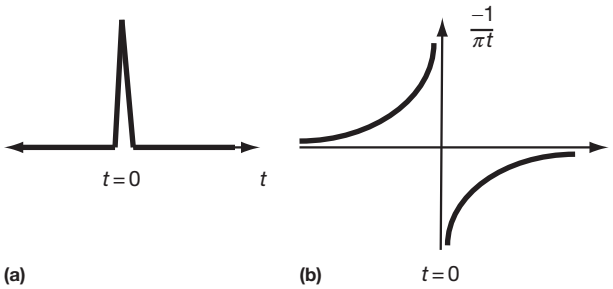

Figure 7 (a) Delta function and (b) its Hilbert transform.

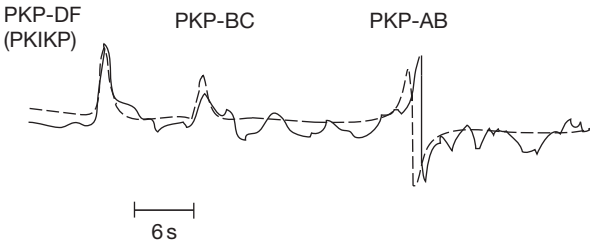

Figure 8 Observed and synthesized PKP waveforms from Choy and Cormier (1983). PKP-AB is Hilbert-transformed with respect to PKP-DF.

These changes in pulse shape are correct in the limit of infinite frequency, but at finite frequency pulse, shapes near the cusps B, C, and D are neither delta-like nor Hilbert-transformed-like. Near these points, the shapes exhibit frequency dependence and appear as some kind of average of the two fundamental shapes. This type of pulse shape can also exist in cases where a reflection/transmission/conversion coefficient of a plane wave becomes complex, as in certain distance ranges of the SKS phase. In these cases, the pulse shape can be represented by a linear combination of a delta function and Hilbert-transformed delta function (Aki and

Richards, 1980, pp. 157–158). In the shadows of cusps and caustics, diffracted waves exist, which decay with increasing frequency and increasing distance from the cusp or caustic (e.g., the diffracted PKP-B in the broadband seismogram in Figure 6).

A turning point of a ray can occur at a point where the ray direction is horizontal and the direction of energy propagation reverses from upward to downward or vice versa. Waves having rays with multiple turning points also exhibit $\pi/2$ phase shifts for each turning point. Examples are PP waves and SS waves that are Hilbert-transformed with respect to the waveforms of the direct P and S waves and waves multiply-reflected along the underside of the core–mantle boundary, such as PKKP, SKKS, PKnKP, and SKnKS (Choy and Richards, 1975). In three-dimensionally varying media and for body waves having multiple turning points in waveguide-like structures, it is possible to have N multiple $\pi/2$ phase shifts for N turning points or N points of tangency to a caustic. N is termed the KMAH index (named after wave theorists Keller, Maslov, Arnold, and Hörmander). The KMAH index is an important parameter to inventory as ray trajectories are computed. In dynamic ray tracing (DRT) (Section 1.06.4.5), the KMAH index can be determined by tracking accumulated sign changes in the determinant of Cerveny's (2001) spreading matrix $\mathbf{Q}$, where geometric spreading R is proportional to the square root of the determinant of $\mathbf{Q}$:

$$R \propto \sqrt{\det(\mathbf{Q})} \qquad [10]$$

In a vertically continuous flat Earth, $\det(\mathbf{Q})$ takes the form

$$\det(\mathbf{Q}) = \frac{\cos(i)}{V}\frac{\cos(i_o)}{V_o}\frac{X}{p}\frac{dX}{dp} \qquad [11a]$$

and in spherically symmetrical Earth models,

$$\det(\mathbf{Q}) = (rr_o)^2\frac{\cos(i)}{V}\frac{\cos(i_o)}{V_o}\frac{\sin(\Delta)}{p}\frac{d\Delta}{dp} \qquad [11b]$$

In eqns [11a] and [11b], vertical takeoff angle i, velocity V, and radius r having the subscript o are evaluated at a ray origin or source point, and unsubscripted quantities are evaluated at a ray endpoint or receiver. X is the distance measured from source to receiver along the surface of the Earth model, and Δ is the great circle distance of the source to the receiver measured in radians. In eqn [11a], the ray parameter p is that for rays in plane-layered models ($p = \sin(i)/V = \text{constant} = dT/dX$), but in eqn [11b], p is that for rays in spherically layered models ($p = r\sin(i)/V = \text{constant} = dT/d\Delta$).

Head waves are another effect of a discontinuous velocity increase with depth that can induce frequency-dependent effects and waveform complexity. Head waves travel along the underside of a boundary in the higher-velocity medium. Depending on vertical gradient of the medium below the discontinuity, a head wave can either have an amplitude inversely proportional to frequency (no gradient) or be represented by an interference or a whispering gallery of waves multiply-reflected along the underside of the discontinuity (e.g., Cerveny and Ravindra, 1971; Menke and Richards, 1980).

In some distance ranges, surface waves and phases best described by modal representations interfere with body waves. Examples include late arriving body waves having multiple interactions with the core–mantle boundary and/or the free surface that interfere with fundamental mode Love and Rayleigh waves. Another example is shear-coupled PL waves that are generated by SV waves that turn in the mantle and excite converted P waves trapped in the crust (Baag and Langston, 1985). Shear-coupled PL waves can arrive as a dispersive wave train immediately following an SV wave in some distance ranges.

1.06.3.2 Shallow Earth Structural Problems

Problems of interest in the crust and upper mantle include both academic and commercial applications, involving the deployment of dense arrays of seismometers to image and interpret complex 3D and anisotropic elastic structure (Chapters 1.11 and 1.15). Academic examples include structures associated with continental collisions (Chapter 6.09), subduction zones (Chapter 1.20), spreading ridges (Chapter 1.13), intrusive bodies and hot spots (Chapters 6.04 and 6.08), volcanoes (Chapter 4.15), and fault zones (Chapter 4.07). Commercial applications include the imaging of stratigraphic traps for oil and gas formed by anticlines, faults, and salt domes and the characterization of fracture distributions and shapes for enhanced oil and gas recovery and remediation of contaminated groundwater (Chapters 11.15, 11.16, and 11.06).

1.06.3.3 Deep Earth Structural Problems

In the deep Earth, problems of greatest research interest are structural zones of rapid spatial variation that introduce waveform complexity in the form of triplications, caustics, shadow zones, diffractions, head waves, and multipaths. For teleseismic observations, the zones of rapid spatial variation that are most often studied are the crust–mantle discontinuity (Moho), regionally varying low-velocity zones in the upper mantle (including the lithosphere to asthenosphere transition); narrow zones or discontinuities in velocity and density at or near 400, 500, and 660 km depth; a zone of regionally varying velocities between 100 and 300 km above the core–mantle boundary; and 100–300 km regions on both sides of the inner core boundary.

Key to the interpretation of these zones of rapid spatial variation is the relative changes in P velocity, S velocity, and density. From body wave modeling, it is often only possible to make an estimate of velocity changes, either P or S velocity, but neither simultaneously, with little or no constraint on the associated density change. An example of this is the estimate of the velocity increase required to reproduce the spacing of travel time branches in the ranges of the triplicated portion of a travel time curve due to a rapid increase in velocity with depth (e.g., Figures 5 and 6). The amplitudes of the body waves in the triplicated range, where one travel time branch corresponds to a wave totally (post-critically) reflected from the discontinuity, have little or no sensitivity to any density change associated with the velocity change. The amplitude of a reflected body wave at more vertical incidence, however, is much more sensitive to the product of density and velocity changes (Figure 9). By combining observations of narrow angle and grazing incidence waves to a discontinuity, it is possible to remove or reduce the trade-offs between velocity and density change.

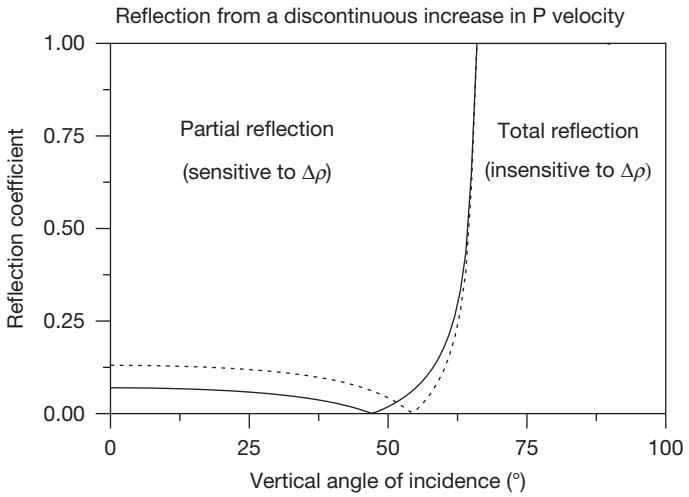

Figure 9 Example of a reflection coefficient showing total and partial reflection for a discontinuity for two cases: (1) velocity and density increase (solid) and (2) velocity increase identical but a different density increase (dashed). Note the insensitivity of total reflection region to the size of the density increase.

Combined modeling of P and S waveforms for both narrow- and wide-angle incidence then makes it possible to separately estimate P, S, and density changes at a discontinuity. From these estimates, it is possible to distinguish the nature of the discontinuity, for example, is it a chemical change or a solid–solid mineral phase change?

When P and S wave waveform analyses are available, an additional diagnostic tool can be the calculation of the change in bulk sound velocity V_K, where

$$V_K^2 = V_P^2 - \frac{4}{3}V_S^2 \qquad [12]$$

and V_P and V_S are the P and S velocities, respectively (Su and Dziewonski, 1997). Bulk sound velocities are more directly observed in high-pressure mineral physics experiments and theory and can be directly compared against known mineralogy (Zhao and Anderson, 1994). Other constraints in interpreting 3D variations in velocity are provided in comparing theoretical and observed estimates of the relative fractional changes in P velocity, S velocity, and density, $\mathrm{d}\ln V_P/\mathrm{d}\ln V_S$ and $\mathrm{d}\ln Vs/\mathrm{d}\ln\rho$ (e.g., Trampert et al., 2001). Care, however, is sometimes needed in comparing the frequency band of an observation with that of theoretical predictions due to the dispersive effects of viscoelasticity (**Section 1.06.7.4** and Karato, 1993).

The effect of temperature on velocity is known from experimental and theoretical predictions. Known temperature derivatives, or even practical bounds on the temperature derivative, can be used to determine whether a rapid velocity change is due to either a spatially sharp temperature or chemical or phase change. In this analysis, it is also important to consider the effects of thermal diffusivity. For example, given an estimate of the thermal diffusivity, the spatial extent of a thermally induced velocity anomaly cannot persist at a scale smaller than a certain size. Thermally induced anomalies below this size diffuse away over time periods shorter than the timescale at which they are created by mantle circulation.

Estimating whether a region of velocity change is a true discontinuity or a transition spread out in space requires careful study of the frequency content of reflected and converted waves interacting with the region of rapid velocity change. This has been an enduring challenge in interpreting rapid changes in velocity in the upper mantle as solid–solid phase changes. Waves reflected at wavelengths much longer than the depth range of a gradient transition cannot distinguish a transition from a discontinuity. Shorter wavelength waves, however, will not be reflected at narrow incidence angles. Reflected and converted waves at grazing incidence to a depth zone of rapid transition are relatively insensitive to the width of the transition even for a relatively broad frequency band of recording (e.g., Ward, 1978). Taking these sensitivities together, the frequency-dependent behavior of the amplitudes of body waves partially reflected at narrow angles of incidence to regions of rapid transition in depth can help diagnose whether a structure is a true discontinuity or transition zone. In practice, only a lower bound on the width of a depth transition can be safely diagnosed (e.g., Richards and Frasier, 1976), since there is typically an upper bound on the frequency (lower bound on wavelength) on observable teleseismic body waves (usually 2–3 Hz and 2–5 km).

1.06.4 Modeling Algorithms and Codes

Modeling of body waves can be broadly classified into four approaches: (1) transform methods for spherically symmetrical or plane-layered media, with some extensions for weak heterogeneity and anisotropy; (2) ray-based methods for regions in ray theory is a good approximation; (3) mode summation methods; and (4) full or partial numerical solutions to elastic equations of motion that can treat the cases of strong heterogeneity, anisotropy, and small spatial scales of heterogeneity. A summary of these modeling methods follows. Published applications of each method are extensive, and an attempt is made to primarily cite material in which the theory of each method is most completely developed. In many cases, this will be a textbook rather than a journal paper. Good

starting points to obtain software for many approaches are the Orpheus Software Library (www.orfeus-eu.org/Software/software.html), codes deposited with the World Data Center as part of the *Seismological Algorithms* text (www.ngdc.noaa.gov/hazard/seisalgo.shtml), codes and tutorials by R. Hermann (www.eas.slu.edu/People/RBHerrmann/CPS/CPS330.html), example synthetics and codes distributed by the SPICE Project (www.spice-rtn.org), codes distributed on a CD supplied with the International Handbook for Earthquake and Engineering Seismology (Lee et al., 2002), and computational seismology software available from the Computational Infrastructure in Geodynamics (CIG) web page (www.geodynamics.org).

1.06.4.1 Reflectivity

Reflectivity (Fuchs and Müller, 1971; Kennett, 1983, 2001; Kind, 1985; Müller, 1985) is perhaps the most general and popular transform method of modeling seismograms in radially symmetrical or plane-layered Earth models. Planar homogeneous layers parameterize the Earth model, after an Earth-flattening approximation (EFA) is applied. Plane wave solutions of the wave equation are found in the frequency domain, with boundary conditions handled by propagator matrix techniques. This approach is used to derive a transformed solution at great circle distance Δ_o for displacement, $u(\omega, p, \Delta_o)$, in ray parameter p and frequency ω space, where p is related to the horizontal component of the wave number vector by $k_x = \omega p / r_e$, with r_e the mean spherical radius of the Earth. The time domain solution $U(t, \Delta_o)$ is then found by inverting Fourier transforms represented by

$$U(t, \boldsymbol{\Delta}_o) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega e^{-i\omega t} \int_{\Gamma} dp\, u(\omega, p, \Delta_o) \qquad [13]$$

Transform inversion is commonly accomplished by integrating $u(\omega, p, \Delta_o)$ along a contour Γ confined to a finite segment of the real p or k_x axis for the series of discrete 2^N frequencies required to invert the complex frequency spectrum by a fast Fourier transform (FFT).

Depending on the needs of the modeler, the integrand of eqn [13] can be constructed to contain either one or several body wave arrivals interacting with major discontinuities, fundamental or higher mode surface waves, or a complete seismogram. In common applications, the integrand is constructed to represent the reflection a body wave incident on a stack of layers in a reflection zone (**Figure 10**). Above the reflection zone, the incident wave is assumed to be transmitted down through and back up the layers overlying the reflection zone. Neglecting details of the source excitation, the factors making up $u(\omega,p,\Delta)$ include transmission coefficients T_D down and T_U up through the layers above the reflection zone, the reflection R_U from the reflection zone, and phase factor $\exp(i\omega p \Delta_o)$ accumulated through horizontal propagation to the great circle distance Δ_o, or

$$u(\omega, p, \Delta_o) \propto T_D R_U T_D \frac{\exp[i(\omega p \Delta_o - \pi/4)]}{\sqrt{\omega p \sin(\Delta_o)}} \qquad [14]$$

The reflectivity response R_U can include all internal multiples and P to SV conversions within the thin homogeneous layers of the reflection zone. The reflectivity can be calculated from fundamental **F** and propagator **P** matrices, for example, eqns [7] and [8]. R_U for SH waves can be calculated by solving the system

$$\mathbf{F}_o(z_1) \begin{pmatrix} 1 \\ R_U^o \end{pmatrix} = \mathbf{P}(z_1, z_N) \mathbf{F}_N(z_N) \begin{pmatrix} T_D^N \end{pmatrix} \qquad [15]$$

where R_U^o is the total wave field reflected upward at the top of the boundary of the layered reflection zone and T_D^N is the total wave field transmitted through the bottom boundary $z = z_N$ of the reflection zone. A similar system can be set up for P and SV reflectivity, but care must be taken to rearrange the system to exploit algebraic cancelation of exponentially growing terms for certain domains of ray parameter (Abo-Zena, 1979). Elimination of these troublesome terms can also be accomplished by rearranging the multiplication of fundamental matrices in such a way that also enables identification of infinite series of internal layer multiples. These interlayer multiples can be neglected after a small finite number of reverberations (Kennett, 1983, 2001). Truncation of these internal multiples helps eliminate later arriving energy that folds back into the finite time window required given by finite length Fourier transforms. An alternative approach is to add a small imaginary part to each frequency $-i/\tau$ in the evaluation of the reflectivity response before inverting the Fourier transform (Bouchon and Aki, 1977; Chapman, 2004, p. 361). Using the damping theorem of Fourier transforms, at each time point, the inverted signal is then multiplied by the exponential $\exp(t/\tau)$.

After choosing a method to eliminate acausal late arriving multiples, one must still decide on how to best suppress the numerical noise of all the causal internal layer multiples of the thin layers used to approximate a continuously varying model. This numerical noise can be minimized by either low-pass filtering the response before inverting the Fourier transform or making layer thicknesses smaller than 1/4 the shortest wavelength corresponding to the highest frequency of interest to model (**Figure 11**).

Parameterization of the spherical Earth by plane homogeneous layers with depth z first requires an EFA of velocities $v(r)$ of the type

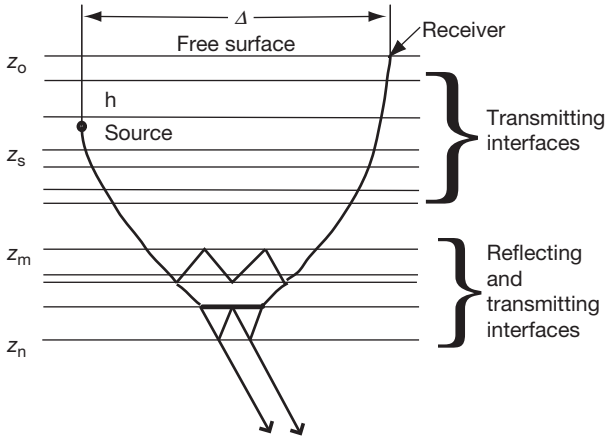

Figure 10 A typical layered model used in reflectivity synthesis, showing a transmission zone and rays reverberating in a reflection zone.

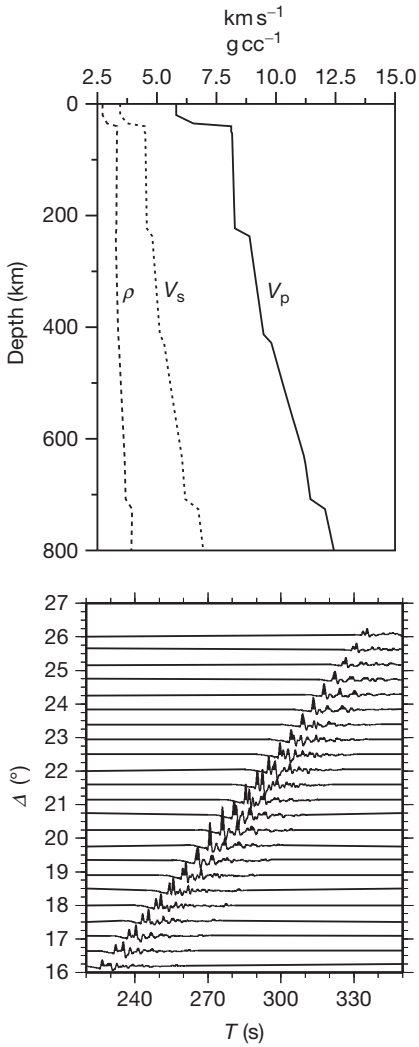

Figure 11 P waves synthesized by the reflectivity method using the program and example input provided by Kennett in the Orpheus web pages (www.orpheus-eu.org). Note the increase in amplitude around 20° associated with overlapping triplications induced by an upper mantle model having rapid velocity increases near 400 and 700 km depths.

$$v_f(z) = \frac{r_e}{r} v(r) \qquad [16a]$$

$$z = r_e \ln\left(\frac{r}{r_e}\right) \qquad [16b]$$

(Müller, 1977), where v_f is the Earth-flattened velocity. Errors on the order of $1/\omega$ are introduced in synthetic seismograms in this process and include problems associated with the decoupling of P and S wave potentials and the lack of an ideal density transformation (Chapman, 1973). The EFA will also breakdown at the center of the Earth ($r=0$), limiting accurate modeling to body waves that penetrate only the upper 500 km of the inner core. With this limitation and unless applied to a region in which velocity gradients are anomalously high at very low (<0.01 Hz) frequencies, the EFA combined with thin homogeneous layering can usually be applied without introducing significant errors.

Another variant of the reflectivity method is the discrete wave number method, in which the integral over ray parameter p is replaced by a sum over discrete horizontal wave numbers, k_x (Bouchon, 1979; Bouchon and Aki, 1977). One advantage of this method is that it can include the zero wave number, which provides a solution for the static displacement near an earthquake source (Honda and Yomogida, 2003). The need for fictitious image sources to treat the surface boundary conditions introduces some complexity in the formulation of the discrete wave number method, but both SH and P-SV codes are available and well developed. The representation of sources by sums of discrete wave numbers can also be useful in the implementation of boundary element methods to synthesize seismic wave fields scattered by irregular boundaries and inclusions (Campilo and Bouchon, 1985).

Because its input parameters are simple to understand, the reflectivity method is probably the most popular forward modeling technique. Input consists of an Earth model specified by velocities and densities in a stack of homogeneous layers, starting and ending points of integration along a real ray parameter axis, a time window and sampling rate, and a simple source description. Some 2D extensions are now available, allowing separate models to be specified in the source and receiver regions (see **Section 1.06.7.1**). Aside from simplicity of the input parameters, an advantage of reflectivity is that it easily allows the investigation of vertical transition zones in properties modeled by arbitrarily thin layers. Some caution in exploiting this advantage must be maintained not to violate constraints on physically realistic bounds on radial derivatives of elastic moduli and density. Compared to ray-based methods that assume asymptotic approximations to vertical wave functions discussed in the following sections, reflectivity can be numerically expensive for problems requiring thousands of thin layers.

1.06.4.2 Generalized Ray

The method commonly dubbed the generalized ray technique (GRT) originated from a technique of handling the integral transform inversions from ray parameter and frequency to time and space by the Cagniard–de Hoop method. It was recognized that most important teleseismic arrivals can be calculated by a first motion approximation, allowing the time domain solution for ray interactions in each homogeneous layer, both reflected and head waves, to be solved analytically (Helmberger, 1974; Helmberger and Harkrider, 1978). Ray solutions within each layer are summed, usually just the first multiples. The volume of published applications using the GRT method is probably the largest of any other method, but its available computer codes are less widely circulated than those employing reflectivity methods. An application of GRT synthetics (Burdick and Helmberger, 1978) was instrumental in the first major revision of standard Earth models originating from the pioneering work of Jeffreys and Bullen, namely, the replacement of a zone of strong velocity gradient in the upper mantle (Jeffreys, 1936) with two first-order discontinuities at 400 and 660 km depths (**Figure 12**).

The GRT commonly assumes an EFA and ignores higher than first-order internal multiples in each layer. It has been tested against other methods in many standard, vertically

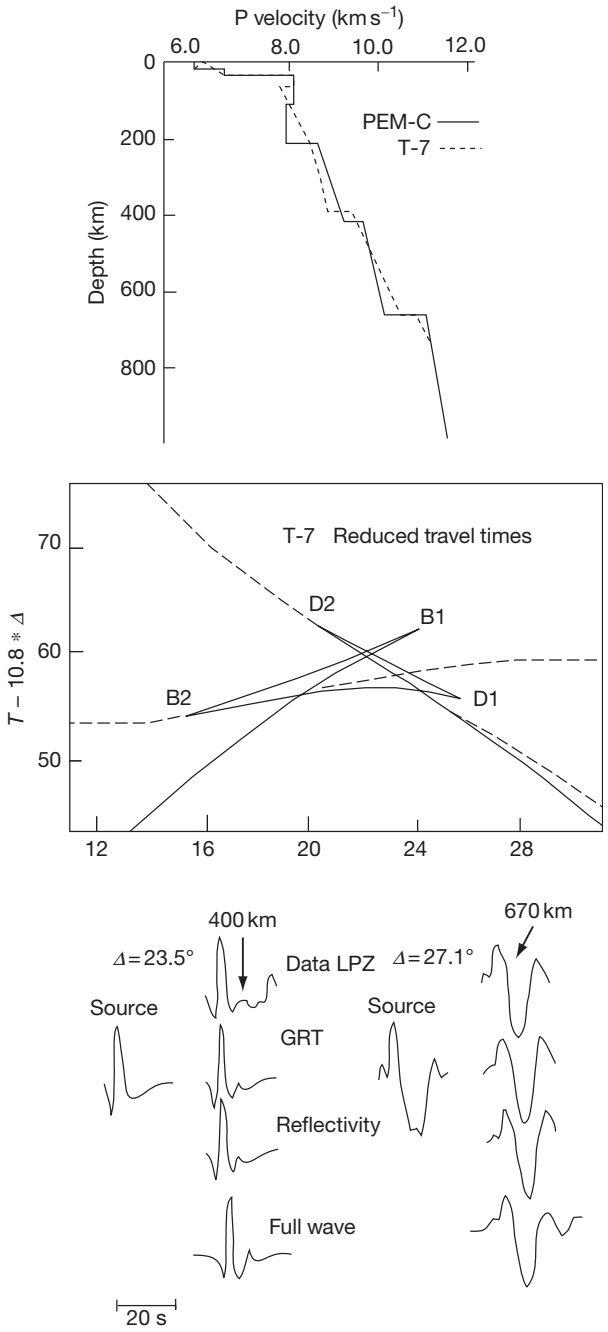

Figure 12 Top: Two models of P velocity in the upper 1000 km of the Earth. Middle: Discontinuities at 400 and 650 km depths create two overlapping triplications in the travel time curve and multiple phase arrivals in the great circle range 10°–30°. Bottom: A comparison of observed and synthesized seismograms in the T-7 model for three different methods of synthesis that include diffraction effects. Burdick LJ and Orcutt JA (1979) A comparison of the generalized ray and reflectivity methods of waveform synthesis. *Geophysical Journal of the Royal Astronomical Society* 58: 261–278: Cormier VF and Choy GL (1981) Theoretical body wave interactions with upper mantle structure. *Journal of Geophysical Research* 86: 1673–1678.

varying, Earth models and usually produces seismograms that are indistinguishable from those calculated by other common methods discussed in this chapter.

1.06.4.3 WKBJ–Maslov

An important feature of this technique is that thin homogeneous layers no longer parameterize the Earth model. Vertical gradients in depth or radius are allowed in velocity, and asymptotically approximate, WKBJ, solutions of the vertically separated part of the wave equation are assumed. In contrast to homogeneous layers, where the up- and down-going vertical wave functions are simply $\exp[\pm ik_z(z-z_{\text{ref}})]$, the WKBJ solution approximates the vertical wave functions by

$$g^{(1)}_{(2)}(r,p,\omega) = \frac{e^{i\pi/4}}{\omega r}\sqrt{\frac{V}{\xi(r)}}\exp(\pm i\omega\tau) \qquad [17a]$$

where the superscripts (1) and (2) and signs + and − refer to up- and down-going waves, respectively. $\xi(r)$ is the vertical component of the slowness vector and is related to the cosine of the angle of incidence of a ray at any level r by $\xi(r) = \cos(i)/V = \sqrt{1/V^2 - p^2/r^2}$. τ is the delay time obtained by integrating the vertical component of the slowness vector from the turning point radius r_p,where $\cos(i) = 0$, to r:

$$\tau = \int_{r_p}^{r} \sqrt{1/V^2 - p^2/r^2}\,dr \qquad [17b]$$

The accuracy of these high-frequency approximations increases as the ratio λ/s decreases, where λ is the wavelength and s is the scale length of the medium. The scale length s is defined by

$$s = \min\left(\frac{V_S}{|\nabla V_S|}, \frac{V_P}{|\nabla V_P|}, \frac{\rho}{|\nabla\rho|}, r_b\right) \qquad [18]$$

where r_b is a radius of curvature of a first-order discontinuity in density or elastic velocity (Beydoun and Ben-Menahem 1985; Kravtsov and Orlov, 1980). Separability of P and S wave potentials is assumed in each vertically or radially inhomogeneous layer and frequency-dependent reflections, and P to S conversions by regions of strong gradients are ignored. Hence, transition zones, which may be of interest to mantle solid–solid phase changes, should be handled by thin layers of weaker gradient where the asymptotic approximations remain valid. For problems consisting of a body wave reflected by or bottoming above a discontinuity, the integrand $u(\omega, p, \Delta_o)$ in eqn [13] is replaced by

$$u(\omega,p) = \omega^{1/2}\Pi(p)e^{i\omega\theta}(p) \qquad [19a]$$

where

$$\theta(p) = \int_{r_p}^{r_s}\sqrt{1/v^2 - p^2/r^2}\,dr + \int_{r_p}^{r_o}\sqrt{1/v^2 - p^2/r^2}\,dr + p\Delta_o \qquad [19b]$$

$\Pi(p)$ is a product of the plane wave reflection coefficient of the discontinuity and the plane wave transmission coefficients through layers above the discontinuity. The factor $\theta(p)$ in the phase originates from the phases associated with the WKBJ solutions to vertical wave functions in the transmission region above the discontinuity and the horizontal wave function for propagation to great circle distance Δ_o. Hence, the name WKBJ is applied to this method. In this method, body waves are synthesized by summing a series of representations of the type given by [19a]. Each body wave in this sum is assumed to be associated with rays that are either reflected by or turn just above the first inhomogeneous layer above each discontinuity (Figure 13).

Inversion to the time and space domain of the transformed solution $u(\omega, p, \Delta_o)$ of eqn [13] is performed by a slowness method rather than by a spectral method as commonly done in reflectivity methods. In slowness methods, the inversion to the time domain is performed analytically, recognizing that separate frequency-dependent factors in the integrand can be written as convolutions in the time domain. The final inversion to the space domain is performed by numerical integration over p by a method in which the combined phase factor $\theta(p) - t$ is sampled in slowness intervals corresponding to a fixed sampling rate in time t (Figure 14). This key step is contained in the phase sampling subroutine THETAC of Chapman's WKBJ original codes. The integration over horizontal slowness is truncated at points along the real p axis, which introduces truncation phases in the synthetic. These can be removed by approximating the phase function's dependence on ray parameter from the truncation slownesses to $\pm$ infinity, assuming a linear dependence on p, and analytically integrating the approximation (Chapman, 1978). A well-documented package of the WKBJ algorithm by A.R. Gorman, tailored toward continental-scale reflection and refraction, exists in the PLOTSEC package available at the website www.eos.ubc.ca/personal/amor/plotsec/plotsec_wkbj.html. A code for teleseismic applications and example inputs can be obtained from Chapman's contribution to the Seismological Algorithm text. Software for the evaluation of the delay time $\tau(p)$ in many standard Earth models can be obtained from the TauP Toolkit (Crotwell et al., 1999). Due to the need of separately describing ray interactions with discontinuities, the input to WKBJ codes is less black box-like than the input to typical reflectivity codes.

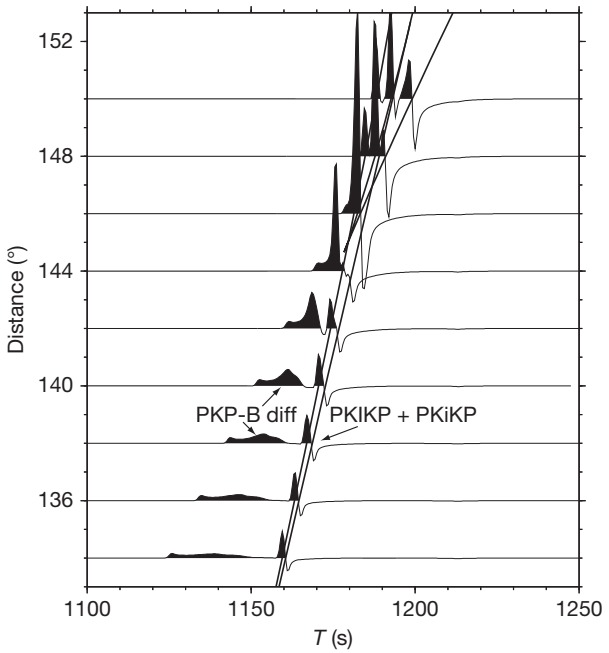

Figure 13 Seismograms synthesized by the WKBJ method for P waves interacting with the Earth's core using the program and example input by Chapman et al. (1988) distributed with *Seismological Algorithms*.

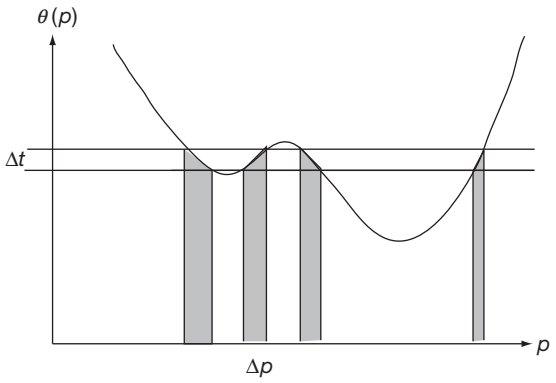

Figure 14 The ray parameter integrand in the WKBJ method is performed numerically by taking ray parameter intervals Δp equal to the desired sampling rate in time Δt as mapped by the total WKBJ phase function $\theta(p)$.

The Maslov technique (Chapman and Drummond, 1982) generalizes the WKBJ seismogram technique to 2D and 3D velocity variations. The restrictions of the asymptotic approximations still apply, that is, the medium scale length in any inhomogeneous region must be greater than the wavelength. Full implementation of the technique sometimes requires a careful averaging of solutions in slowness p space with those in the physical x space. Each of these spaces can contain caustics where a weight factor or geometric spreading factor becomes singular. Regions of models having strong spatial gradients, where the asymptotic approximations are failing, are often characterized by closely spaced caustics in slowness space and physical space for waves at grazing incidence to the strong gradient regions. In these regions, the weight factors averaging the solutions in phase and physical space can be difficult to design. This situation can exist if high-gradient zones define the boundaries of a thin high- or low-velocity zone (e.g., a subducting slab or the fault zone structure shown in Figure 17(a)). In these situations, it is better to define the anomalous structures by first-order discontinuities and apply boundary conditions for multiply-reflected and refracted body waves.

Compared to the reflectivity method, the WKBJ and its related Maslov extensions are computationally much faster and, hence, better suited to problems in waveform inversion that may require many repeated syntheses to evaluate a misfit or object function. The speed of these methods is due to the use of an asymptotically approximate solution in spatially varying layers. Therein, however, lies the limitation of these methods. The vertical variation must be sufficiently weak so as not to exceed the errors associated with the approximation. When there is a need to sum ray interactions with more than two or three first-order discontinuities in a distance range, the input parameters describing the separate ray interactions in some WKBJ codes can become complex unless a user-friendly input interface is provided.

1.06.4.4 Full-Wave Theory and Integration in Complex p Plane

The term full-wave theory can be applied to any technique that incorporates frequency-dependent effects of wave interactions with boundaries, including diffraction and tunneling. Any transform approach that includes a broad enough domain in frequency and wave number to simulate these frequency-dependent effects, often due to poles or branch cuts in the

response function, can be called a full-wave theory. This term was specifically applied to 1D structure by Cormier and Richards (1977) to an asymptotic spectral technique that inverts the slowness integral by paths Γ in the complex p plane and substitutes a Langer approximation for the WKBJ approximation to the vertical wave functions. The vertical wave function in the Langer approximation is given by

$$g^{(1)}_{(2)}(r,p,\omega) = \frac{\pi\rho_s V_s}{2\rho V}\frac{V_s e^{\pm i\pi/6}}{\omega\xi}\sqrt{\frac{\omega\tau}{V\xi}}H^{(1)}_{1/3}(\omega\tau) \qquad [20]$$

The Langer approximation remains regular at grazing incidence to boundaries where ξ and τ vanish but returns the WKBJ approximation where it is accurate. The integration over the contour Γ is carried out numerically, with Γ extended into regions off the real p axis where the integrand in eqn [13] exponentially decays. For portions of Γ along the real p axis, the integrand can be very oscillatory, and integration can be handled efficiently by Filon's method (Frazer and Gettrust, 1984). Full-wave theory includes tunneling, diffraction, and other phenomena related to frequency dependence of reflection–transmission coefficients at grazing incidence to boundaries. An example of the importance of these phenomena includes the very strong frequency dependence of the P wave that bottoms just above the core–mantle boundary and tunnels across the core–mantle boundary, exciting compressional (K) waves in the liquid outer core that multiply reflect along the underside of the core–mantle boundary (PKnKP waves; e.g., Richards, 1973). **Figure 15** compares a synthesis of SV waves interacting with the Earth's core by the asymptotically approximate full-wave method with a numerical method described in a later section (Rondenay et al., 2010). Full-wave theory has been extended (Rial and Cormier, 1980) to synthesize body waves that are strongly focused at the antipode (**Figure 16**) by using several asymptotic approximations to the Legendre function, which contributes to the phase for propagation in the horizontal or Δ direction.

The theory is most completely developed in Chapter 9 of Aki and Richards (2002) and in *Seismological Algorithms* (Cormier and Richards, 1988) where example codes and inputs are distributed. As an asymptotic theory, full-wave theory shares the limitations of WKBJ codes, in that care must be taken not to assume too strong a velocity and density gradient

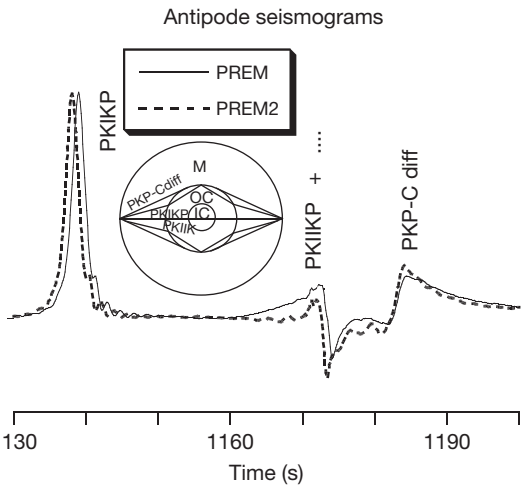

Figure 16 Synthetic seismograms computed by the full-wave method (Cormier and Richards, 1988) for the vertical component of ground motion for an explosive source-time function observed at 180° from the epicenter for the PREM and Song and Helmberger 's (1995) PREM2 modification of PREM's inner core.

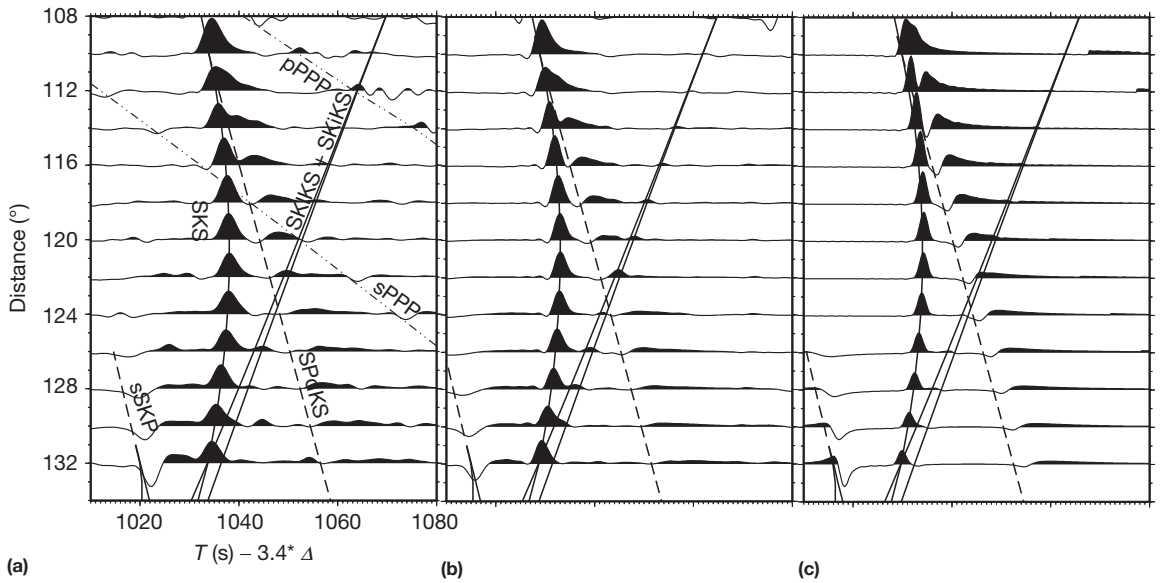

Figure 15 Radial component of displacement synthesized for a radial vector point source at 500 km depth synthesized (a) by the pseudospectral method with no Earth attenuation, (b) by the pseudospectral method with no S attenuation but the P attenuation model of PREM doubled to suppress interactions with discontinuities in the upper mantle, and (c) by an asymptotically approximate full-wave method with no attenuation. PREM-predicted ray theoretical travel times of SKS and SKIKS + SKIIKS + ··· + SKiKS are shown by solid lines; predicted earliest arrival times of diffracted SPdKS and the caustic diffraction of sSKP by dashed lines; and sPPP and pPPP by a dash–dot lines.

in each inhomogeneous layer. Added to the complexity in the description of ray interactions shared with WKBJ code input, the construction of full-wave theory integrands and complex integration paths can be challenging, particularly for interference head wave and antipodal problems. Often, it is best to start with example input files specifying ray descriptions and integration paths for these problems, which are distributed with *Seismological Algorithms*.

1.06.4.5 Ray Theory, DRT, and Gaussian Beams

Ray theory solutions to the elastic equation of motions consist of body wave pulses arriving at the least or stationary-phase time, scaled by amplitude factors due to products of plane wave reflections and transmissions and geometric spreading. In an inhomogeneous isotropic or anisotropic medium, the ray theory solution for a body wave is an asymptotic approximation that converges to an exact solution as frequency tends to infinity. Solutions for the vector displacement U of a body wave in the frequency domain start from a trial solution in the form of vector factors multiplying inverse powers of radian frequency ω:

$$U(\omega) = \sum_n \frac{\vec{A}}{\omega^n} \exp(\mathrm{i}\omega t) \qquad [21]$$

Substitution of the earlier form into the elastic equation of motion leads to the eikonal equation for ray trajectories and the transport equations for geometric spreading. Solution of the transport equation can be cast in the form of a system of linear equations in a ray-centered coordinate system termed the DRT equations. The errors in the approximation given by $n=0$ remain small for wavelengths much smaller than the scale length of the medium given by [18]. In practice, no more than the $n=0$ term is ever calculated because higher-order terms are expensive to calculate and can never properly include the frequency-dependent effects of waves reflected and converted by regions of high spatial gradients in velocity and density. Cerveny (2001) and the review in **Chapter 1.05** provided further details on the derivation, accuracy, and frequency-dependent corrections to asymptotic ray theory and review the relations between DRT, WKBJ/Maslov, and Gaussian beam summation.

The shape of the wave front can be estimated from the first and second spatial derivatives of the wave front at the end point of each ray on the wave front. This is referred to as a paraxial (close to the axis of the ray) approximation of the wave front. To calculate the first- and second-order spatial derivatives of the wave front, a system of linear equations must be integrated. These include (1) equations that solve the eikonal equation for ray trajectory by the method of characteristics, which describe the evolution of ray trajectory, its vector slowness $\mathbf{p}$, and travel time; (2) an equation to describe the rotation of ray-centered coordinates in which S wave polarization remains fixed; and (3) the DRT equations for matrices $\mathbf{P}$ and $\mathbf{Q}$ needed to describe the evolution of wave front curvature and geometric spreading. The vector slowness $\mathbf{p}$ is simply the spatial gradient of travel time, and the geometric spreading is related to the wave front curvature or second spatial derivatives of travel time. When a receiver is not near a caustic, the quantities determined from integrating the DRT system can be used to determine the frequency-independent ray theory solution, consisting of geometric spreading, travel time, and products of reflection/transmission coefficients. The paraxially estimated phase from the $\mathbf{P}$ and $\mathbf{Q}$ matrices of the DRT system can be used to either avoid two-point ray tracing by spatially extrapolating the travel time near a ray or iteratively solve the two-point ray-tracing problem. The travel time at a point $\mathbf{x}$ in the vicinity of a ray end point at $\mathbf{x}_o$ can be estimated by

$$T(\mathbf{x}) = T(\mathbf{x}_o) + \Delta\mathbf{x}^t\mathbf{p} + \frac{1}{2}\Delta\mathbf{x}^t\mathbf{H}\mathbf{M}\mathbf{H}^t\Delta\mathbf{x} \qquad [22]$$

where

$$\mathbf{M} = \mathbf{P}\mathbf{Q}^{-1}$$

and

$$\Delta\mathbf{x} = \mathbf{x} - \mathbf{x}_o$$

The 2×2 matrices $\mathbf{P}$ and $\mathbf{Q}$ are determined by integrating the system

$$\frac{\mathrm{d}\mathbf{P}}{\mathrm{d}s} = -v^2\mathbf{V}\mathbf{Q}$$

$$\frac{\mathrm{d}\mathbf{Q}}{\mathrm{d}s} = v\mathbf{P} \qquad [23]$$

along the ray path s. In eqn [22], $\mathbf{H}$ is the transformation from ray-centered coordinates to Cartesian coordinates. The columns of $\mathbf{H}$ are the vector basis of the ray-centered coordinate system at the ray point $\mathbf{x}$. $\mathbf{V}$ is a matrix of second spatial derivatives of velocity in the ray-centered coordinate system. The spreading $\mathbf{Q}$ can also be used to calculate geometric spreading [10]. The DRT system in eqn [23] can be generalized using a propagator, fundamental matrix formalism, similar to that used for propagating the solution to vertically separated equations of motion, except that in this system, the solutions are quantities related to wave front curvature and ray density rather than components of displacement and stress. Additional matrices need to be inserted into products of DRT propagator matrices to properly handle effects of discontinuities in both medium velocities and their first-order spatial derivatives.

Superposition of Gaussian beams is an extension of ray theory closely related to the WKJB/Maslov techniques. It amounts to a superposition of approximated wave fronts, weighted by a Gaussian-shaped window in space centered about each ray. Gaussian beams are defined by adding a small imaginary part to the matrix $\mathbf{M}$ in the paraxially extrapolated phase in eqn [22], which gives an exponential decay of a beam in space away from the central ray. The amplitude of each beam is proportional to real part of $\exp(\mathrm{i}\omega T)$, where T is made complex in eqn [22] by the inclusion of a complex $\mathbf{M}$. Beam summation remains regular in the vicinity of ray caustics, where geometric spreading vanishes and ray theory solutions become singular. It supplies approximate estimates of frequency-dependent diffraction in the shadow of caustics and grazing incidence to boundaries.

To properly model classical head waves, some care must be used in the design of beam weighting and beam widths. Weight

factors of beams are determined such that a superposition of beams returns a zero-order ray theory solution for the complex spectrum, that is, $U(\omega, x) = \exp(i\omega t)/\mathrm{sqrt}(\det(\mathbf{Q}))$, under a stationary-phase approximation to an integral over ray parameter or takeoff angles. WKBJ/Maslov is a special case of Gaussian beam summation. Superposition of Gaussian beams can give a nonsingular approximation to the solution of the wave field near a caustic, but does not suffer the problem the Maslov method has in combining caustics in phase (slowness) space. Restrictions on the validity of the Gaussian beam summation tend to be similar to that of the WKBJ/Maslov method. The scale length of the medium needs to be much larger than the wavelength and also larger than the beam widths (Ben-Menahem and Beydoun, 1985). **Figure 17** compares superposition of Gaussian beams with DRT for P waves interacting with a low-velocity fault zone.

For grazing incidence to regions of strong velocity gradient, such as the example shown in **Figure 17**, the paraxial approximation quickly fails and caustics become closely spaced, making it difficult to design optimal beam widths such that the paraxial approximations of the individual beams have small error in regions far from the beam axes.

The **P** and **Q** matrices and the propagator matrix of the DRT system developed by Cerveny and his coworkers are powerful tools that can simplify the coding and understanding of any problem requiring the use of ray theory. DRT can be exploited to calculate the integrand for Kirchhoff integrals (**Section 1.06.7.2**) and the banana-shaped sensitivity kernels, or Fresnel volumes, needed for frequency-dependent tomography (**Section 1.06.7.3**).

Computer codes for modeling seismic wave fields in 2D and 3D laterally varying structures by ray theory and Gaussian beam superposition can be obtained from Cerveny's group at Charles University (website: www.sw3d.mff.cuni.cz) as well as the World Data Center. The best-developed codes are tailored to continental-scale reflection–refraction problems. One version (ANRAY) is one of the rare codes that combine general anisotropy with 3D variations. A teleseismic-oriented version of DRT and beam summation was written by Davis and Henson (1993), with a user-friendly graphic interface.

1.06.4.6 Modal Methods

Solutions of the elastic wave equations can be obtained from either a superposition of ray/wave front solutions or a superposition of modes. Rays and mode representations are fully equivalent in accuracy if properly applied to a specific Earth model and frequency domain. In a modal approach, the eigenfunctions of free oscillation of a sphere have a characteristic frequency and are classified by the position of nodes at the surface and at depth where displacements go through a zero and change sign (e.g., Lapwood and Usami, 1981). For a modal solution to be accurate at the lowest frequencies of free oscillation, restoring forces due to gravity and rotation of the Earth must be included as additional forces in eqn [1]. In a spherically symmetrical, nonrotating, isotropic (SNREI) Earth, modes can be separated into either spheroidal or toroidal modes of oscillation. The motions of spheroidal modes are analogous to those of P and SV body waves and Rayleigh surface waves: those of toroidal modes to those of SH body waves and Love surface waves. Summation of normal modes of the Earth can provide a complete image of the wave field at the surface and at every depth (Dahlen and Tromp, 1998). Every body wave observed at the surface can be represented by a

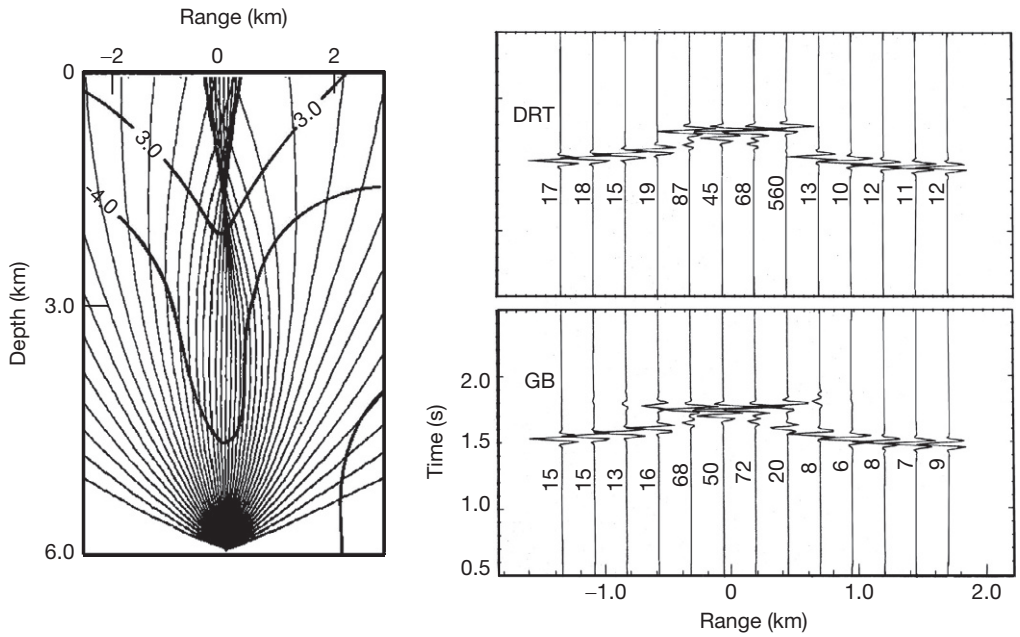

Figure 17 Left: Cross section of a fault zone P velocity structure and P wave rays for a hypocenter in the seismogenic zone. Right top: Ray theoretical synthetic seismograms calculated by dynamic ray tracing (DRT). Right bottom: Gaussian beam synthetic seismograms. Note the larger amplitudes (560 and 87) in the DRT synthetics compared to the smaller amplitudes and diffractions of the Gaussian beam synthetics near the ray caustics. A detailed discussion appears in Cormier and Spudich (1984).

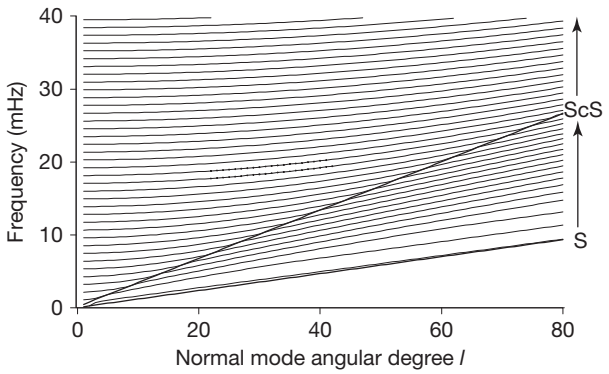

Figure 18 Toroidal modes plotted by connecting straight lines to discrete integer angular order number as a function of frequency. When summed, modes lying in the regions above the thick solid lines correspond to S and ScS. Reproduced from Dahlen FA and Tromp J (1998) *Theoretical Global Seismology*, 944 pp. Princeton: Princeton University Press, with permission.

subset of normal modes (**Figure 18**). The frequency-dependent effects of diffraction at ray grazing incidence to boundaries are also included in mode sums. The normal modes of a SNREI Earth can be efficiently computed on a single processor for frequencies up to 0.1 Hz. A code by G. Masters for synthesizing seismograms from sums of normal mode are included on the CD supplied with the International Handbook for Earthquake and Engineering Seismology (Lee et al., 2002).

An advantage of mode summation is that input parameters are especially simple, basically just an Earth model parameterization, a frequency band, and desired number of modes. Mode summation is routinely used in the inversion of complete seismograms to retrieve moment-tensor representations of earthquake sources (Dziewonski et al., 1981). A disadvantage is that it is limited to lower frequencies for practical computation on a single workstation. Effects of gravity, Earth rotation, anisotropy, and lateral heterogeneity remove degeneracy from SNREI modes and couple spheroidal with toroidal modes. Extensive literature exists on incorporation of the mode coupling induced by lateral heterogeneity by applying perturbation techniques to SNREI modes (e.g., Dahlen, 1987; Li and Tanimoto, 1993).

Another modal-type approach is that of locked modes. Here, the modes are not whole-Earth modes of free oscillation, but rather the surface wave modal energy that exponentially decays with increasing depth from the surface. Modes are numbered by sign changes in displacement with depth, the 0th mode corresponding to either the fundamental mode of the Love or Rayleigh surface wave. The integrand $u(\omega, p)$ in eqn [13] must first be constructed to include all interactions with the surface. The locked mode approach then evaluates the ray parameter or wave number integral of eqn [13] in the frequency domain by deforming the integration contour in the complex plane and applying the residue theorem to the integrand. A high-velocity capping layer is placed at depth, which locks plate-like modes into layers above the capping layer. The capping layer is placed deep enough such that mode sums representing waves of interest in a particular time window all turn or refract above the capping layer. Since all body waves, multiply-reflected in the layers above the capping layer, are included, the locked mode technique has a problem shared with the conventional reflectivity technique in which late arriving waves are folded back into a finite length time window. Similar to reflectivity, this problem can be handled by adding a small complex part to frequency. Harvey (1981) illustrated derivation of the technique in models described by plane homogeneous layers and available codes. An extension to vertically inhomogeneous layers using the Langer approximation is given by Cormier et al. (1991).

1.06.4.7 Numerical Methods

Fully numerical solutions of the elastic equations of motion can treat wave propagation in an arbitrarily complex 3D Earth, having velocity variations over a broad range of scale lengths. A full solution is obtained, containing body waves, surface waves, and all diffraction, head wave and leaky mode effects. **Chapter 1.07** reviews numerical techniques concentrating on current methods that can handle fully 3D models and complete seismograms. This subsection is a brief summary of some of the techniques that occur in the expanded discussions by Tromp, including both 2D and 3D techniques and those that are applied to primarily the highest-frequency body waves and shorter time windows.

The principal numerical techniques are finite difference and finite element. For accuracy up to ranges of 100–1000 wavelengths, conventional finite difference solutions typically are performed with fourth to eighth order difference approximations to spatial derivatives. The equations of motion are most commonly solved for particle velocity and stress on a staggered grid (Mozco, 2007; Virieux, 1985, 1986). The pseudospectral version of the finite difference method calculates spatial derivatives in the wave number domain, multiplying by ik and inverse Fourier transforming back to space (**Figure 19**). The pseudospectral method is computationally more expensive than higher-order differences but achieves much higher accuracy at long ranges, typically having little grid dispersion in applications to ranges of 10 000 wavelengths or higher. For this reason, the pseudospectral method can be an ideal choice for teleseismic applications where high accuracy is desirable at both regional and teleseismic ranges. Kosloff and Kessler (1990) and Fornberg (1998) reviewed both conventional finite difference and pseudospectral numerical approaches, estimating error and stability conditions.

An approximation that can greatly speed up numerical computation in complex 3D media is to start with a one-way or paraxial wave equation, in which backscattered energy is neglected for small perturbations in the medium and the predicted wave field is restricted to a narrow angular range around one direction, usually vertical or horizontal. Applications of this approach include the split-step Fourier transform method, the phase screen, and pseudo screen approaches (Wu et al., 2007).

Yet another method of efficiently handling the effects of 3D propagation of a point source is a model in which velocities and densities can be assumed to be functions of only two coordinates. This is often termed 2.5D modeling. For 2.5D numerical modeling, Randall (1991) described the velocity–stress finite formulation of finite differences, and Furumura and Takenaka (1996) described the pseudospectral approach.

The spectral element method formulated with the SPECFEM code (Komatitsch and Tromp, 1999, 2002; Komatitsch and Vilotte, 1998) is currently one of the few numeric methods

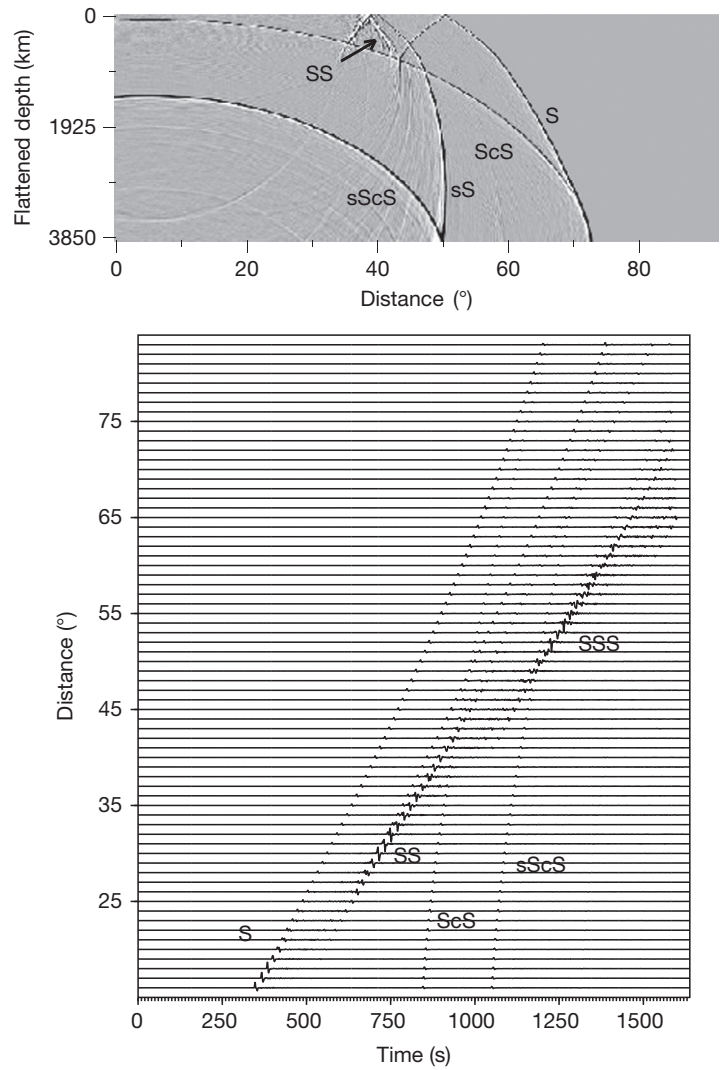

Figure 19 Wave fronts (top) and complete transverse (SH) component seismograms (bottom) synthesized by the pseudospectral method from Cormier (2000). Note the increase in amplitudes occurring at roughly 20° intervals in S, SS, and SSS due to rapid increases in velocity at upper mantle solid–solid phase transitions.

designed to handle a fully 3D Earth model. SPECFEM has a well-developed interface to grid the elements needed for arbitrarily complex 3D models. Versions of SPECFEM are available for both local/regional-scale problems for ranges on the order of 0–100 km and global- or teleseismic-scale problems. Another popular regional-scale code is the elastic finite difference program by Larsen and Schultz (1995), which has been applied to the effects of 3D basins and extended fault slip (e.g., Hartzell et al., 1999).

The direct solution method (DSM) is a technique that numerically solves a weak formulation of the equations of motion (boundary conditions specified by surface integrals) for a series of frequencies and wave numbers required for inversion to the time and space domain by a FFT (Cummins et al., 1994a,b). The particular numerical technique consists in expanding displacements in the frequency and wave number domain by a series of basis functions consisting of a product of splines in the vertical direction and spherical harmonics in the angular direction. In DSM, the coefficients for the basis functions are found by the method of weighted residuals (Geller and Ohminato, 1994). The SH and P-SV seismograms computed by DSM are complete, in that they contain all possible body and surface waves. Hence, DSM is a viable alternative to summing modes of free oscillation in higher-frequency bands. Weak 3D perturbations to a radially symmetrical background model are possible in DSM at a computational cost not much higher than that required for the background model (Takeuchi et al., 2000).

Computational time is a practical limitation to numerical modeling. Since most numerical techniques require Earth models specified on a spatial grid or elements, it is straightforward to parallelize the computation by decomposing the spatial grid or elements over multiple processors. Practical computations can be defined by time required to compute a problem. Depending on the algorithm and frequency band, common computer resources in most labs allow a complete teleseismic wave field to be synthesized in 1 or 2 days using 10–100 processors in parallel. Typical body waves having a

high signal-to-noise ratio in the teleseismic range (10°–180°) exist up to 2 Hz. Practical 2D modeling can be currently performed at teleseismic range up to 1 Hz with finite difference and pseudospectral methods; 3D problems with the SPECFEM finite element method can be done up to 0.1 Hz in this time period with a similar number of processors. At ranges less than 100 km, 3D problems can be practically performed at frequencies up to 1 or 2 Hz (order of 200 wavelengths). This range and frequency band just starts to cover the frequencies of interest to strong ground motion. Frequencies up to 10 Hz at 2000 km range (>5000 wavelengths) in complex 3D structure are of interest to the problem of discriminating earthquake sources from underground nuclear tests. This is a research problem that is still inaccessible with small to moderate size clusters (<100 nodes) and numerical methods.

A large body of literature exists in the application of finite difference and pseudospectral solutions for local-scale problems up to 100 km for exploration applications and strong ground motion applications (e.g., Hartzell et al., 1999; Olsen, 2000). Significantly smaller amounts of published work exist for applications at regional distances (100–2000 km), in which waves are primarily trapped in the crust and the uppermost mantle, and a much smaller amount exists for teleseismic propagation (e.g., Cormier, 2000; Furumura et al., 1998; Igel, 1999).

1.06.5 Parameterization of the Earth Model

An important choice in modeling a seismogram will be the parameterization of the Earth model or how to describe the spatial variation of its elastic moduli and density (Figure 20). The choice of parameterization can have important geodynamic and geochemical implications and is often tightly coupled to the choice made for the modeling algorithm.

1.06.5.1 Homogeneous Layers Separated by Curved or Tilted Boundaries

Certain parameterizations allow seismograms to be synthesized by simple analytic formulas. For example, if the Earth is isotropic and homogeneous, then ray paths are straight lines. The amplitude of body waves are inversely proportional to distance between source and receiver, $1/|\mathbf{x}_o - \mathbf{x}|$. A received waveform is simply the far-field approximation of the source-time function $S(t)$ evaluated at the retarded time, $S(t - |\mathbf{x}_o - \mathbf{x}/v|)$. This simple solution can be extended to models described by sequences of homogeneous layers bounded by planes of varying dip by incorporating elastic boundary conditions at each boundary to calculate reflection/transmission/conversion coefficients. Snell's law is applied in an incidence plane defined by ray direction and interface normal. Geometric spreading can be calculated from a simple function of ray length in each layer. This algorithm is just ray tracing and DRT applied to homogeneous layers.

Stacks of homogeneous layers can accurately describe continuous spatial variations, provided that the discretization of the model is much finer than the shortest wavelength of interest. The accuracy of the ray solution depends on the ratio of wavelength to the shortest radius of curvature of the boundaries. The frequency dependence of reflection by curved boundaries can be treated by the Kirchhoff integral technique.

1.06.5.2 Vertically Inhomogeneous Layers

Except for the case of back-of-the envelope calculations and the limiting case of layering much finer than wavelength, the Earth cannot often be well approximated by either homogenous planar or radially symmetrical layers. Velocities and densities vary in all three coordinate directions, but the next most important approximation of the Earth is to make this variation occur in the vertical direction. If this vertical variation is approximated by thin homogeneous plane layers and an EFA (Section 1.06.4.1), then simple plane wave or analytic

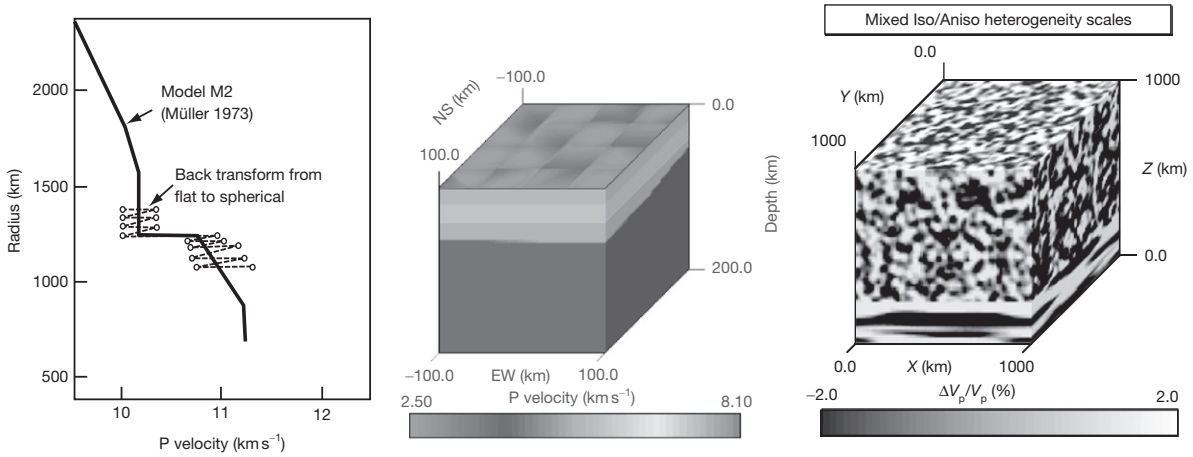

Figure 20 A comparison of the PREM model parameterized by continuous polynomials in radius versus the EFA and discrete homogeneous layers and discrete parameterization back-transformed to a spherical model (Aki and Richards, 2002; Müller, 1973). Bottom left: A 3D model of the crust and uppermost mantle beneath Nilore, Pakistan, parameterized by Delaunay tetrahedra constructed from codes by Sambridge and Gudmundsson (1998). Bottom right: A 3D model for testing the effects of possible structure near the core–mantle boundary having P velocity perturbations with both isotropic and anisotropic spatial distributions, constructed using the techniques described by Frankel and Clayton (1986).

solutions to the wave equation can still be effectively employed in each layer. In addition to errors associated with the EFA, this discretization should consider physical constraints of finite strain and buoyancy neutrality to be realistic, or at least the consequences of those constraints need to be evaluated. Except at or near-vertical incidence, body waves are notoriously insensitive to density variations, and it is especially easy to ignore unphysical effects of any constraints on the velocity–density relations of known materials or the geodynamic effects of buoyancy. The parameterization of the Earth by polynomials analytic in depth was proposed in PREM (Dziewonski and Anderson, 1981) in part to obey the constraints of stable stratification. Modifications to PREM and other reference Earth models should attempt to take similar care in obeying such constraints. Methods using asymptotic ray approximations to vertical wave functions (e.g., WKBJ, full-wave, and GRT) are readily adaptable to this parameterization simply by extending the calculation of delay time $\tau(p)$ to numerical integration over radius or depth. Alternative parameterizations are computationally more efficient, including some that allow $\tau(p)$ to be obtained by analytic integration (Cerveny, 2001), but little penalty is involved with current generation processors by calculating $\tau(p)$ by numerical integration over radius.

1.06.5.3 General 3D Models

Tomographic images are often the starting point of synthetic modeling in 3D. The two most common parameterizations of these 3D models are either by spherical harmonics (e.g., Gu et al., 2001; Masters et al., 2000; Ritsema and van Heijst, 2000; **Chapter 1.10**) or by block volumetric elements (e.g., Grand et al., 1997). Except in fully 3D modeling methods such as SPECFEM, a choice made in all 2D modeling methods is to assume that body wave propagation remains in the sagittal plane and to compute motions in a 2D model derived by taking a cross section of the 3D model. If velocity perturbations are assumed to be the same as the typically small (<3%) perturbations of the original tomographic model, the assumption of propagation remaining within or close to the sagittal plane is quite accurate. Indeed, to be consistent with the assumptions of linearized tomographic inversion, it is appropriate to even assume that paths are unperturbed from those in a reference model in the computation of travel times in ray-based methods. In this case, the results of the forward modeling can be disappointing, in that the only change in synthetic seismograms from those computed in a reference model will be small changes in relative travel times with little or no waveform perturbations. Larger variations in amplitudes and waveforms can be achieved with higher perturbations that violate the assumptions of linearized tomographic inversions.

Since tomographic imaging can smear a more intensely perturbed anomaly over its sampled ray paths into a smoother, less intense anomaly, one approach used in forward waveform modeling is to multiply the perturbations of the tomographic starting model by a scale factor. Some success in matching waveforms by this technique has been achieved using factors of 2–3 to multiply the images of tomographically estimated perturbations to shear velocity (Ni et al., 2000). Some adjustments in the boundaries of anomalies were also necessary to obtain good matches with observed waveforms. Starting with a tomographic model parameterized by spherical harmonics, Bréger and Romanowicz (1998) and To et al. (2005) achieved a good match to S waves interacting with the core–mantle boundary by preserving the boundaries between the largest-scale positive and negative velocity anomalies but increasing the maximum and minimum values of velocity perturbation. These ideas have been extended by Sun and Helmberger (2011) to include the possibility of multipathing induced by very strong velocity perturbations outside of the domain of validity required by linearized travel time tomography. Steps in the analysis include an inversion for waveform multipaths represented by summing a predicted signal $S(t)$ in a reference model with one or more delayed echoes of that signal. Modeling then proceeds by trial and error modeling, followed by a rigorous fitting of complex waveforms to numerically computed waveforms in 3D models constructed by amplifying the strongest perturbations found in the tomographic inversion (**Figure 21**). Important to the success in the waveform fitting is an accurate representation of the far-field source-time function, which may be separately determined by either modeling or empirical observation in distance ranges without multipathing. Assessing the nature of multipathing in complex 2D and 3D structures is an important step both in the construction of an Earth model and in the choice of the waveform modeling method. Useful tools in assessing multipath behavior include the computation of the Lyapunov exponent along a ray, for example, Cerveny et al. (2007).

Another model attribute important to its physical plausibility is the intensity of small-scale velocity (on the order of wavelength) and density fluctuations. The coda of body waves interacting with crustal heterogeneity is consistent with the scaling of P velocity and density fluctuations such that $\mathrm{d}\ln\rho/\mathrm{d}\ln V_\mathrm{p} = 0.8$ (Sato et al., 2012). In the mantle, however, it is difficult to sustain such high-density fluctuations because the anomalies would buoyantly sink or rise. Geodynamic modeling of mantle convection commonly assumes a much lower scaling ($\mathrm{d}\ln\rho/\mathrm{d}\ln V_\mathrm{p} < 0.1$) between the density and velocity fluctuation.

Sophisticated and user-friendly tools for gridding 3D models have existed in exploration and engineering applications for some time but are often available only as expensive commercial packages. One public domain package is distributed with the finite element SPECFEM code. Another set of tools are those that employ irregular cells specified by Voronoi tetrahedra, which use a nearest-neighbor interpolation to calculate velocities and their first spatial derivatives on irregularly spaced 3D grids (Sambridge and Gudmundsson, 1998). This can be used in conjunction with the convex hull grid mapping software from the University of Minnesota (www.geom.uiuc.edu/welcome.html) to retrieve a physical quantity and its spatial derivatives at any coordinate point. One example where this approach can be examined are the 3D slab models shown in Sambridge's web pages (www.rses.anu.edu.au/seismology/projects/RUM/slabs/slabs.html), where velocity perturbations have been centered on Benioff zone seismicity.

Some computational difficulties can arise in the parameterization of general 2D and 3D models due to the handling of first- and higher-order spatial derivatives of velocity. Ray and asymptotically approximate methods of solving elastic propagation are strictly valid for relatively slow spatial variation of

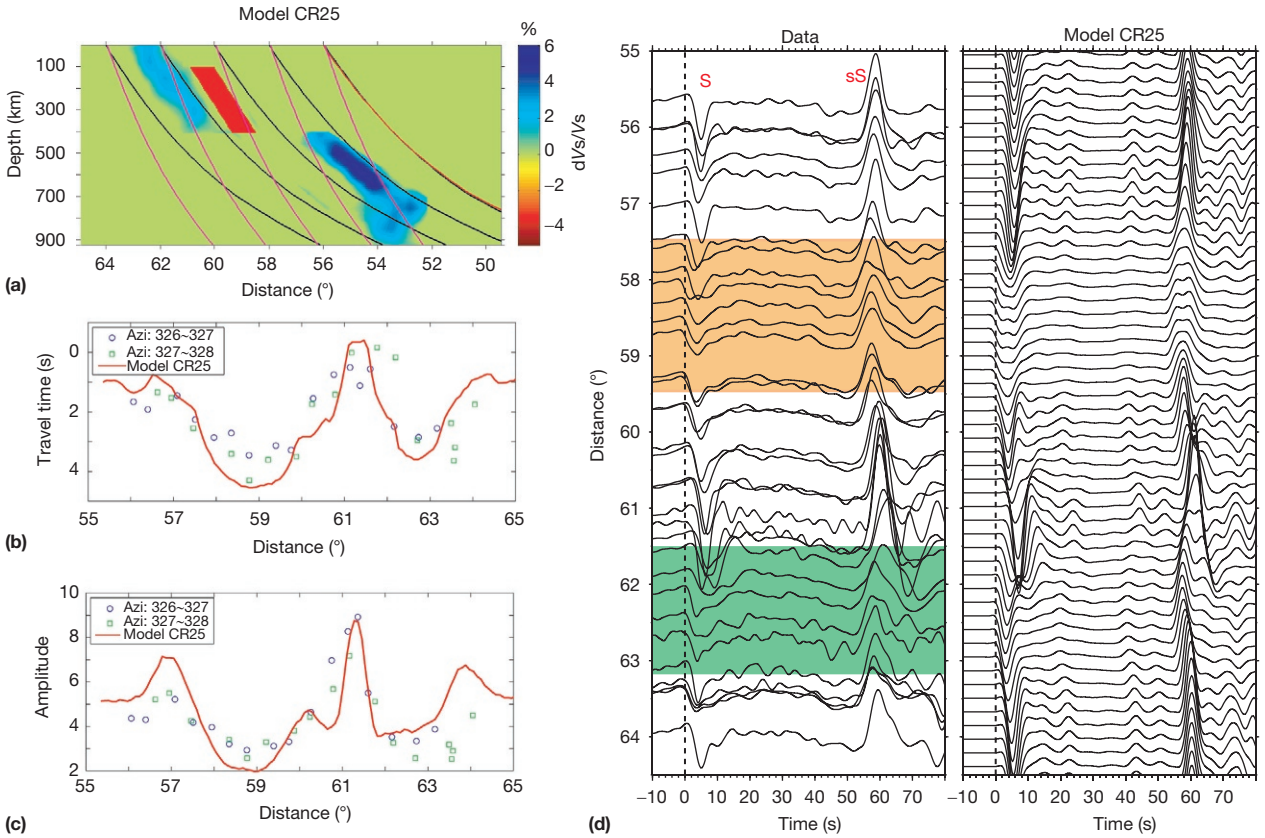

Figure 21 2D modeling of the S and sS waveform data from Sun and Helmberger (2011). The best-fitting model CR25 in (a) was produced by removing small structures and inflating features producing the multipathing in a P tomographic model. The top blue region is inflated by 2.5 and the bottom one is inflated by 4. The comparisons of travel time and amplitude of S are displayed in (b) and (c). (d) Comparison of data against 2D finite difference (FD) synthetics from model CR25. The model produces the strong multipathing around 58° (yellow region) and 62° (green region) for both S and sS phases in the data. The large amplitude at 61° is also predicted by this model. Reproduced from Sun D and Helmberger DV (2011) Upper-mantle structures beneath USArray derived from waveform complexity. *Geophysical Journal International* 184: 416–438, with permission.

velocity, where medium scale lengths are much larger than wavelength. Some parameterizations that interpolate velocities in space can introduce high gradients in velocity that lead to false caustics where geometric spreading fails. Spatially continuous interpolations like spherical harmonics and cubic splines can introduce large first- and second-order spatial derivatives of velocity as perturbations increase. Some DRT codes of the Cerveny group use a spline under tension routine (Cline, 1974) to interpolate between velocities specified at grid points to reduce the size of spurious gradients introduced by the interpolation. In cases of high perturbations with sharp boundaries, wave interactions with the anomalies must be treated by solving boundary conditions on the boundaries of the anomalies (e.g., Imhof, 1996; Korneev and Johnson, 1993), including numerical implementations of the boundary element method (e.g., Gerstoft and Schmidt, 1991; Pointer et al., 1998).

A simple parameterization allowing for fast analytic computation of amplitudes and ray paths is that used by the code Ratrace3D by Menke (2005), which can be downloaded from the IRIS website (www.iris.edu). The Earth model is parameterized by tetrahedra constructed from a grid specified in Cartesian coordinates. Linear interpolation of velocities between knots ($v = a + bx + cy + dz$) is assumed in each tetrahedral element, allowing ray paths to be computed analytically as summed segments of circles. Raytrace3D is primarily intended for calculating travel times rather than synthetic seismograms at local and regional ranges. The fast analytic computation of travel times and ray paths of this code is ideal for nonlinear tomographic inversions where it is necessary to assume large perturbations from a background model. Although Raytrace3D provides an option for calculating geometric spreading, modifications are necessary for the code to properly handle the effects on geometric spreading given by discontinuities in the first-order derivatives (see **Section 1.06.4.5**) of velocity at tetrahedra facets.

Rapid advances in computation have made it possible to more routinely include the effects of heterogeneity on the scale of wavelengths using numerical finite difference and finite element methods. It is usually impossible to know fine-scale structure except in a statistical sense as a spatial spectrum of heterogeneity. The most common way of constructing these types of models is to impose a random number generator at finite difference or element grid points, Fourier transform the grid from physical space to wave number space, filter by an assumed spatial spectrum of

heterogeneity, and inverse Fourier transform to physical space (Frankel and Clayton, 1986). This idea has been extended to media that may be composed of 2 or n types of specific rocks or medium phases (Holliger et al., 1993).

1.06.6 Instrument and Source

Assuming an Earth model and one of the algorithms previously described, a Green's function solution of the elastic equation of motion can be computed for a vector point force localized by a delta function in time and space. Linearity of the elastic equation of motion makes it possible to apply a principle of superposition to write the solution for a generalized source as a convolution of the source representation with Green's function solution. For three components of motion, Green's function of an elastic medium is a tensor $G_{nm}\left(\vec{x}_r, \vec{x}_s\right)$ representing the response of the model to a unit vector of force applied in a coordinate direction m at the source point $\vec{x}_s$ and observed at a receiver $\vec{x}_r$ along coordinate direction n (Snieder, 2002). Depending on the time window of interest, Green's function may contain all possible body, surface, and multiply-scattered waves in a structure or just one or several body waves due to a vector point source. A property of the elastic Green's function useful for imaging is reciprocity, in which the position of the source and receiver can be reversed if the orientation of the vector point force is exchanged with the orientation of the received component of motion, that is, $G_{nm}\left(\vec{x}_r, \vec{x}_s\right) = G_{mn}\left(\vec{x}_s, \vec{x}_r\right)$.

Once the model Green's functions are determined, the remaining tasks in synthesizing a seismogram consist of either incorporating or removing the effects of the seismograph response and source-time function. This task can again be simplified using the ideas of superposition and linear systems. Body waves observed at teleseismic range can be thought of as a series of convolutions with a model response $M(t, \Delta_o)$ consisting of one or more components of Green's function, an instrument operator $I(t)$, a source-time function $S(t)$, a receiver crustal response $C(t, \Delta_o)$, and an attenuation operator $A(t, \Delta_o)$:

$$U(t, \Delta_o) = I(t) * \mathbf{S}(t) * \mathbf{C}(t, \Delta_o) * \mathbf{A}(t, \Delta_o) * \mathbf{M}(t, \Delta_o) \qquad [24]$$

The crustal response $C(t, \Delta_o)$ is composed of a sum of multiply-reflected and converted body waves trapped inside the crust excited by a P or S wave at near-vertical incidence on the crust beneath the receiver.

Two common choices are either to (a) convolve all of the operators in eqn [24] and compare the resultant synthetic seismogram with an observed synthetic seismogram or to (b) deconvolve as many operators as possible to retrieve the model response to a delta function impulse. The first choice has been the more common, but as the density of receiver and source arrays has approached that common in exploration seismology, the deconvolution choice has become increasingly popular. Deconvolution can increase (whiten) the frequency content of the wave field and hence its spatial sensitivity. It allows different sources, receivers, and instruments to be combined to invert an observed wave field to an image of reflectors and scatterers (e.g., Rost and Thomas, 2002).

1.06.6.1 Instrument Responses and Deconvolution

The Fourier transform of $I(t)$, or $I(\omega)$, is a filter that is typically a narrow band-pass of particle velocity. (A complete review of seismic instrumentation is given in Chapter 1.02.) Most instrument responses are now reported by complex poles, ω_p^i, and complex zeros, ω_o^i, from which the complex frequency response $I(\omega)$ of the seismograph can be represented by the representation

$$I(\omega) = \frac{(\omega - \omega_o^1)(\omega - \omega_o^2)\ldots(\omega - \omega_o^n)}{(\omega - \omega_p^1)(\omega - \omega_p^2)\ldots(\omega - \omega_p^n)} \qquad [25]$$

The effect of the instrument can then be included by filtering the synthetic spectrum by multiplying by $I(\omega)$ and inverse Fourier transforming the result to the time domain. Alternatively, the instrument can be deconvolved by spectral division, but $I(\omega)$ must be modified by adding a constant term (water level) to avoid division by zero as the response goes to zero outside the passband of the instrument. The instrument response can be deconvolved to displacement, velocity, or acceleration (Figure 22). The deconvolved particle velocity in the passband of 0.01–2 Hz usually offers the best compromise between useful information content and high signal-to-noise ratio for teleseismic body waves. Deconvolved displacement, however, offers nearly a direct observation of the far-field source-time function, given by shape of the P or S wave displacements in the range of 35°–90°. In this range, the waveform of the observed displacement is primarily affected by the pulse broadening due to viscoelastic attenuation.

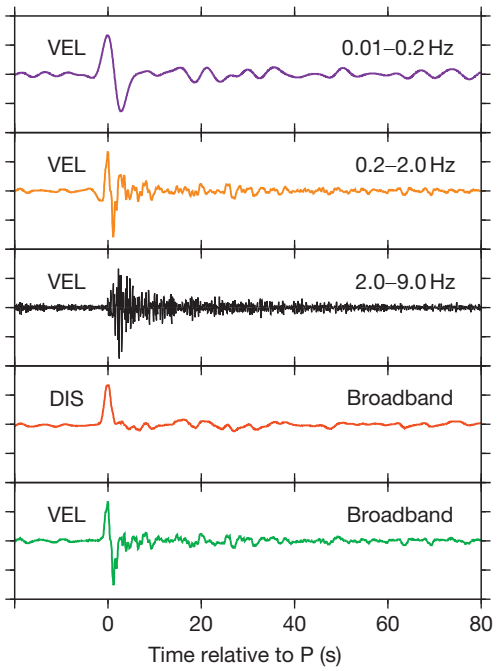

Figure 22 Filtered, instrument-deconvolved, particle velocity and displacement of a P wave typical of a magnitude 5.5–6.8 earthquake observed at great circle distance 68.72°.

1.06.6.2 Far-Field Source-Time Function

Detailed and accurate representation of the forcing function of the elastic equation of motion, or source-time function, requires the input of both theory and experiment for brittle failure and stick-slip friction. Chapter 4.02 provides a review of source representations and the physical assumptions behind them. For most modeling applications, a simple far-field representation and a judicious choice of earthquakes are all that is needed to begin to separate the effects of source from the effects of structure.

The far-field displacement is proportional to the time derivative of a moment-rate tensor $d\mathbf{M}(t)/dt$. A common scalar moment M_o can be factored out of $d\mathbf{M}(t)/dt$, leaving a far-field source-time function $S(t)$. In the case of an earthquake faulting source, $S(t)$ is proportional to the time derivative of its slip history (e.g., Shearer, 1999, Ch. 9). An operator combining the convolution of $S(t)$, $A(t, \Delta_o)$, and $C(t, \Delta_o)$ can be derived from either inversion or empirical observations of instrument-deconvolved P wave displacements at all distances between 30° and 90°.

The $S(t)$ of many earthquakes having body wave magnitudes less than 6.5 often can be adequately represented by a simple triangle-shaped pulse, where the triangle width is related to the corner frequency and fault length in a Brune (1970) model of the source spectrum. A body wave magnitude of 5.5 is often the practical lower limit to modeling because earthquakes smaller than this size rarely generate sufficient teleseismic recordings of body waves having a high signal-to-noise ratio. After factoring out the time-dependent factor $S(t)$ and scalar moment M_o from the moment-rate tensor, a radiation pattern $R(\phi, p)$ can be constructed from weighted elements of the moment-rate tensor where ϕ is the azimuth and p is the ray parameter of a body wave ray connecting source and receiver. This weighting is equivalent to representing general faulting by three fundamental types of faulting or source types (e.g., Aki and Richards, 2002, Ch. 4).

The process of factoring out a slip time history from a point-source radiation pattern should be avoided for earthquakes having body wave magnitude greater than 6.5 or fault lengths greater than 50 km. For these larger earthquakes, a simple point-source representation fails, and the time history and the slip distribution become too complex to be easily separated from the waveform complexities due to structure.

If it were not for the fact that the majority of earthquakes are at depths of 20 km or less, incorporating a radiation pattern $R(\phi, p)$ in the integrand of eqn [13] would be all that is needed to include an earthquake source at teleseismic range. Since most earthquakes are shallow, the effects of surface reflections near the source (pP, sP) generally need to be included in modeling a 5–10 s time window surrounding an observed body wave. The effect of different radiation patterns for the near-source reflections is helpful in inversion of teleseismic P waves for the far-field moment-rate tensor (Langston and Helmberger, 1975). The inverted source depth and point-source representation (centroid moment-rate tensor) can be used to construct a predicted equivalent source-time function and radiation pattern containing P + pP + sP waves (Figure 23). Alternatively, the effect of the surface reflections can be handled by incorporating the moment-rate representation at the appropriate depth in reflectivity or mode summation techniques or be included by separately adding predicted pP and sP waveforms to P waveforms synthesized by either ray-based or transform methods.

At local and regional ranges, surface interactions as well as a more detailed source description can often still be handled by superposing far-field point-source representations. These point-source representations can be distributed at discrete points along the fault plane, delayed by the time slip initiates and stops at each discrete point. This type of source representation is said to be kinematic rather than dynamic because the slip history is prescribed rather than resulting from a condition related to either crack failure or friction on the fault surface. At very close range, the wave field can be well approximated by a few simple directly arriving body waves, and the far-field Green's function for each body wave can be calculated by ray theory. The synthesis problem can then be reduced to an integral over the fault plane in which the integral is carried out over lines of equal arrival time of energy (isochrones) corresponding to the sum of the rupture time to a point on the fault and the travel time of a body wave to a receiver (Spudich and Frazer, 1984). The effects of 3D structure or frequency-dependent diffraction can be incorporated in this technique by substituting Green's functions calculated by ray theory, Gaussian beam summation (e.g., Cerveny et al., 1987), and/or WKBJ/Maslov superposition of plane waves. See Chapter 4.20 for a complete review of algorithms for synthesis at local ranges in which spatially extended slip models are required for earthquake slip inversions and simulation of strong ground motions.

1.06.7 Heterogeneity, Attenuation, and Anisotropy

1.06.7.1 Adapting 1D Codes to 2D and 3D

Since the delay time $\tau(p)$ in the WKBJ, GRT, and full-wave methods can be calculated from integrals of vertical slowness up to ray turning points, it is simple to calculate $\tau(p)$ in an Earth model with different 1D velocity and density profiles beneath the source and receiver above the ray turning points. For example, to calculate the effect of the upper mantle in the eastern United States to a station in the western United States, one might use two different models, keeping track of where rays enter and leave the two models (Helmberger et al., 1996). In reflectivity methods, it is a little more difficult, but not impossible, to incorporate different receiver and source-side models. One would need to separately consider a receiver and source-side transmission response. Control of ray expansions within thin layers as in Kennett's formulation of the reflectivity method makes it possible to consider the effects of more general 2D models.

Purely ray-based methods, such as theory and its extensions as a superposition of Gaussian beams or Maslov plane waves, can consider continuously varying models in 2D or 3D space. Modal methods, including the locked mode method, can be adapted to 2D, 3D, and anisotropic models by calculating the coupling between modes, including interactions between Love and Rayleigh modes. Maupin (1989), Maupin and Kennett (1987), Kennett (1998), and Panza et al. (2001) described

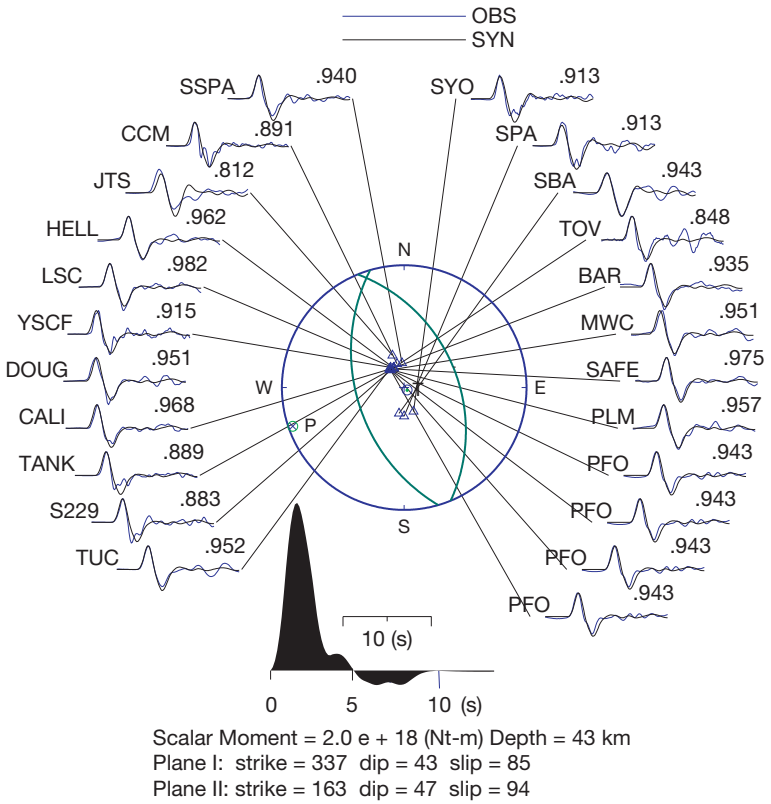

Figure 23 P wave particle velocities from an earthquake beneath Chile that occurred 3 November 1997. Numbers near the waveforms are the cross correlation of the observed with synthetic waveform. Waveforms are displayed at azimuths from the source around a lower hemisphere plot of the fault-plane solution. The far-field source-time function of displacement, shown by the black-filled waveform, is determined from modeling the P waves as a combination of P and surface reflected pP and sP waves.

schemes for calculating modal coupling and showed seismograms synthesized for rapid crustal transitions. Deuss and Woodhouse (2004) developed methods to calculate full normal mode coupling, which Irving et al. (2008) have used to calculate the effects of general anisotropy in the inner core on low-frequency body waves.

1.06.7.2 Hybrid Methods

To save computation, it is sometimes necessary to combine two methods, a computationally cheaper method in a large region and a computationally more expensive method in a small region, to study structural complexity near a boundary or region of rapid velocity or density transition. Usually, the computationally more expensive method is a numerical method, such as finite difference or spectral element. The usual way in which the two methods are connected is to compute a Kirchhoff integral. The integral is carried out on a surface or boundary that separates the structurally complex region from the simple region, employing Huygens principle to connect the wave fields in the two regions by allowing each point on a wave front to propagate as a new point source. Kirchhoff integrals can also be used to calculate the effects of scattering by inclusions or the frequency-dependent reflection or transmission across a curved interface when the radius of curvature is on the order of a wavelength. A hybrid method of this type was used by Wen and Helmberger (1998) to study heterogeneity in the lowermost mantle using a finite difference method, connecting it to GRT in a radially symmetrical overlying mantle. The most detailed treatment of fully elastic integrands for P, SV, and SH waves can be found in Frazer and Sen (1985). Probably due to the need for intense customization for specific problems, codes for Kirchhoff integrals are not generally distributed. A good starting point for any application are the acoustic problems described in Shearer (1999, pp. 138–140), which can then be generalized using the elastic formulas in Frazer and Sen (1985).

Capdeville et al. (2003a) developed a hybrid method that allows modal solutions in large homogeneous or weakly heterogeneous regions to be coupled to the numerical spectral element (SEM) solutions in strongly heterogeneous regions. This hybrid method has been applied to a thin, strongly heterogeneous, D″ region at the base of the mantle sandwiched between a homogeneous core and mantle (Capdeville et al., 2003b; To et al. 2005). A similar approach might also be feasible at higher frequencies and local and regional ranges by coupling locked surface wave modes to SEM solutions.

1.06.7.3 Frequency-Dependent Ray Theory

Recognition that ray theory is an approximation applicable at high-frequency, corrections to the ray theoretical approximation can be based on a Born approximation that corrects amplitude and travel times in such a way that a finite region

in space determines the amplitude and travel time of a body wave, making both dependent on frequency (Dahlen et al., 2000). **Chapter 1.05** provides reviews and additional references on this calculation. Cerveny (2001) and Cerveny et al. (2007) also described these and other frequency-dependent corrections. One way in which the banana–doughnut sensitivity kernels needed to calculate the frequency dependence of travel times and amplitudes is to use the paraxial approximation around a central ray provided by DRT. Sensitivity kernels derived from the Born approximation show that travel time is most sensitive to velocity along the boundaries of the banana or rim of the doughnut away from the central ray, whereas amplitude is most sensitive to velocity in the center of the banana in the doughnut hole. The travel time sensitivity is closely related to the behavior of the stationary-phase approximation, in which the path is assumed to be invariant for variations in velocity along the central ray. It is important to recognize that an accurate measurement of the frequency-dependent effects on travel time depends on waveform measurements in which the effects on amplitude and phase are combined. To properly incorporate these combined effects in a tomographic inversion, a synthetic waveform must be cross correlated with an observed waveform to obtain a travel time residual. Except in tomographic inversion, these frequency-dependent corrections to ray theory using the Born approximation have not yet been used or tested as a general forward modeling technique. It is as yet unknown how the weak dispersion due to velocity variation trades off with the weak dispersion due to viscoelasticity (**Section 1.06.7.4**) or how accurate the amplitude correction due to a simple Born approximation is compared to that predicted by the generalized Born approximation of Coates and Chapman (1991).

The frequency-dependent, banana-shaped, sensitivity kernels of seismic rays can also be calculated from a modal approach using a nonlinear perturbation theory (Li and Romanowicz, 1995). In this case, the forward modeling approach is mode summation. The approximations and behavior of errors due to asymptotic approximations of the effects of heterogeneous structure are better understood in this method but are practically limited to frequencies on the order of 0.1 Hz and lower.

1.06.7.4 Attenuation

Romanowicz and Mitchell in **Chapter 1.25** and Cormier (2011) review physical mechanisms and global models of seismic attenuation. Jackson (2007) reviews laboratory experiments that investigate microscopic mechanisms of intrinsic attenuation. This subsection reviews common procedures for incorporating attenuation into the synthesis of body waves.

Viscoelasticity is the term that best describes the type of seismic attenuation resulting from the dissipation of elastic energy into heat. This heat dissipation is analogous to the heat dissipated in electric circuits, where stress is analogous to current, voltage is analogous to strain, and complex impedance is analogous to a complex compliance (reciprocal of a complex elastic modulus). For ray-based and integral transform-based methods, viscoelastic attenuation is most directly treated by making velocity complex through the square root of a complex modulus divided by density under the assumption of the correspondence principle (Borcherdt, 2009; Carcione, 2007). The effect of attenuation on the spectrum of a propagating body wave can be written as

$$A(\omega) = e^{i\omega T(\omega)} \qquad [26]$$

where $A(\omega)$ is just the Fourier transform of the attenuation operator $A(t)$ in eqn [24]. The complex travel time $T(\omega)$ is determined by integrating a ray over a path in which velocity is complex and frequency-dependent, or $T(\omega) = \int_{path} ds/V(\omega)$.

The frequency dispersion of velocity in a viscoelastic medium is similar to the dispersion of a complex index of refraction in electromagnetic propagation, in which absorption is always associated with dispersion. In body waves, this dispersion is small and difficult to detect with narrow band instrumentation. In sufficiently broadband recordings, viscoelastic dispersion is detectable as an asymmetry in the propagation of delta function time pulse. High frequencies travel faster than low frequencies, making a steeper rise time than fall time as the pulse propagates (**Figure 24**). Velocity dispersion was first recognized to be important in global seismology when the elastic moduli derived from the study of low-frequency free oscillations were found to be smaller than those derived from the travel times of high-frequency body waves (Dziewonski and Anderson, 1981).

There is a consensus that the quality factor, Q, in the attenuation of teleseismic body waves is nearly independent of or slowly varying with frequency from 0.001 to 0.1 Hz, with possibly some stronger frequency dependence beginning between 0.1 and 1 Hz. For frequencies close to neither the low- nor the high-frequency corner of a relaxation spectrum (absorption band) of constant Q, this assumption leads to an approximate formula for complex velocity of the type

$$V(\omega) \cong V(\omega_r)\left(1 + \left(\frac{1}{\pi Q}\right)\ln\left(\frac{\omega}{\omega_r}\right) - i\left(\frac{1}{2Q}\right)\right) \qquad [27]$$

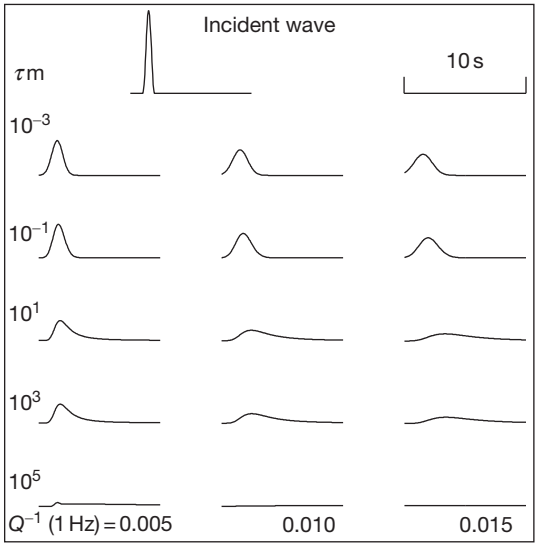

Figure 24 Attenuation operators convolved with a given wavelet for varying parameters of a viscoelastic relaxation spectrum from Li and Cormier (2002).

where $V(\omega_r)$ is a real velocity at a reference frequency. Substitution of $V(\omega)$ into the ray path integral for complex time $T(\omega)$ in eqn [26] and inverting the complex spectrum defines a time domain attenuation operator that is commonly termed the Futterman (1962) or Carpenter (1967) Q operator. This operator is valid in regions of the relaxation spectrum where attenuation $(1/Q)$ is constant. It is not valid near the corners of the true relaxation spectrum, where $1/Q$ decays as ω^{-1}. It is relatively simple, however, to derive a formula for complex velocity that is valid across the entire relaxation spectrum (e.g., Cormier and Richards, 1988). The pulse dispersions shown in **Figure 24** were calculated with this formula.

The width of relaxation spectra in which attenuation $1/Q$ is nearly constant or slowly varying (often observed to be $\omega^{1/3}$) is typically five decades in frequency (Anderson and Given, 1982). A problem often not considered in modeling the effects of viscoelasticity is the limitation viscoelastic theory imposes on the difference between the static (relaxed) elastic modulus and the infinite frequency (unrelaxed) modulus. There are limits on the band over which viscoelastic Q can be constant given by this modulus difference or defect, which is typically bounded by 25%. In practice, this means that any Q inferred from a body wave pulse width or spectrum that has an exceptionally low value, for example, 10 or lower, is an apparent Q probably resulting from scattering rather than viscoelasticity.

Slowness or ray-based methods often treat attenuation by solving the equations of motion with real velocities defined at the reference frequency (often chosen to be 1 Hz) and then convolving the result with the time domain attenuation operator of eqn [26] appropriate for each ray path. Since the unit of this ray path integral is time, a parameter often cited in the literature of teleseismic body waves is t^*. Considering only the real part of eqn [26] and assuming eqn [27] for $V(\omega)$, each frequency is exponentially attenuated by the factor $\exp(-\omega t^*)$, where

$$t^* = \int_{\text{path}} \frac{1}{V(\omega_r)Q}\,\mathrm{d}s \qquad [28]$$

The parameter t^* is found to vary relatively slowly with range and path length of P waves in the mantle and is on the order of 1 s for frequencies between 0.01 and 0.2 Hz in the distance range 30–90°.

Spectral methods that first compute the complex spectrum of the solution of the equation of motion (e.g., reflectivity, discrete wave number, full-wave, the DSM, and mode summation) can treat attenuation simply by substituting a complex velocity and analytically continuing all formulas in propagator matrices and phase factors that contain wave numbers and elastic moduli to complex numbers. To include the dispersive effect of attenuation in DRT and beam summation, a Futterman-type Q operator can be convolved with the computed amplitude of each ray or beam calculated in a model specified at a reference frequency. Another more general approach would be to compute amplitudes by DRT at the real velocities, $\mathrm{Re}(V(\omega))$, defined at each frequency and then multiply each spectral component by an exponential scale factor $\exp\left(-\omega\int \mathrm{Im}\left(\frac{1}{V(\omega)}\right)\mathrm{d}s\right)^{-}$.

In finite difference methods that integrate the equation of motion in the time domain, it is not practical to handle viscoelastic attenuation by a convolution. Instead, it is possible to design a system of stress–strain memory functions that can be simultaneously integrated in the time domain with the equations of motion (Robertsson et al., 1994). Using a memory function for only three specific relaxation times, it is usually possible to reproduce the effects of a relaxation spectrum of nearly constant attenuation in a frequency band of interest.

1.06.7.5 Anisotropy

Chapter 1.09 reviews elastic anisotropy and computational approaches for its many unique effects, including differences between phase and group velocities of body waves and shear wave singularities. Summarized here are some simple considerations related to ray- and transform-based methods of body wave synthesis.

Elastic anisotropy removes the degeneracy of the S wave eigenvalue/eigenvector solutions to the wave numbers of propagating plane waves. The SH and SV definitions defined by source and receiver geometry are no longer useful for formulating boundary conditions needed for calculating reflection and refraction. S polarization is best resolved into components of motion along two orthogonal quasi-S wave eigenvectors, with motion on both the transverse and radial components of motion generally consisting of a combination of two quasi-S waves. A pure radial (SV) polarized wave incident on a weakly anisotropic region excites two transmitted quasi-S waves such that the transverse (SH) component of the transmitted wave has the approximate shape of the time derivative of the radial (SV) component (Silver and Chan, 1991).

A special case of anisotropic propagation is that of transverse isotropy with a vertical axis of symmetry. In this case, the two quasi-S waves are exactly polarized in the SH and SV directions defined by source–receiver geometry but with two different velocities. Transverse isotropy can be an accurate representation for Earth models consisting of thin planar or radially symmetrical layers, having alternating or randomly fluctuation velocities and layer thicknesses much smaller than the smallest wavelength of interest (Backus, 1962). Transverse isotropy can be easily incorporated in all layered 1D body wave codes by modifying the calculations of reflection–transmission coefficients and the $\tau(p)$ function in the phase factor of WKBJ, GRT, or full-wave techniques (e.g., Chapman, 2004).

General anisotropy breaks the symmetry upon which some integral transforms and spherical harmonic analysis are based. Body waves can propagate in and out of the sagittal plane. This makes the problem of synthesizing body waves in a generally anisotropic model automatically a 3D problem. In plane-layered models and Cartesian coordinates, the generalized wave number superposition leads to reflectivity formulations that require integration over two horizontal wave numbers to invert wave number transforms to the spatial domain (Fryer and Frazer, 1984, 1987). Similarly, the WKBJ/Maslov methods can be generalized by integrals over two horizontal slownesses (Garmany, 1989). Some approximations for weak general anisotropy and expansion of the phase near its stationary point can be employed to simplify the problem to integration over a single wave number corresponding to waves propagating in and near the sagittal plane. For seismograms synthesized by ray methods, the equations for ray trajectory and travel times can be extended to the case of general anisotropy.

A system for dynamic quantities corresponding to the **P** and **Q** matrices can be formulated for summation of Gaussian beams (Hanyga, 1986; Klimes, 1994). A very simple approach for computing quantities related to geometric spreading is to take difference derivatives of ray positions and slownesses (Gajewski and Psencik, 1987, 1990).

1.06.7.6 Scattering

Chapter 1.24 reviews seismic scattering. A comprehensive reference is Sato et al. (2012). A few fundamental effects important to consider in the of synthesis body waves are reviewed here, some of which are computationally simple to include.

Single scattering by small-scale heterogeneity can be incorporated by a Born approximation (e.g., Chapman, 2004, Chapter 1.11). The Born approximation effectively treats small perturbations in velocity and density from a background medium as seismic sources by moving terms due to the difference in perturbed velocity from the background velocity to the source side of the wave equation. The strength of these scattering sources that reradiate energy is proportional to the energy of the wave incident on the heterogeneity and the size of its perturbations. For wavelengths much greater than the heterogeneity, each heterogeneity can be treated by a point-source representation similar to the moment-rate tensor representation of earthquake sources (Wu and Aki, 1985). The effects of many small-scale heterogeneities can be obtained by summing the radiated body waves of each small scatterer. Green's function solutions of the equations of motion must be known from the source to the position of each scatterer and from the scatterer to the receiver. These Green's functions can be calculated by any of the methods described in Section 1.06.4. The volume of the region of scatterers contributing to a specific time window surrounding a body wave is the banana-shaped region surrounding a least-time ray described in Section 1.06.7.3. An example of this approach is the synthesis of the precursor coda of PKIKP from scatterers near the core–mantle boundary (Cormier, 1999).

Forward scattering in the direction close to the direction of the least-time ray can affect the pulse shape of broadband body waves. A finite frequency band of observation can blur the effects of many scatterers, whose arrivals can occur over time spacings much shorter than the shortest period in the passband of observation. This broadening and multipathing can be mistaken for the effects of viscoelastic attenuation. Unlike viscoelastic attenuation, where energy is lost to heat, scattering attenuation simply redistributes high-frequency energy in time and space out of a finite time window surrounding the pulse observed at a particular location. One approximate method including this effect is the theory of dynamic composite elastic moduli of Kaelin and Johnson (1998). This technique can be formulated in terms of a complex wave number, allowing it to be treated in much the same way as complex velocities in viscoelasticity (e.g., Cormier and Li, 2002). Calvet and Margerin (2008) described a method in which the statistics of heterogeneity can be more directly included to estimate the attenuation and waveform dispersion due to multiple scattering.

1.06.7.7 Imaging

Increased availability of dense global data has made it worthwhile to synthesize seismograms to image deep Earth structure using the schemes commonly employed in exploration seismology to image shallower, smaller-scale, structure. The goal is to find Earth structure that minimizes object functions of the type

$$\left|D\left(t,\vec{x}\right)-U\left(t,\vec{x}\right)\right|^{n} \qquad [29]$$

where $D\left(t,\vec{x}\right)$ is an observed seismogram, $U\left(t,\vec{x}\right)$ is a synthetic seismogram, and n is a positive integer, usually 2 for least-squares linearized inversion.

Waveform imaging is a very nonlinear inverse problem, making it possible to fall into a localized minimum when a linearized least-squares approach is taken from a starting Earth model. Smart Monte Carlo methods such as simulated annealing and genetic algorithms (Sambridge and Mosegaard, 2002) are one way to insure that the Earth model space is sampled well enough to obtain an image that does not lie in a local minimum of the object function. Because many seismograms must be synthesized in many models, Monte Carlo methods are ideally suited for body wave algorithms that are computationally cheap, especially methods based on ray theory.

The linearized problem minimizes the residual wave field given by eqn [29], Taylor expanding the synthetic wave field. Subsequent processing treats the residual wave field like a seismic source at the imaging point (Mora, 1988; Tarantola, 1984). The strength of this source will be proportional to the perturbation from the background medium given by the starting Earth model. An important step in linearized imaging is the computation of the so-called differential seismograms or partial derivatives of seismograms with respect to model parameters (elastic moduli and density). Efficient methods for computing differential seismograms or differential spectra are well developed for modal methods (e.g., Du et al., 1998; Gomberg and Masters, 1988). A computationally cheap method for computing differential seismograms with the reflectivity approach of Kennett has been developed and described by Randall (1988).

An evolving imaging strategy in inversion of body waveforms is to perform the inversion at a series of increasing frequencies, imaging successively finer-scale structure with each iteration. With this approach, it is feasible to change the forward modeling algorithm as the iteration progresses, perhaps starting from ray theory in a radially or plane-layered reference structure and changing to a computationally more expensive or numerical method as smaller-scale and more intense perturbations to structure are determined. Driven by practical problems of resource exploration and enhanced oil recovery, innovation in imaging algorithms and strategies are occurring continuously and are best found in recent exploration literature.

1.06.8 Conclusions

Most of the algorithms for synthesizing body waves in radially symmetrical (1D) structure have been successfully tested and verified against each other (e.g., Choy et al., 1980; Figure 12). Factors to consider in choosing an algorithm include the accuracy in a required frequency band and distance range, the width of the time window and number and types of seismic

phases, the speed of computation, the number of synthetics needed for modeling or imaging, the completeness of documentation, and the existence and accessibility of software.

The frequency band of calculation is probably the foremost important factor. When working in the frequency band less than several 0.1ths of a Hz, the modal summation and the direct solution method are good choices because they easily include all possible body waves, surface waves, and frequency-dependent interactions with discontinuities in an arbitrarily wide time window at an acceptable computational cost on a single workstation. Using a perturbation approach, they can also handle weak lateral heterogeneity (several percent perturbation in velocity and density) with little additional computational overhead. At higher frequencies, reflectivity/GRT or locked mode approaches in thin homogeneous layers or asymptotically approximate ray-based methods (WKBJ/full-wave/Maslov/DRT and Gaussian beams) in homogeneous layers are efficient and produce identical results if carefully used.

In either low- or high-frequency bands, the most important limitations of each algorithm are related to its accurate reproduction of the waveform effects of the broad spatial spectrum of Earth structure. In all algorithms, it is important to consider the effects of neglecting small-scale structure on the order of a wavelength or smaller. In high-frequency algorithms, limitations are related to either the validity of the EFA, the physicality of thin-layer representations, or the validity of asymptotic approximations of wave functions in layers having continuous and large spatial gradients. Understanding these limitations is also key to the problems of separating the effects of anisotropy from heterogeneity and viscoelasticity from scattering.

Computational hardware now makes it possible to routinely model seismic waveforms to invert for both radially symmetrical (1D) Earth structure and simple point-source representations of earthquake faulting. Recent advances in digital recording and network telemetry have now made these inversions possible in near real time. The remaining advance needed to fully exploit the real-time capabilities of 1D modeling lies in making user-friendly software interfaces.

Efforts to test and verify 3D modeling algorithms against each other (Igel et al., 2000) will continue. The participation of the broad community in these efforts, however, remains challenging due to the limitations of computational hardware. Ray-based 3D modeling is feasible on single workstations in smooth models having a relatively large ratio of scale length of heterogeneity to wavelength and for relatively mild velocity and density perturbations (less than several percent). Likewise, perturbation approaches based on mode summation or the DSM can be performed with modest computational overhead for relatively weak velocity perturbations (several percent) and at large-scale lengths (1000s of km). Investigation of effects of very small-scale heterogeneity (10 km or less) at high frequencies (>1 Hz) can be done in 3D but is currently only practical with numerical methods for ranges on the order of 100s of wavelengths using clusters of several hundred or less processors. Growing community access to larger clusters of processors, including recent advances with GPU processors (Yuen, et al., 2013), will increasingly favor the use of fully numerical solutions of the seismic wave field.

1.07.1 Introduction

Synthetic seismograms are at the heart of modern global seismology. For spherically symmetrical, that is, one-dimensional (1D), Earth models, normal-mode summation is the preferred method for the calculation of broadband seismograms (e.g., Dahlen and Tromp, 1998; Gilbert, 1970). Normal-mode synthetics incorporate effects due to fluid–solid boundaries, transverse isotropy with a radial symmetry axis, and attenuation. Mode synthetics are frequently used as reference seismograms, for example, to make cross correlation body-wave travel time measurements or to characterize fundamental Love and Rayleigh surface-wave dispersion.

Before fully 3D numerical techniques became available and practical, one had to resort to asymptotic methods for the calculation of synthetic seismograms. Over the years, numerous asymptotic methods have been – and are continuing to be – developed. For example, in the path-average or great-circle approximation (e.g., Nolet, 1990; Woodhouse and Dziewonski, 1984), one assumes that a seismogram may be calculated based upon a spherically symmetrical Earth model that is characteristic of a particular source–receiver combination. From an inverse theory perspective, in this approximation, a change in the waveform is related to a change in the Earth model via a 1D Fréchet or sensitivity kernel. By asymptotically accounting for mode coupling, Li and Tanimoto (1993) extended the path-average method to gain 2D sensitivity to structure in the source–receiver plane. In this approach, changes in the waveform are related to model changes through a 2D sensitivity kernel (Li and Romanowicz, 1995, 1996; Marquering and Snieder, 1995, 1996). Nowadays, seismologists are calculating fully 3D synthetic seismograms at the scale of the globe, and the relationship between waveforms and Earth structure is expressed in terms of 3D sensitivity kernels. The calculation of such kernels for spherically symmetrical reference models may be accomplished based upon mode summation (Marquering et al., 1998; Zhao et al., 2000) or ray theory (Dahlen et al., 2000; Hung et al., 2000; Montelli et al., 2004), but for 3D reference models, such calculations involve the use of the so-called adjoint simulations (e.g., Akçelik et al., 2002, 2003; Talagrand and Courtier, 1987; Tarantola, 1984; Tromp et al., 2005).

The number of numerical techniques that can handle seismic wave propagation in 3D Earth models accurately is rather limited. All the classical numerical methods have been employed, for example, finite difference method (FDM) and pseudospectral method (PM), but thus far, these techniques have been restricted either to portions of the globe, that is, limited in terms of the dimensions of the modeling domain (e.g., Furumura et al., 1998, 1999; Igel, 1999; Wang et al., 2001), or to purely shear/acoustic problems, that is, incorporating only shear/compressional waves (e.g., Igel and Weber, 1995; Thomas et al., 2000).

Numerical simulations based upon integral or weak implementations of the equation of motion have been most successful in terms of capturing the full complexity of global Earth models. Coupled-mode methods (CMMs), in which the modes of a 3D Earth model are expressed as a sum over the modes of a spherically symmetrical reference Earth model (e.g., Capdeville et al., 2000; Lognonné and Romanowicz, 1990; Park, 1986; Park and Yu, 1992), or direct solution methods (DSMs), which use more general basis functions (e.g., Geller and Ohminato, 1994; Hara et al., 1991; Takeuchi et al., 2000), are capable of calculating synthetic seismograms in 3D Earth model at relatively long periods.

To date, the most successful numerical technique for simulating global seismic wave propagation has been the spectral element method (SEM) (Chaljub, 2000; Chaljub et al., 2003;

Komatitsch and Tromp, 2002a,b; Komatitsch et al., 2002, 2003). See Komatitsch et al. (2005) and Chaljub et al. (2007) for detailed recent reviews of the method. Like CMM, DSM, and finite element method (FEM), the SEM is based upon an integral or weak implementation of the equation of motion. It combines the accuracy of the global PM with the flexibility of the FEM. The wavefield is typically represented in terms of high-degree Lagrange interpolants, and integrals are computed based upon Gauss–Lobatto–Legendre (GLL) quadrature, which leads to a simple explicit time scheme that lends itself very well to calculations on parallel computers. Capdeville et al. (2003a,b) demonstrated how the computational burden associated with the SEM may be reduced by coupling it to a normal-mode solution. This allows one to reduce the cost of the method by assuming a spherically symmetrical solution in a portion of the Earth, for example, the core, using spectral elements only in the remaining parts of the model, for example, the mantle.

The purpose of this chapter is to introduce and review various numerical methods used in global seismology to generate synthetic seismograms in 3D Earth models. We begin by posing the challenges associated with simulating global seismic wave propagation. We then introduce the elastic wave equation, which forms the basis of all numerical simulations of seismic wave propagation. We discuss the basic boundary conditions that arise in Earth models with a free surface and a variety of internal solid–solid and fluid–solid discontinuities. Complications due to anisotropy, attenuation, and self-gravitation are important in the context of seismic wave propagation, but for the sake of simplicity, these effects are only discussed peripherally. We distinguish between numerical methods based upon the equation of motion in its differential form subject to certain boundary conditions, referred to as differential or strong implementations, for example, FDM and PM, and numerical methods based upon an integral or weak implementation of the equation of motion that contains the boundary conditions implicitly, for example, CMM, DSM, FEM, and SEM. We conclude by discussing the potential for using 3D numerical simulation to address the inverse problem. We will assume basic knowledge of tensor notation and algebra.

1.07.2 The Challenge

The calculation of accurate synthetic seismograms for 3D global Earth models poses a significant computational challenge, both in terms of the demands on the numerical algorithm and with regard to computer hardware (i.e., memory and CPU requirements). This section enumerates the main algorithmic issues that need to be addressed and resolved in the context of simulating global seismic wave propagation. Few numerical techniques can currently accommodate all the demands imposed by this daunting problem:

Gridding. Any numerical technique involves a grid on which the wavefield is evaluated, be it a finite difference stencil or the GLL points of a hexahedral spectral element. Gridding – or meshing – the globe is challenging for two key reasons, both related to spherical geometry. First, to grid the entire surface of the globe, one has to design a scheme that covers the unit sphere evenly. A simple grid in terms of latitude and longitude, frequently used in strong implementations, leads to an uneven grid spacing with an undesired concentration of points near the poles.

The second difficulty is associated with the fact that the spherical geometry tends to lead to a concentration of grid points with depth and a singularity at the center of the Earth. Thus, one needs to design a gridding scheme that increases the grid spacing with depth to reduce the computational burden and improve numerical stability. The fact that wave speeds generally increase with depth further enhances the need for coarsening the grid with depth for reasons of numerical stability and efficiency.

Surface waves. At the scale of the globe, surface waves are an important source of information for two main reasons. One, they help constrain shallow upper-mantle structure beneath ocean basins, which are difficult to image with body waves. Two, they are widely used to constrain the source characteristics of earthquakes. Any numerical technique aimed at simulating global seismic wave propagation must therefore be able to accurately simulate the propagation of surface waves. The numerical challenges lie in the implementation of the stress-free surface boundary condition and in the fact that surface waves travel at relatively slow phase speeds requiring a fine grid spacing of more than five grid points per wavelength.

Diffracted waves. At greater epicentral distances, a number of body waves diffract at the core–mantle boundary (CMB), for example, P_{diff} and S_{diff}. These waves contain important information about the lowermost mantle, in particular the intensely studied D″ region, and it is important that 3D simulations accurately capture these diffraction effects. Part of the difficulty involves the implementation of the fluid–solid boundary condition mentioned next.

Fluid–solid boundaries. Typical Earth models have three main fluid–solid boundaries: the ocean floor, the CMB, and the inner core boundary (ICB). These boundaries need special attention in the sense that the traction is normal to the boundary and continuous across it; the normal component of displacement is also continuous, but the tangential component of displacement is discontinuous, that is, there may be slip across the boundary. The implementation of fluid–solid boundaries typically involves domain decomposition between the fluid and the solid, such that one solves an (an)elastic wave equation in the solid crust, mantle, and inner core and an acoustic wave equation in the liquid outer core and ocean, matching the two solutions at the fluid–solid boundary.

Attenuation. The shear quality factor is observed to be fairly small in the upper mantle and, in particular, in the inner core. Surface waves and waves that turn or reflect in the upper mantle are significantly attenuated, an effect that needs to be accommodated in numerical simulations. Observational global seismologists routinely use data over a broad frequency range, from short-period PKP waves in the 1–2 Hz range to long-period surface waves in the 5 mHz range. Because we are dealing with such broadband signals, we must take into account the fact that in an anelastic Earth model, the wave speeds become frequency-dependent. Such physical dispersion can have a dramatic effect on both body and surface waveforms.

Anisotropy. Global Earth models frequently exhibit anisotropy, that is, a directional dependence of the wave speed. Even 1D models are generally transversely isotropic (e.g., PREM) to accommodate the observed dispersion of Love and Rayleigh

waves. Thus, suitable numerical techniques should incorporate the effects of an anisotropic constitutive relationship on seismic wave propagation. The related additional model parameters increase the memory requirements and the CPU time.

Rotation and self-gravitation. At periods longer than about 150 s, surface waves are affected by the Earth's rotation, and Rayleigh wave propagation needs to accommodate the effects of self-gravitation, that is, the perturbations in the gravitational field induced by the seismic motions. Normal-mode summation codes routinely incorporate the effects of self-gravitation, and this provides an excellent benchmark for more general, 3D codes.

Ellipticity, topography, and bathymetry. The Earth is to a close approximation elliptical in shape, and the numerical grid should reflect this. Furthermore, there is significant topography and bathymetry associated with mountain ranges and the ocean basins. The grid should be adjusted to reflect these topographic variations, and the numerical implementation of the free surface boundary conditions should account for the undulations. Free surface boundary conditions are notoriously difficult to implement, in particular in the context of strong formulations of the equations of motion.

Crustal thickness. The Earth's crust varies in thickness by an order of magnitude, with depths of approximately 8 km underneath the oceans to depths of more than 70 km underneath the Andes and Tibet. These crustal thickness variations have a profound effect on the dispersion of short- and intermediate-period surface waves. They also affect the travel time and amplitude of surface-reflected phases, for example, PP and SS. Various asymptotic techniques attempt to accommodate lateral variations in crustal thickness by making a 'crustal correction,' but in particular for surface waves, such 'corrections' quickly become inadequate.

Oceans. Some 1D models incorporate an ocean layer. Such a layer gives rise to complications associated with fluid–solid interfaces, as discussed in a previous item. The presence of oceans is mostly relevant for the dispersion of Rayleigh waves, as well as for surface-reflected phases, such as pP, PP, SS, and SP. Normal-mode summation codes routinely incorporate the effects of a water layer, thus providing a good benchmark. For 3D Earth models, the oceans pose a much more significant challenge related to their highly variable depth.

Core. The fact that the Earth has a liquid outer core and a solid inner core poses significant computational challenges. In addition to the fluid–solid boundary conditions mentioned in an earlier item, we need to solve an (an)elastic wave equation in the inner core, which is coupled across the ICB to an acoustic wave equation in the outer core, which is coupled across the CMB to an (an)elastic wave equation in the mantle and crust. Thus, the need arises for two distinct solvers for the fluid and solid regions of the model, which are coupled across the fluid–solid boundaries. Meshing the inner core is another nontrivial issue that requires the use of highly uneven grids, in particular with depth.

In what follows, we will discuss the merits and demerits of the various numerical techniques in the context of the challenges laid out in this section.

1.07.2.1 Benchmarking

Any numerical method aimed at simulating global seismic wave propagation must be carefully benchmarked against semianalytic methods, for example, normal-mode summation, as well as other 3D techniques. At the scale of the globe, such benchmarks are difficult and must be carefully executed. In this section, we briefly enumerate some of the main challenges associated with benchmarking.

First, rather obviously, the Earth model must be exactly the same in all techniques competing in the benchmark, which means among other things that all first- and second-order discontinuities must be honored. At a first-order discontinuity, a function – and possibly its first derivative – is discontinuous, whereas at a second-order discontinuity, a function is continuous but its first derivative is not. Most 1D Earth models, for example, PREM, have both types of discontinuities. Special attention must be paid to the implementation of the crust. Seemingly subtle model differences, for example, in crustal thickness or a division in terms of upper and lower crust, can have a profound effect on surface-wave dispersion and surface-reflected body-wave amplitudes. The presence of an ocean layer has a profound effect on the dispersion of Rayleigh waves and can affect the amplitudes of surface-reflected P–SV body waves. Most 1D Earth models incorporate radial models of attenuation, and one must ensure that the associated effects are properly implemented. As mentioned among the challenges, in an anelastic medium, the shear and compressional wave speeds become frequency-dependent, an effect that most normal-mode codes incorporate. So, besides reducing wave amplitudes, attenuation can have a strong effect on the phase of a broadband signal. The fact that we need to simulate seismograms over more than three decades in frequency, that is, periods from shorter than 1 s to longer than 1000 s, makes the implementation of such physical dispersion in numerical algorithms a necessity. Finally, one needs to decide whether or not effects due to self-gravitation and transverse isotropy, both readily accommodated in normal-mode algorithms, will form part of the benchmark.

The COSY project (Igel et al., 2000) brought together several research groups in an attempt to benchmark numerical algorithms for spherically symmetrical and 3D Earth models. The results are summarized in a special issue of *Physics of the Earth and Planetary Interiors* (volume 119, 2000). Even for 1D models, the COSY benchmarks are disappointing in terms of their relatively low level of agreement, in particular for surface waves. This serves as an illustration of the great difficulties associated with developing, implementing, and benchmarking numerical techniques for the simulation of global seismic wave propagation.

1.07.3 Equation of Motion

An isotropic, elastic Earth model may be characterized in terms of three parameters: the distribution of mass density ρ, the compressional wave speed α, and the shear wave speed β. Rather than the compressional and shear wave speeds, one may also use the bulk modulus or incompressibility κ and the shear modulus or rigidity μ. The two sets of model parameters are related by $\alpha = [(\kappa + (4/3)\mu)/\rho]^{1/2}$ and $\beta = (\mu/\rho)^{1/2}$. In a spherically symmetrical (1D) Earth model, such as PREM (Dziewonski and Anderson, 1981), IASP91 (Kennett and Engdahl, 1991), or AK135 (Kennett et al., 1995), the model

parameters vary only as a function of the radius, whereas in a general 3D Earth model, the model parameters also vary laterally. The model parameters may exhibit a number of discontinuities as a function of depth, for example, at the ocean floor, the Moho, across the upper-mantle phase transitions, at the CMB, and at the ICB. The most general spherically symmetrical Earth model is not isotropic but rather transversely isotropic. Such an Earth model is characterized by five elastic parameters: A, C, L, N, and F (Love, 1911). Alternatively, one may use a representation in terms of the speeds of horizontally and vertically propagating compressional waves $\alpha_v = (C/\rho)^{1/2}$ and $\alpha_h = (A/\rho)^{1/2}$, the speeds of vertically and horizontally propagating horizontally polarized shear waves $\beta_h = (L/\rho)^{1/2}$ and $\beta_h = (N/\rho)^{1/2}$, and the dimensionless parameter $\eta = F/(A-2L)$. Because the widely used PREM is a transversely isotropic Earth model, numerical simulations of global seismic wave propagation should facilitate the use of such models. The parameters that characterize an isotropic or transversely isotropic Earth model need to be specified at all grid points used by the numerical method.

Let $\mathbf{s}$ denote the displacement field induced by an earthquake. In an isotropic, elastic Earth model, the stress tensor $\mathbf{T}$ is determined in terms of the elastic moduli κ and μ and the strain tensor $\epsilon = \frac{1}{2}\left[\nabla\mathbf{s} + (\nabla\mathbf{s})^{\mathrm{T}}\right]$ by Hooke's law:

$$\mathbf{T} = \left(\kappa - \frac{2}{3}\mu\right)\mathrm{tr}(\epsilon)\mathbf{I} + 2\mu\epsilon \qquad [1]$$

Here, $\mathbf{I}$ denotes the 3×3 identity tensor and a superscript T denotes the transpose. Note that the strain and stress tensors are both symmetrical tensors, $\epsilon^{\mathrm{T}} = \epsilon$ and $\mathbf{T}^{\mathrm{T}} = \mathbf{T}$. In the fluid regions of the Earth model, for example, in the oceans and in the outer core, the shear modulus vanishes, and Hooke's law [1] reduces to $\mathbf{T} = \kappa\,\mathrm{tr}(\epsilon)\mathbf{I}$. Hooke's law [1] is an example of a constitutive relationship between stress and strain. The most general linear relationship between stress $\mathbf{T}$ and strain ϵ involves the fourth-order elastic tensor $\mathbf{c}$:$\mathbf{T} = \mathbf{c}$:ϵ. Because both the stress and the strain tensor are symmetrical, and due to certain thermodynamic considerations (Aki and Richards, 1980; Dahlen and Tromp, 1998), the elastic tensor exhibits the following symmetries: $c_{ijkl} = c_{jikl} = c_{ijlk} = c_{klij}$. These symmetries reduce the number of independent elastic parameters from 81 to 21. For mathematical and notational convenience, we will sometimes use the anisotropic constitutive relationship, rather than the more practical isotropic version [1].

The Earth is not a perfectly elastic body, and effects due to attenuation should be incorporated. In an anelastic medium, the stress $\mathbf{T}$ at time t is determined by the entire strain history $\epsilon(t)$, and in its most general anisotropic form, Hooke's law becomes (e.g., Aki and Richards, 1980; Dahlen and Tromp, 1998)

$$\mathbf{T}(t)\int_{-\infty}^{t} \partial_t \mathbf{c}(t-t') : \nabla\mathbf{s}(t')\mathrm{d}t' \qquad [2]$$

Attenuation is well represented by an absorption-band solid, which may be approximated by using a series of standard linear solids (Liu et al., 1976). Numerically, the behavior of the standard linear solids is modeled by tracking the so-called memory variables (e.g., Carcione et al., 1988; Emmerich and Korn, 1987; Komatitsch and Tromp, 1999; Moczo et al., 1997; Robertsson et al., 1994). In the Earth, bulk attenuation is several hundred times less significant than shear attenuation. Therefore, as far as attenuation is concerned, one can safely assume that it is sufficient to model the time evolution of the shear modulus. In this chapter, we will avoid the mathematical and numerical complications associated with attenuation, but suffice it to say that these effects can be readily accommodated in most numerical simulations. The main difficulty is the increase in computer memory requirements.

Having introduced various possibilities for the constitutive relationship, the displacement field $\mathbf{s}$ generated by an earthquake is governed by the elastic wave equation, which may be written in the form (e.g., Aki and Richards, 1980)

$$\rho\partial_t^2\mathbf{s} = \nabla\cdot\mathbf{T} + \mathbf{f} \qquad [3]$$

For earthquakes that are small enough such that they can be treated as a point source, the force $\mathbf{f}$ in [3] may be expressed in terms of the moment tensor $\mathbf{M}$ as (e.g., Aki and Richards, 1980; Dahlen and Tromp, 1998)

$$\mathbf{f} = -\mathbf{M}\cdot\nabla\delta(\mathbf{x}-\mathbf{x}_s)S(t) \qquad [4]$$

The location of the point source is denoted by $\mathbf{x}_s$, $\delta(\mathbf{x}-\mathbf{x}_s)$ is the Dirac delta distribution located at $\mathbf{x}_s$, and $S(t)$ is the source-time function. For a source of finite size, such as a fault plane Σ_s, the force $\mathbf{f}$ in [3] may be written in terms of the moment-density tensor $\mathbf{m}$ as

$$\mathbf{f} = -\mathbf{m}(\mathbf{x}_s, t)\cdot\nabla\delta(\mathbf{x}-\mathbf{x}_s) \quad \mathbf{r}\in\Sigma_s \qquad [5]$$

For simplicity, we work with the point source representation [4] in the rest of this chapter.

The equation of motion [3] must be solved subject to a number of boundary conditions. On the Earth's surface, the traction $\hat{\mathbf{n}}\cdot\mathbf{T}$, where $\hat{\mathbf{n}}$ denotes the unit outward normal to the free surface, should vanish, that is, $\hat{\mathbf{n}}\cdot\mathbf{T} = 0$. On solid–solid boundaries, such as the Moho or the upper-mantle discontinuities, both the traction $\hat{\mathbf{n}}\cdot\mathbf{T}$ and the displacement $\mathbf{s}$ need to be continuous, whereas on fluid–solid boundaries, such as the ocean floor, the CMB, and the ICB, both the traction $\hat{\mathbf{n}}\cdot\mathbf{T}$ and the normal component of displacement $\hat{\mathbf{n}}\cdot\mathbf{s}$ need to be continuous.

When our modeling domain is not the entire Earth, seismic energy needs to be absorbed on the fictitious boundaries of the domain. To accomplish this, one generally uses a paraxial equation to damp the wavefield on the edges (Clayton and Engquist, 1977; Quarteroni et al., 1998). In recent years, a significantly more efficient absorbing condition called the perfectly matched layer has been introduced (Bérenger, 1994), which is now being used in regional numerical simulations (e.g., Basu and Chopra, 2003; Collino and Tsogka, 2001; Festa and Vilotte, 2005; Komatitsch and Tromp, 2003). In this chapter, we largely ignore the numerical complications associated with absorbing boundary conditions.

At periods longer than about 150 s, self-gravitation and rotation start to play a role in global seismic wave propagation. The equation of motion for a rotating, self-gravitating Earth model is significantly more complicated than [3] (e.g., Dahlen and Tromp, 1998). Nevertheless, numerical simulations based upon a weak implementation of the equation of motion frequently do take these complications into account. In this chapter, we do not incorporate these long-period complications for the sake of simplicity.

Numerical solutions to the elastic wave equation may be subdivided in to two categories: strong and weak

implementations. Strong implementations use the differential form of the wave equation subject to certain explicit boundary conditions, whereas weak implementations are based upon an integral form that contains the free surface boundary conditions implicitly. Both implementations are popular in global seismology, and for each category, we discuss a number of numerical applications.

1.07.4 Strong Implementations

Strong implementations of the equation of motion typically involve rewriting eqn [3] and the constitutive relationship as a system of coupled first-order differential equations in space and time, known as the velocity–stress formulation:

$$\partial_t \mathbf{v} = \rho^{-1}(\nabla \cdot \mathbf{T} + \mathbf{f}), \quad \partial_t \mathbf{T} = \mathbf{c} : \nabla \mathbf{v} \qquad [6]$$

where $\mathbf{v} = \partial_t \mathbf{s}$. For brevity, we have used the general anisotropic constitutive relationship and one of the symmetries of the elastic tensor. The system of eqn [6] must be solved for the three components of velocity $\mathbf{v}$ and the six independent components of the stress tensor $\mathbf{T}$ subject to the appropriate boundary conditions, that is, a total of nine unknown parameters. FDM and PM, which are discussed in the next two sections, are frequently based upon the velocity–stress formulation [6].

1.07.4.1 Finite Difference Method

Perhaps, the most intuitively appealing numerical technique is the FDM (e.g., Madariaga, 1976; Virieux, 1984, 1986). In this approach, the first-order spatial and temporal derivatives in eqn [6] are approximated by taking differences between neighboring grid points. To limit numerical grid dispersion and anisotropy, one typically uses a fourth-order scheme on a staggered grid in space and a second-order scheme in time (e.g., Levander, 1988). For example, consider a function f sampled at N grid points with a grid spacing Δx: $f_n = f(n\Delta x)$, $n = 0, \ldots, N-1$. The derivative of f on this grid may be approximated accurate to second order in Δx by the centered-difference expression (often called a stencil)

$$\frac{\mathrm{d}}{\mathrm{d}x} f(n\Delta x) = (f_{n+1} - f_{n-1})/(2\Delta x), \quad n = 1, \ldots, N-2 \qquad [7]$$

and accurate to fourth-order by the centered-difference stencil

$$\frac{\mathrm{d}}{\mathrm{d}x} f(n\Delta x) = (-f_{n+2} + 8f_{n+1} - 8f_{n-1} + f_{n-2})/(12\Delta x), \quad n = 2, \ldots, N-3 \qquad [8]$$

These results are valid in the interior of the domain. Near the domain boundaries, less accurate one-sided difference operators come in to play, and for this reason, the implementation of free surface boundary conditions is often problematic, and in particular, surface waves are poorly simulated (e.g., Graves, 1996; Ohminato and Chouet, 1997; Robertsson, 1996). Recently developed optimal or compact finite difference operators will perhaps improve this situation (e.g., Zingg, 2000; Zingg et al., 1996); see also the optimal finite difference operators introduced by Geller and Takeuchi (1995) in the context of weak applications.

An example of a 2D (axisymmetric) staggered finite difference grid used to simulate acoustic (purely compressional) wave propagation by Thomas et al. (2000) is shown in **Figure 1**.

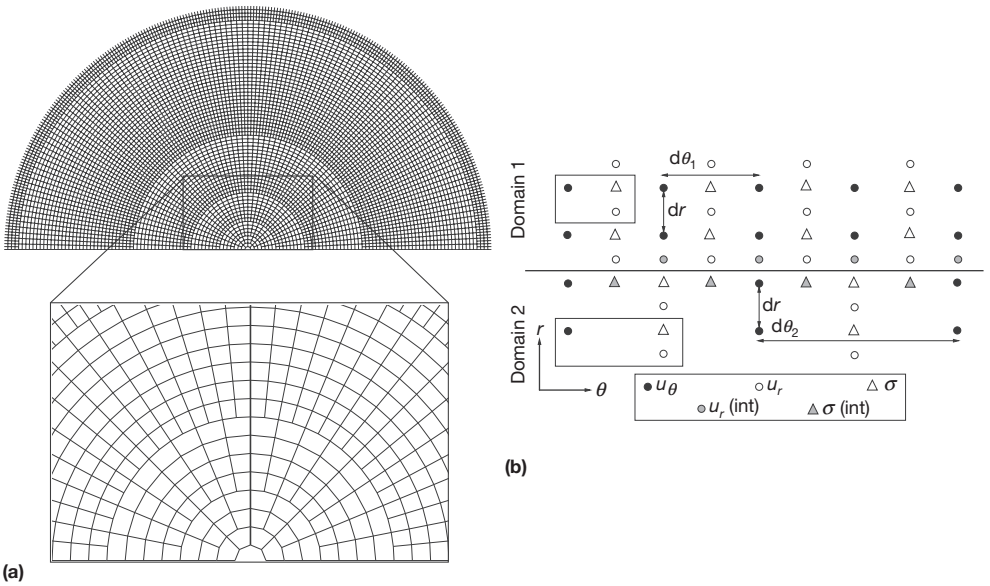

Figure 1 (a) Two-dimensional finite difference grid used in the axisymmetric simulations of Thomas et al. (2000). The lateral grid spacing is increased each time the arc length is halved. (b) Staggered grid and domain decomposition. The vertical (u_r) and lateral (u_θ) components of the velocity and the pressure (σ) are evaluated based upon a fourth-order accurate scheme on different, staggered grids. At the domain boundaries, where the lateral grid spacing is increased from $\mathrm{d}\theta_1$ to $\mathrm{d}\theta_2$, some fields have to be interpolated (dashed symbols) to connect the domains, and a second-order accurate approach for the derivatives and the interpolation is used. The radial grid spacing ($\mathrm{d}r$) remains unchanged across the boundary. Courtesy of Thomas C, Igel H, Weber M, and Scherbaum F (2000) Acoustic simulation of P-wave propagation in a heterogeneous spherical Earth: Numerical method and application to precursor waves to PKPdf. *Geophysical Journal International* 141: 6441–6464.

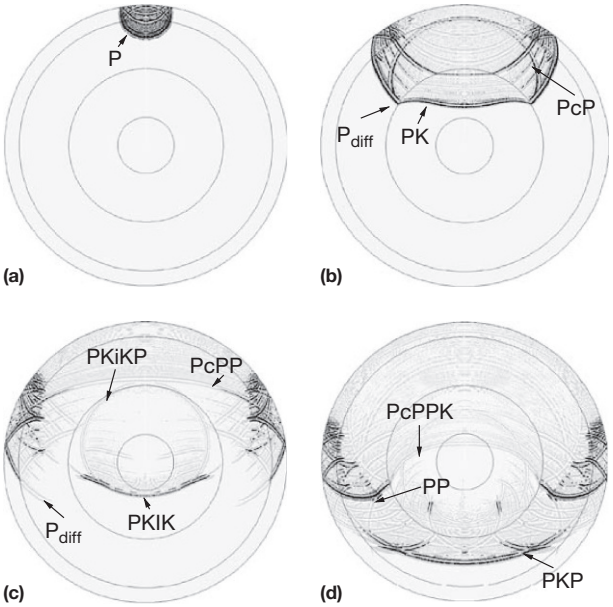

Figure 2 Finite difference snapshots of P-wave propagation through PREM for a source at the surface. The 2D simulations are based upon the acoustic wave equation involving the grid shown in **Figure 1**. The dominant period is 20 s. (a) P wavefield after 150 s, (b) 450 s, (c) 750 s, (d) 1050 s. The 670 km discontinuity, the CMB, and the ICB are shown by the concentric circles, and some of the main phases have been labeled. Courtesy of Thomas C, Igel H, Weber M, and Scherbaum F (2000) Acoustic simulation of P-wave propagation in a heterogeneous spherical Earth: Numerical method and application to precursor waves to PKPdf. *Geophysical Journal International* 141: 6441–6464.

Snapshots of such a simulation are shown in **Figure 2**. The FDM is widely used to calculate the wavefield in 3D local and regional models (e.g., Graves, 1996; Ohminato and Chouet, 1997), most recently for finite rupture scenarios, and has a long and distinguished record in exploration seismology. On the scale of the globe, it has only been used to a limited extend (e.g., Chaljub and Tarantola, 1997; Igel and Gudmundsson, 1997; Igel and Weber, 1995, 1996; Thomas et al., 2000) and never at the scale of the entire globe.

The main advantage of the FDM is its relative ease of implementation. Still, at the scale of the globe, designing a good grid with an even number of grid points per wavelength and a relatively constant stability condition is difficult because one needs to resort to unevenly spaced stencils. In particular, the poles and the Earth's center pose challenges. Perhaps, the main disadvantage of the FDM is its poor representation of surface waves due to the difficulty of implementing accurate free surface boundary conditions.

1.07.4.2 Pseudospectral Method

The motivation behind the PM is a desire for more accurate spatial derivative operators. Such operators are obtained by expanding the components of the velocity–stress wavefield in terms of known global basis functions, for example, sines and cosines or Chebyshev polynomials, and calculating derivatives based upon fast transforms. For example, consider a function f sampled at N grid points with a grid spacing Δx: $f(n\Delta x)$, $n=0, \ldots, N-1$. This function may be transformed to the wave number domain based upon the 1D fast Fourier transform (FFT) to obtain

$$F(l\Delta k) = \Delta x \sum_{n=0}^{N-1} f(n\Delta x)\exp(-2\pi i n l/N), \quad l=0,\ldots,N-1 \qquad [9]$$

where $\Delta k = 2\pi/(N\Delta x)$. The derivative of the function may now be calculated in the wave number domain by simply multiplying by $i(l\Delta k)$ and using an inverse FFT to go back to the spatial domain:

$$\frac{d}{dx} f(n\Delta x) = \frac{1}{N\Delta x} \sum_{l=0}^{N-1} i(l\Delta k) F(l\Delta k)\exp(2\pi i n l/N), \quad n = 0,\ldots,N-1 \qquad [10]$$

This derivative operation is based upon information from all available N grid points and is therefore much more accurate than a derivative operator based upon first and second neighbors, as in the finite difference expressions [7] and [8].

The PM has been used to address regional (e.g., Carcione, 1994) and global (e.g., Hung and Forsyth, 1998; Tessmer et al., 1992) seismic wave propagation problems. Fourier basis functions (e.g., Furumura et al., 1998, 1999; Kosloff and Baysal, 1982; Kosloff et al., 1984; Wang and Takenaka, 2001; Wang et al., 2001), Chebyshev basis functions (e.g., Carcione and Wang, 1993; Igel, 1999; Igel et al., 2002; Kosloff and Tal-Ezer, 1993; Kosloff et al., 1990; Tessmer, 1995; Tessmer and Kosloff, 1994), and combinations of Fourier and Chebyshev basis functions (e.g., Tessmer et al., 1992) have all been used. Because the Fourier basis is periodic, one often introduces periodic boundary conditions. At the free surface, this is not an option, and less accurate approximations need to be invoked. The advantage of the Chebyshev basis over the Fourier basis is that it is nonperiodic and uses unevenly spaced grid points with a concentration of points near the edges of the domain, which leads to more accurate surface waves due to a more precise implementation of the free surface boundary conditions. An implementation based upon wavelets, which does not use the velocity–stress formulation [6], was introduced by Hong and Kennett (2002). Like FDMs, one typically uses a second-order accurate time scheme in a PM.

Because of the use of global basis functions, the pseudospectral technique is limited to smooth media, and numerical noise appears in the presence of sharp discontinuities in the model, such as first-order solid–solid upper-mantle discontinuities. Such ringing can be avoided by using a domain decomposition approach (e.g., Hung and Forsyth, 1998; Wang and Takenaka, 2001).

An example of a 2D axisymmetric elastic pseudospectral simulation by Wang et al. (2001) for model IASP91 is shown in **Figure 3**. The implementation is based upon a Fourier basis. Unlike the acoustic FDM simulation shown in **Figure 2**, one can see both compressional and shear waves in this simulation. Igel (1999) used a PM based upon a Chebyshev implementation for the simulation of 3D seismic wave propagation in a section of the globe, as illustrated in **Figure 4**. Snapshots from a simulation for PREM are shown in **Figure 5**. The 3D simulation is restricted to a section of the globe to save memory and to avoid problems associated with diminishing grid spacing and related numerical instabilities toward the Earth's center.

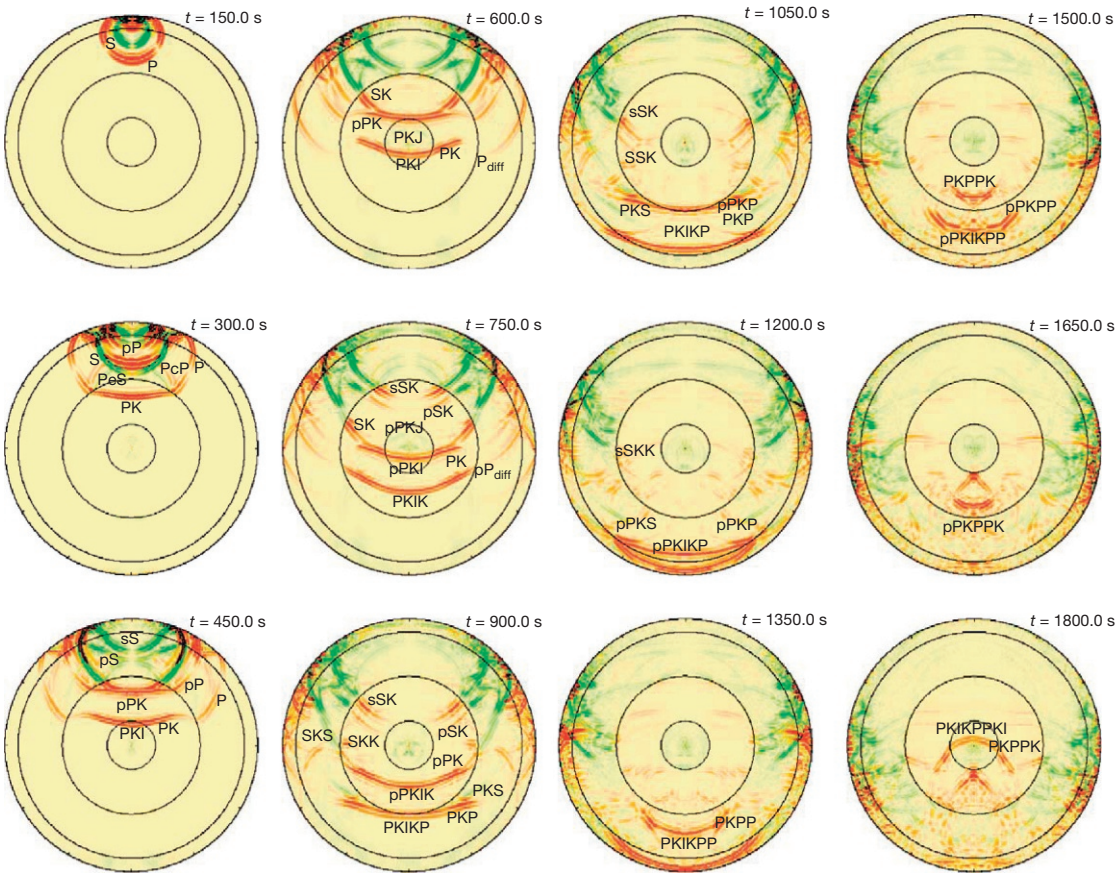

Figure 3 Snapshots of an axisymmetric pseudospectral simulation in the IASP91 model for a source at a depth of 600 km. The 2D simulations solve the elastic wave equation in cylindrical coordinates. The red and green colors represent P and S waves, respectively. Concentric circles denote the 660 km discontinuity, the CMB, and the ICB. It is instructive to compare these elastic pseudospectral snapshots with the purely acoustic finite difference snapshots shown in **Figure 2**. (*Note*: however the difference in source depth.) The shortest period in the synthetics is 30 s. The main advantage of the PM is its precision for smooth isotropic and anisotropic models. Its main demerits are related to the difficulties of designing effective fast transforms for the sphere and the generally poor representation of surface waves. Transform methods frequently impose an undesirable grid spacing that reflects geometry rather than material properties. Large simulations on parallel machines with distributed memory are challenging because subsequent FFTs in the x-, y-, and z-directions require repeated gather–scatter operations that are computationally expensive.

1.07.5 Weak Implementations

For a number of numerical techniques, one works with a modified version of the equation of motion called the integral or weak formulation of the problem. It is obtained by taking the dot product of the momentum (eqn [3]) with an arbitrary test vector $\mathbf{w}$ and integrating by parts over the volume V of the Earth:

$$\int_V \rho \mathbf{w} \cdot \partial_t^2 \mathbf{s} \, \mathrm{d}^3\mathbf{x} = -\int_V \nabla \mathbf{w} : \mathbf{T} \mathrm{d}^3\mathbf{x} + \mathbf{M} : \nabla \mathbf{w}(\mathbf{x}_s) S(t) \qquad [11]$$

Equation [11] is equivalent to the strong formulation [6] because it holds for any test vector $\mathbf{w}$. The term on the left-hand side is related to the mass matrix in finite element parlance, and the first term on the right leads to the stiffness

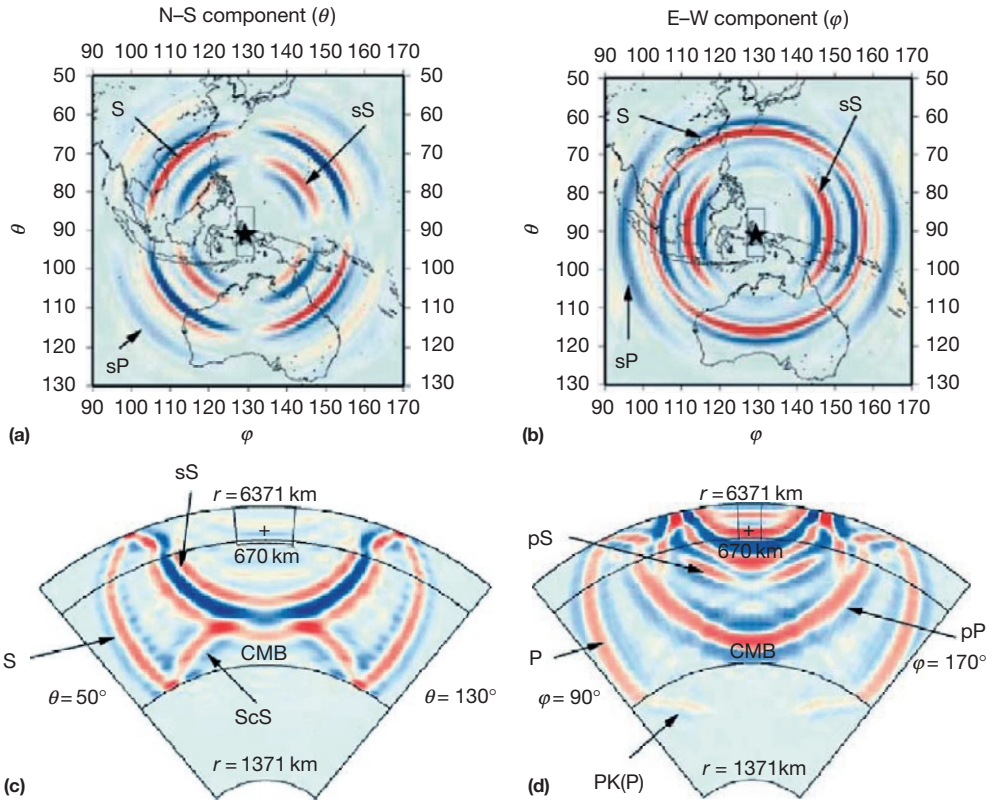

Figure 5 Top: Pseudospectral snapshots of the north–south (left) and east–west (right) components of the velocity field at the Earth's surface at 550 s. Red and blue colors denote positive and negative velocities, respectively. The epicenter is indicated by the star, and the hypocenter is located at a depth of 600 km. The dominant period is 50 s, and the spherically symmetrical Earth model is PREM. We clearly see the S and sS arrivals; at this stage in the simulation, the compressional waves P and pP have already been absorbed by the boundaries. Bottom: Snapshots of the velocity field in a longitudinal cross section through the hypocenter. Left: Transverse component of motion at 550 s. Notice that, as expected, there are no shear waves in the core. Right: Radial component of motion at 300 s. Notice how compressional waves are entering the core. Courtesy of Igel H (1999) Wave propagation in three-dimensional spherical sections by the Chebyshev spectral method. *Geophysical Journal International* 136: 559–566.

matrix. The second term on the right is the source term [4], which has been integrated explicitly by using the properties of the Dirac delta distribution. Note that, like the velocity–stress strong form [6], only the first-order spatial derivatives of the displacement field and the test vector are involved in the weak form [11] but that, unlike the velocity–stress formulation, the temporal derivatives are of second order.

It is important to appreciate that the traction-free surface condition $\hat{\mathbf{n}}\cdot\mathbf{T}=0$ is imposed naturally and automatically during the integration by parts, because the contour integral over the free surface simply vanishes. In other words, the free surface condition is a natural condition of the problem. In the context of regional simulations, an additional term appears in eqn [11], which represents the absorption of energy on the artificial boundaries of the domain (e.g., Komatitsch and Tromp, 1999).

In the next section, we introduce Rayleigh–Ritz methods, of which CMM and DSM are examples. Other numerical methods based upon the weak formulation [11] that are discussed in subsequent sections are FEM and SEM.

1.07.5.1 Rayleigh–Ritz Method

The idea behind a Rayleigh–Ritz method is to expand the unknown displacement field $\mathbf{s}$ in terms of a set of known trial or basis functions $\mathbf{s}_k$ (Dahlen and Tromp, 1998):

$$\mathbf{s}=\sum_k q_k\mathbf{s}_k \qquad [12]$$

In this approach, one seeks to determine the expansion coefficients q_k. Notice that at this stage, we need not be specific about the exact choice of the basis functions. Rayleigh–Ritz methods are generally implemented in the frequency domain. It is readily shown that the weak form of the frequency domain version of the equation of motion [3] is (Dahlen and Tromp, 1998; Geller and Ohminato, 1994)

$$-\omega^2\int_V \rho\mathbf{w}\cdot\mathbf{s}\,\mathrm{d}^3\mathbf{x}=-\int_V \nabla\mathbf{w}:\mathbf{T}\,\mathrm{d}^3\mathbf{x}+\mathbf{M}:\nabla\mathbf{w}(\mathbf{x}_\mathrm{s})S(\omega) \qquad [13]$$

Upon substituting the expansion [12] in [13] and choosing the test vector $\mathbf{w}=\mathbf{s}_{k'}$, we obtain the matrix equation

$$\sum_k \left(V_{k'k}-\omega^2 T_{k'k}\right)q_k(\omega)=S_{k'}(\omega) \qquad [14]$$

where we have defined the matrix and vector elements

$$V_{k'k}=\int_\Omega \nabla\mathbf{s}_{k'}:\mathbf{c}:\nabla\mathbf{s}_k\,\mathrm{d}^3\mathbf{x},\quad T_{k'k}=\int_\Omega \rho\mathbf{s}_{k'}\cdot\mathbf{s}_k\,\mathrm{d}^3\mathbf{x},\quad S_{k'}(\omega)=\mathbf{M}:\nabla\mathbf{s}_{k'}(\mathbf{x}_\mathrm{s})S(\omega) \qquad [15]$$

For brevity, we use the full anisotropic elastic tensor in the definition of the matrix elements $V_{k'k}$. Because the test vector

$\mathbf{w}$ and the basis functions $\mathbf{s}_k$ are the same, the Rayleigh–Ritz method is also referred to as a Galerkin method. By introducing the $(\infty \times \infty)$-dimensional kinetic and potential energy matrices

$$\mathbf{T} = \begin{pmatrix} \vdots & & \\ \cdots & T_{k'k} & \cdots \\ \vdots & & \end{pmatrix}, \quad \mathbf{V} = \begin{pmatrix} \vdots & & \\ \cdots & V_{k'k} & \cdots \\ \vdots & & \end{pmatrix} \qquad [16]$$

and the ∞-dimensional source vector

$$\mathbf{S} = \begin{pmatrix} \vdots \\ S_{k'} \\ \vdots \end{pmatrix} \qquad [17]$$

the solution to [14] may be formally expressed as

$$\mathbf{q}(\omega) = \left(\mathbf{V} - \omega^2 \mathbf{T}\right)^{-1} \mathbf{S}(\omega) \qquad [18]$$

In an anelastic Earth model, the potential energy matrix also depends on frequency, $\mathbf{V}=\mathbf{V}(\omega)$, because in that case, the elastic tensor $\mathbf{c}$ becomes frequency-dependent (see eqn [2]). Of course, in practice, one uses a finite-dimensional set of basis functions $\mathbf{s}_{k'}$ leading to a finite-dimensional matrix solution [18]. This truncation of the eigenvalue problem leads to inaccuracies in the synthetics. Such truncation errors are most pronounced in models with sharp heterogeneities, which induce a wide coupling band.

Let us denote the $\hat{\boldsymbol{\nu}}$ component of the displacement by $s=\hat{\boldsymbol{\nu}} \cdot \boldsymbol{s}$, and let us define the receiver vector elements $R_k = \hat{\boldsymbol{\nu}} \cdot \boldsymbol{s}_k$. Upon introducing the ∞-dimensional receiver vector

$$\mathbf{R} = \begin{pmatrix} \vdots \\ R_k \\ \vdots \end{pmatrix} \qquad [19]$$

and using eqns [12] and [18], it may be shown that the spectrum of the $\hat{\boldsymbol{\nu}}$ component of the displacement is given by

$$s(\omega) = \mathbf{R}^{\mathrm{T}} \left(\mathbf{V} - \omega^2 \mathbf{T}\right)^{-1} \mathbf{S}(\omega) \qquad [20]$$

This expression gives the response of a 3D Earth model to an earthquake and forms the basis of the CMM discussed in **Section 1.07.5.1.1** and the DSM discussed in **Section 1.07.5.1.2**.

Finally, we note that the eigenfrequencies of the 3D Earth model are determined by (Dahlen and Tromp, 1998)

$$\det\left(\mathbf{V} - \omega^2 \mathbf{T}\right) = 0 \qquad [21]$$

1.07.5.1.1 Coupled-mode method

The CMM for calculating 3D synthetic seismograms was pioneered by Park (1986) and gained significant interest (e.g., Capdeville et al., 2000; Lognonné and Romanowicz, 1990; Park and Yu, 1992; Tromp and Dahlen, 1990). In this approach, the basis functions $\mathbf{s}_k$ in eqn [12] are chosen to be the eigenfunctions of a spherically symmetrical Earth model. These eigenfunctions have a radial dependence that is dictated by the radial structure of the spherically symmetrical reference Earth model, for example, PREM, and a lateral dependence that involves (vector) spherical harmonics. Expressions for the coupling matrices [16] based upon these eigenfunctions were first derived by Woodhouse (1980) and are summarized in Dahlen and Tromp (1998).

There are two main problems with the CMM. The first problem is that the basis functions are spherically symmetrical whereas the 3D Earth model is elliptical and has topography and bathymetry. Typically, first-order perturbation theory is used to linearize these boundary undulations, which leads to errors in the forward calculation. A more serious problem has to do with the size of the matrices [16] involved in the coupled-mode calculations. As the frequency content of the synthetics is increased, the size of the matrices grows very rapidly, leading to large matrix–vector operations. Such operations are computationally very expensive, in particular on computers with distributed memory. Therefore, coupled-mode calculations do not scale well on parallel machines, and in recent years, they have largely gone out of favor. Only when one wants to calculate the very long-period response of the Earth, say at periods of 500 s and longer, is the coupled-mode approach the method of choice (e.g., Deuss and Woodhouse, 2001). **Figure 6** shows an example of a coupled-mode calculation for the 9 June 1994 Bolivia deep-focus earthquake. In this calculation, neighboring modes are grouped in supermultiplets, in which the singlets that constitute the multiplets that define the group are coupled through a matrix expression of the form [20].

1.07.5.1.2 Direct solution method

In the DSM pioneered by Geller (e.g., Geller and Hatori, 1995; Geller and Ohminato, 1994; Geller and Takeuchi, 1995; Hara et al., 1991; Takeuchi et al., 2000), the basis functions in eqn [12] are low-order polynomials, for example, splines, or analytic functions. Complications due to the representation of the source term, which may not be representable in terms of these basis functions, are discussed in Takeuchi and Geller (2003). For spherically symmetrical Earth models, the DSM may be used to calculate high-frequency synthetic seismograms, as illustrated in **Figure 7**. At 2 Hz, these synthetics are detailed enough to show the weak ICB-reflected PKiKP arrival. Geller and Takeuchi (1995) had designed finite difference operators that optimize the accuracy of the DSM synthetic seismograms.

DSM synthetics may be used to benchmark other numerical techniques. A comparison between a 2D axisymmetric PS simulation, such as the one shown in **Figure 3**, and 3D DSM for spherically symmetrical Earth model IASP91 is shown in **Figure 8**. To facilitate this comparison, the 2D PS synthetics are mapped to approximate 3D synthetics (Wang et al., 2001). This mapping produces approximately the right 3D geometric spreading and dispersion and produces adequate fits to the body-wave arrivals.

Like coupled-mode synthetics, the DSM generally uses a linearized treatment of boundary undulations, which diminishes the accuracy of the 3D synthetics. Takeuchi (2005) had recently extended the method to include arbitrary perturbations in boundary locations, as illustrated in **Figure 9**. Probably, the main restriction for the DSM, like the CMM, is the need for significant amount of shared memory to perform the necessary matrix–vector manipulations for fully 3D Earth models. Some of the main advantages of the DSM are that it addresses broadband wave propagation at the scale of the entire globe and that it agrees closely with normal-mode algorithms for spherically symmetrical Earth model. For relatively

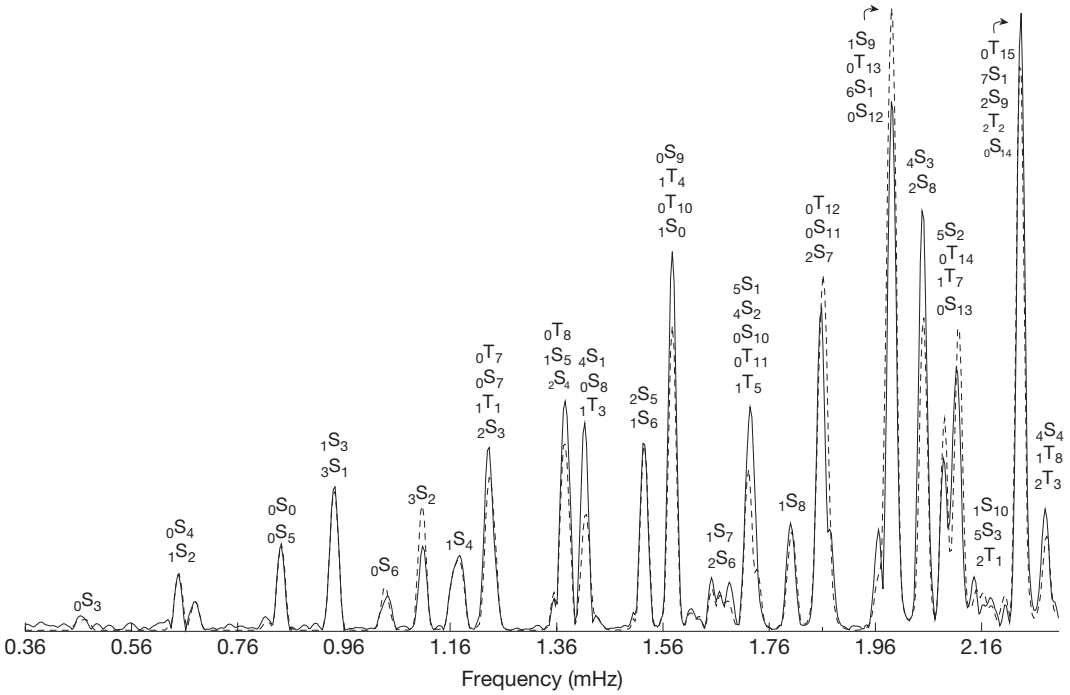

Figure 6 Vertical-component amplitude spectra of the 9 June 1994 Bolivia deep-focus earthquake recorded at station PAS in Pasadena, CA. The solid line shows the observed spectrum; the dashed line shows the synthetic coupled-mode spectrum. Rotation, ellipticity, and the lateral variations in shear wave speed of model SKS12WM13 (Dziewonski et al., 1997) have been accounted for in the calculations. The vertical arrays of mode labels identify the 22 supermultiplets considered. A Hann taper has been applied to both 35 h time series prior to Fourier transformation.

smooth 3D models at longer periods, the method is precise and effective.

1.07.5.2 Finite Element Method

The FEM is very popular in science and engineering (e.g., Hughes, 1987; Zienkiewicz, 1977), but has found limited application in seismology in general, and is currently not used for simulations at the scale of the globe. In the context of regional simulations, for the purpose of seismic hazard assessment, the method is actively being used (e.g., Aagaard et al., 2001; Bao et al., 1998; Bielak et al., 1999; Garatani et al., 2000). The method accommodates previously mentioned difficulties related to the presence of topography on major interfaces by allowing the grid boundaries to follow the local topography. Despite the fact that the FEM is presently not used for simulations in global seismology we discuss the method in some detail, because the SEM, which is extensively used in global seismology, has many common features.

In an FEM, the model domain is subdivided into a large number of small elements, which may take a variety of forms, for example, tetrahedra, hexahedra, pyramids, and prisms. Cartesian points $\mathbf{x}=(x, y, z)$ within a given deformed element Ω are mapped to points $\boldsymbol{\xi}=(\xi, \eta, \zeta)$ in the reference element based upon the transformation

$$\mathbf{x}(\boldsymbol{\xi})=\sum_{a=1}^{n_a} N_a(\boldsymbol{\xi})\mathbf{x}_a \qquad [22]$$

The control points or anchors $\mathbf{x}_a$ define the geometry of the element, and the shape functions N_a provide a means for mapping and interpolation. For example, the geometry of hexahedral elements (deformed cubes) may be controlled by $n_a=8$, 20, or 27 anchors, as illustrated in Figure 10.

As an example, hexahedral shape functions are typically products of degree 1 or 2 Lagrange polynomials. The $n+1$ Lagrange polynomials of degree n are defined in terms of $n+1$ control points $-1\le\xi_\alpha\le 1$, $\alpha=0, \ldots, n$, by

$$\ell_\alpha(\xi)=\frac{(\xi-\xi_0)\cdots(\xi-\xi_{\alpha-1})(\xi-\xi_{\alpha+1})\cdots(\xi-\xi_n)}{(\xi_\alpha-\xi_0)\cdots(\xi_\alpha-\xi_{\alpha-1})(\xi_\alpha-\xi_{\alpha+1})\cdots(\xi_\alpha-\xi_n)} \qquad [23]$$

As a result of this definition, the Lagrange polynomials are equal to either 0 or 1 at any given control point $\ell_\alpha(\xi_\beta)=\delta_{\alpha\beta}$, where δ denotes the Kronecker delta. The two Lagrange polynomials of degree 1 with two control points $\xi=-1$ and $\xi=1$ are $\ell_0(\xi)=\frac{1}{2}(1-\xi)$ and $\ell_1(\xi)=\frac{1}{2}(1+\xi)$, and the three Lagrange polynomials of degree 2 with three control points $\xi=-1$, $\xi=0$, and $\xi=1$ are $\ell_0(\xi)=\frac{1}{2}\xi(\xi-1)$, $\ell_1(\xi)=1-\xi^2$, and $\ell_2(\xi)=\frac{1}{2}\xi(\xi+1)$.

Functions f, for example, components of the displacement field $\mathbf{s}$ or the test vector $\mathbf{w}$, are expanded in the n_a shape functions N_a:

$$f(\mathbf{x}(\boldsymbol{\xi}))=\sum_{a=1}^{n_a} f_a N_a(\boldsymbol{\xi}) \qquad [24]$$

where f_a denotes the value of the function f at anchor $\mathbf{x}_a$. The weak implementation [11] involves gradients of the

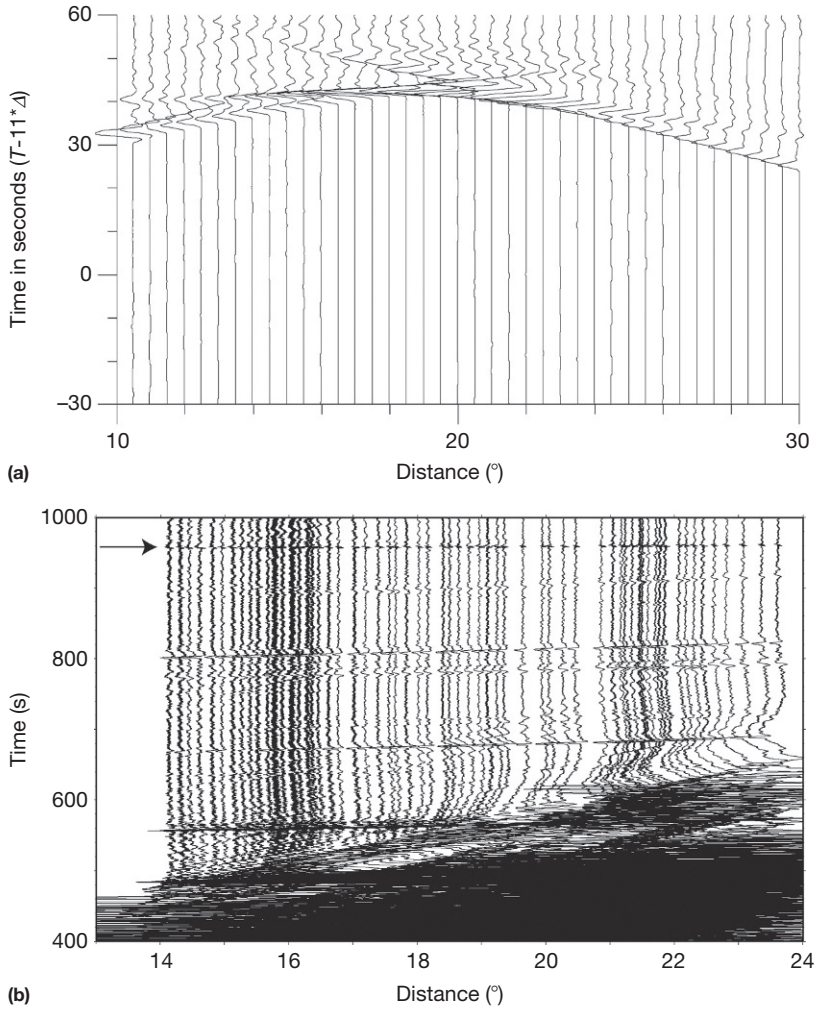

Figure 7 Examples of high-frequency DSM synthetics for isotropic PREM. (a) Displacement synthetic seismograms for upper-mantle triplication phases. The maximum frequency is 1 Hz. (b) Displacement synthetic seismograms for the PKiKP phase (indicated by the arrow). The maximum frequency is 2 Hz. Courtesy of Nozomu Takeuchi.

displacement **s** and the test vector **w**. Thus, the need arises to determine the gradient of functions:

$$\nabla f = \sum_{i=1}^{3} \hat{\mathbf{x}}_i \partial_i f = \sum_{i=1}^{3} \hat{\mathbf{x}}_i \sum_{a=1}^{n_a} f_a \left[\partial_\xi N_a(\boldsymbol{\xi})(\partial_i \xi) + \partial_\eta N_a(\boldsymbol{\xi})(\partial_i \eta) + \partial_\zeta N_a(\boldsymbol{\xi})(\partial_i \zeta) \right] \quad [25]$$

where $\hat{\mathbf{x}}_i$, $i=1, 2, 3$, denote unit vectors in the direction of increasing x, y, and z, respectively, and ∂_i, $i=1, 2, 3$, denote partial derivatives in those directions. The matrix $\partial\boldsymbol{\xi}/\partial\mathbf{x}$ is obtained by inverting the matrix $\partial\mathbf{x}/\partial\boldsymbol{\xi}$, whose elements may be determined by differentiating [22]. The existence of this matrix is a requirement that is imposed during the design of the mesh, that is, the Jacobian of the mapping [22] should never vanish. Notice how in an FEM the accuracy of the gradient [25] is controlled by the polynomial degree of the shape functions. Typically, one uses low-degree polynomials for the shape functions, which leads to relatively inaccurate derivatives, as in a low-degree FDM based upon [7]. Numerically, this leads to grid dispersion and anisotropy. There are the so-called *h-p* FEMs that use higher-degree polynomials for the shape functions to combat this problem (e.g., Guo and Babuška, 1986). A drawback for *h-p* FEMs is that they lead to large systems of linear equations that are difficult to solve, in particular on parallel machines.

The weak form [11] involves numerical integration of functions over the elements. In an FEM, this is generally accomplished based upon Gauss quadrature, such that integrations over elements Ω may be approximated as

$$\int_\Omega f(\mathbf{x}) \mathrm{d}^3\mathbf{x} = \sum_{\alpha=0}^{n} \sum_{\beta=0}^{n} \sum_{\gamma=0}^{n} \omega_\alpha \omega_\beta \omega_\gamma \times f\left(\xi_\alpha, \eta_\beta, \zeta_\gamma\right) \mathcal{J}\left(\xi_\alpha, \eta_\beta, \zeta_\gamma\right) \quad [26]$$

where ω_α, $\alpha=0, \ldots, n$, denote the $n+1$ weights associated with the Gauss quadrature, the $(n+1)^3$ points $(\xi_\alpha, \eta_\beta, \zeta_\gamma)$ denote the associated Gauss integration points, and $\mathcal{J}$ denotes the Jacobian of the mapping [22]. The Gauss weights and integration points are chosen such that in 1D, they exactly integrate a polynomial of degree $2n$. To facilitate the integration of

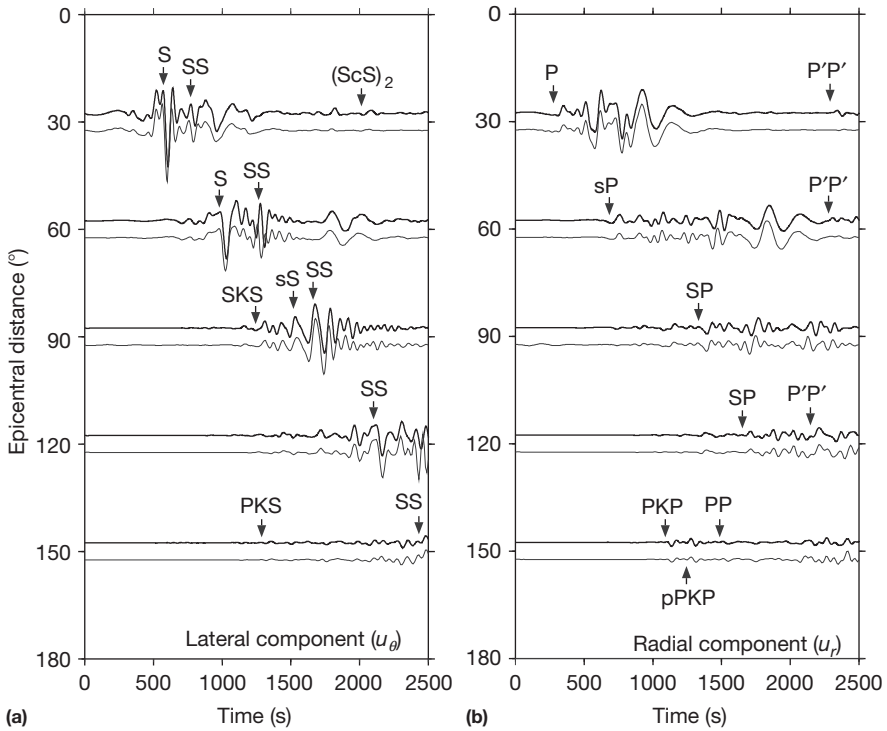

Figure 8 Comparison of axisymmetric pseudospectral (thin line) and DSM (thick line) synthetics at five epicentral distances. (a) Lateral component, (b) vertical component. Both sets of seismograms are band-pass-filtered between 40 and 300 s. The spherically symmetrical Earth model is IASP91. functions and their partial derivatives over the elements, the values of the inverse Jacobian matrix $\partial\boldsymbol{\xi}/\partial\mathbf{x}$ need to be stored at the Gauss integration points for each element.

In a finite element mesh, grid points that lie on the sides, edges, or corners of an element are shared among neighboring elements. Therefore, one needs to distinguish between the grid points that define an element, the local mesh, and all the grid points in the model, many of which are shared among several finite elements, the global mesh. One needs to determine a mapping between grid points in the local mesh and grid points in the global mesh; efficient finite element routines are available for this purpose. Before the system can be marched forward in time, the contributions from all the elements that share a common global grid point need to be summed. This is referred to as the assembly of the system.

The implementation of an FEM on parallel computers involves partitioning the mesh in slices of elements, such that each processor in the parallel machine is only responsible for the elements in one particular slice. At the edges of a slice, results need to be communicated to its neighbors. Therefore, a parallel computer assembly involves communication between adjacent mesh slices. Because the mass matrix in an FEM is nondiagonal, one needs to use an implicit time scheme, that is, one needs to resolve a system of linear equations. On a parallel machine, this too requires communication between distinct compute nodes. We discuss mesh partitioning in more detail in the context of spectral element simulations, which we introduce in the next section.

Like a low-order FDM, the FEM tends to suffer from numerical grid dispersion and anisotropy, which is highly undesirable for seismic wave propagation problems that involve real dispersion and anisotropy. Its main attribute is its flexibility, which allows one to design complicated meshes capturing realistic 3D Earth models.

1.07.5.3 Spectral Element Method

The SEM has been used for two decades in computational fluid dynamics (e.g., Patera, 1984). It has more recently been applied to problems related to 2D (Cohen et al., 1993; Priolo et al., 1994) and 3D local or regional (Faccioli et al., 1997; Komatitsch, 1997; Komatitsch and Tromp, 1999; Komatitsch and Vilotte, 1998; Komatitsch et al., 2004; Seriani, 1998) and global (Chaljub, 2000; Chaljub and Valette, 2004; Chaljub et al., 2003; Komatitsch and Tromp, 2002a,b; Komatitsch et al., 2002, 2003) seismic wave propagation. As in the classical FEM discussed in the previous section, the first step in the SEM is to subdivide the model volume into a number of non-overlapping elements. In an FEM, one can choose from a variety of elements, for example, tetrahedra, hexahedra, or prisms, but in the classical SEM, one uses only hexahedra. In 2D, the SEM has been extended to include triangles (e.g., Komatitsch et al., 2001; Sherwin and Karniadakis, 1995; Taylor and Wingate, 2000), but this leads to complications that are beyond the scope of this chapter. The mesh of elements needs to be geometrically conforming, that is, the six sides of each hexahedral

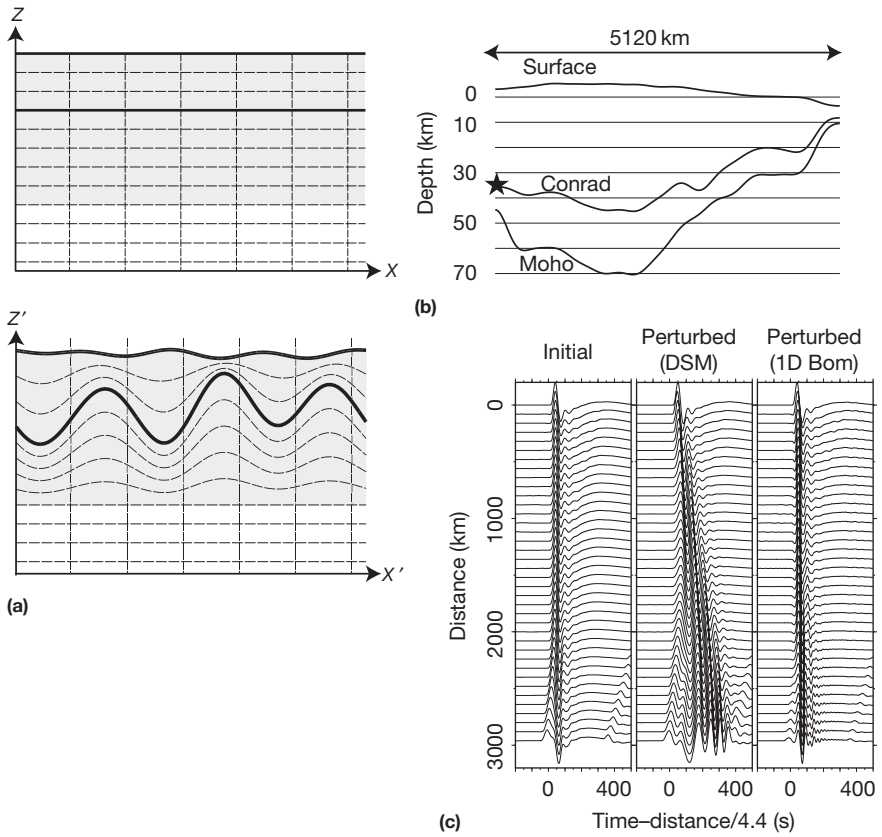

Figure 9 Illustration of the inclusion of topographic effects in the DSM. The basis functions are defined by using a one-to-one mapping of the boundaries in the initial model to those in the perturbed model. (a) Schematic illustration of the one-to-one mapping between the initial, laterally homogeneous model (top) and the perturbed model (bottom). Solid thick lines show the external and internal boundaries, and the shaded area shows the region deformed by the mapping. (b) Two-dimensional model that mimics crustal thickening in the Tibet region. The star shows the location of the source. (c) Example of synthetic seismograms computed for the model shown in (b). Synthetic seismograms for the initial (PREM) model are shown on the left, DSM synthetics for the perturbed model are shown in the middle, and synthetics based upon the conventional first-order Born approximation are shown on the right. Figure 10 The geometry of a hexahedral finite element may be defined in terms of its eight corners, the eight corners plus the 12 edge centers (the 20 black squares), or the eight corners plus the 12 edge centers plus the six face centers (the six open squares) plus the center (the open triangle). In a classical FEM, these 8, 20, or 27 anchors are used to define the shape of the element as well for the interpolation of functions. Courtesy of Komatitsch D and Tromp J (1999) Introduction to the spectral-element method for 3-D seismic wave propagation. *Geophysical Journal International* 139: 806–822.

element must match up exactly with the sides of neighboring elements. The SEM can be adapted to geometrically nonconforming meshes based on what is known as the mortar-matching method (e.g., Chaljub, 2000; Chaljub et al., 2003), but this is also beyond the scope of this chapter. Recent reviews of the SEM in seismology are given by Komatitsch et al. (2005) and Chaljub et al. (2007).

Figure 11 shows an example of a hexahedral SEM mesh for the globe. The mesh is designed based upon an analytic mapping between the cube and the sphere called the cubed sphere (Chaljub, 2000; Ronchi et al., 1996; Sadourny, 1972). Each of the six chunks that constitute the cubed sphere is meshed in such a way that they match perfectly at their common interfaces. Following Chaljub (2000), the singularity of coordinates at the Earth's center is avoided by placing a small cube around the center of the inner core. The mesh within this cube matches up with the cubed sphere mesh at the ICB. This mesh honors all first- and second-order discontinuities in PREM (Dziewonski and Anderson, 1981). Any typical 3D mantle and/or crustal model may now be superimposed on the mesh.

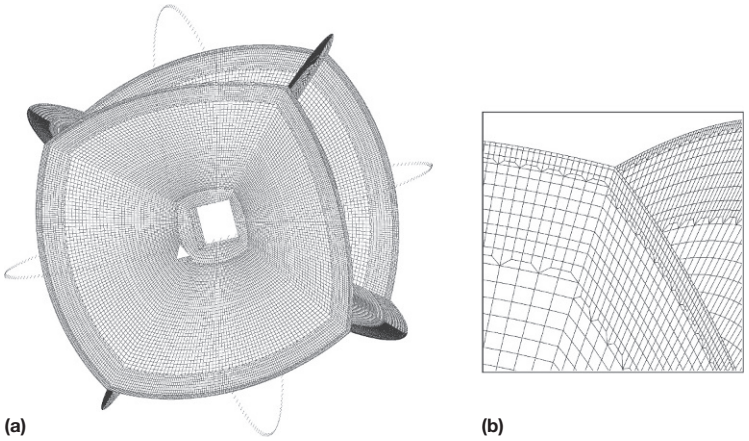

Figure 11 (a) Example of a spectral element mesh in the mantle. (b) Close-up of the mesh doublings in the upper mantle. The spectral element mesh is conforming, that is, every side of every element matches up perfectly with the side of a neighboring element, but nonstructured, that is, the number of elements that share a given point can vary and take any value. The mesh honors first-order discontinuities in PREM at depths of 24.4, 220, 400, and 670 km, the CMB, and the ICB; it also honors second-order discontinuities in PREM at 600, 771 km, and at the top of D″. The mesh is doubled in size once below the Moho, a second time below the 670 km discontinuity, and a third time just above the ICB. Each of the six chunks that constitute the cubed sphere has 240×240 elements at the free surface and 30×30 elements at the ICB. The central cube in the inner core has been removed for clarity of viewing. For a later experiment shown in **Figure 15**, the triangle indicates the location of the source, situated on the equator and the Greenwich meridian. Rings of receivers with a 2° spacing along the equator and the Greenwich meridian are shown by the dashes. Courtesy of Komatitsch D and Tromp J (2002) Spectral-element simulations of global seismic wave propagation. I: Validation. *Geophysical Journal International* 149: 390–412.

In an SEM, one generally uses hexahedral elements, which may be mapped back to the reference cube based upon shape functions expressed in terms of low-degree Lagrange polynomials. After meshing the model, we need to define basis functions to represent the unknown displacement vector **s** and the test vector **w** on an element. In most FEMs, both the geometry of the problem and the vector fields are expressed using shape functions defined in terms of low-degree polynomials, as in eqn [24]. In the SEM, the geometry of the curved elements is also defined using low-degree polynomials, but the displacement field and the test vector are defined using higher-degree polynomials. This is the major difference between SEMs and FEMs. In this regard, SEMs are related to *h-p* FEMs, which also use polynomials of higher degree (but result in a nondiagonal mass matrix) (e.g., Guo and Babuška, 1986).

An SEM typically uses Lagrange polynomials [23] of degree 4–10 for the interpolation of functions. In an SEM, the control points ξ_α, $\alpha = 0, \ldots, n$, needed in the definition [23] are chosen to be the $n+1$ GLL points, which are the roots of $(1-\xi^2)\, P_n'(\xi) = 0$, where P_n' denotes the derivative of the Legendre polynomial of degree n (Canuto et al., 1988). As an example, the five Lagrange polynomials of degree 4 are shown in **Figure 12(a)**, and **Figure 12(b)** illustrates the distribution of associated GLL points on the face of a hexahedral element. As we will see, the combination of Lagrange interpolants with a particular integration rule leads to an exactly diagonal mass matrix, and a diagonal mass matrix leads to a simple explicit time scheme that lends itself very well to numerical simulations on parallel computers.

We note that there are implementations of the SEM based upon Chebyshev basis functions that do not lead to a diagonal mass matrix (e.g., Patera, 1984; Priolo et al., 1994; Seriani, 1998). The main advantages are that the related Gauss–Lobatto–Chebyshev integration rule is exact for the chosen polynomial basis, while it is only approximate in the case of GLL quadrature, and that the Gauss–Lobatto–Chebyshev points and weights are known analytically (in the GLL version, they are computed numerically). The main disadvantage of the Chebyshev approach is that an iterative solver for large matrix systems needs to be implemented and implicit time-marching schemes are frequently used. This implementation is technically difficult but has been used successfully (Seriani, 1997, 1998).

In the weak form of the wave eqn [11], we expand functions f, for example, a component of the displacement field **s** or the test vector **w**, in terms of degree-n Lagrange polynomials:

$$f(\mathbf{x}(\xi, \eta, \zeta)) = \sum_{\alpha=0}^{n} \sum_{\beta=0}^{n} \sum_{\gamma=0}^{n} f^{\alpha\beta\gamma} \ell_\alpha(\xi) \ell_\beta(\eta) \ell_\gamma(\zeta) \qquad [27]$$

where $f^{\alpha\beta\gamma} = f(\mathbf{x}(\xi_\alpha, \eta_\beta, \zeta_\gamma))$ denotes the value of the function f at the GLL point $\mathbf{x}(\xi_\alpha, \eta_\beta, \zeta_\gamma)$. Using the polynomial representation [27], the gradient of a function can be expressed as

$$\nabla f(\mathbf{x}(\xi, \eta, \zeta)) = \sum_{i=1}^{3} \hat{\mathbf{x}}_i \sum_{\alpha=0}^{n} \sum_{\beta=0}^{n} \sum_{\gamma=0}^{n} f^{\alpha\beta\gamma} \left[\ell_\alpha'(\xi) \ell_\beta(\eta) \times \ell_\gamma(\zeta) \partial_i \xi + \ell_\alpha(\xi) \ell_\beta'(\eta) \ell_\gamma(\zeta) \partial_i \eta + \ell_\alpha(\xi) \ell_\beta(\eta) \ell_\gamma'(\zeta) \partial_i \zeta \right] \qquad [28]$$

where a prime denotes the derivative of a Lagrange polynomials. As in the FEM, the matrix $\partial\boldsymbol{\xi}/\partial\mathbf{x}$ is obtained by inverting the matrix $\partial\mathbf{x}/\partial\boldsymbol{\xi}$. Because one typically uses polynomials of degree 4–10, the derivatives calculated based upon [28] tend to be more accurate than those used in an FEM or FDM.

The next step is to evaluate the integrals in the weak form [11] at the elemental level. In the context of classical FEMs, we saw in the previous section that one frequently uses Gauss quadrature [26] for this purpose. In an SEM, a GLL integration rule is used instead, because, as we will see, it leads to a diagonal mass matrix when used in conjunction with GLL interpolation points. Under this approach, integrations over elements Ω may be approximated as

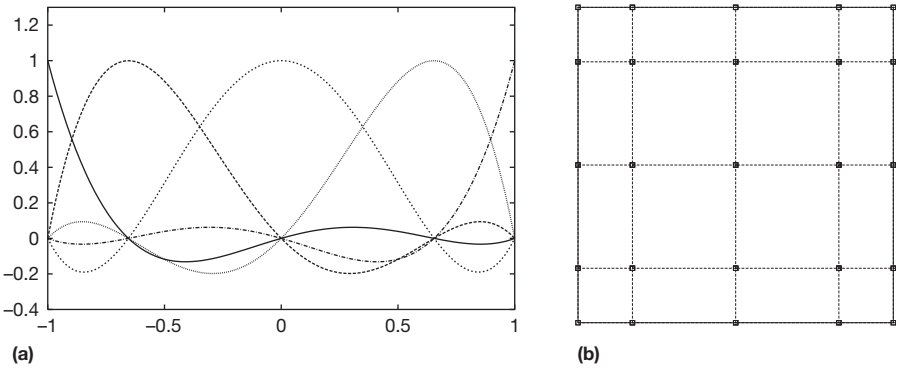

Figure 12 (a) The five Lagrange interpolants of degree $N=4$ on the reference segment $[-1, 1]$. The $N+1=5$ GLL points can be distinguished along the horizontal axis. All Lagrange polynomials are, by definition, equal to 1 or 0 at each of these points. Note that the first and last points are exactly -1 and 1. (b) When Lagrange polynomials of degree n are used to discretize the wavefield, each 3D spectral element contains a grid of $(n+1)^3$ GLL points, and each 2D face of an element contains a grid of $(n+1)^2$ GLL points, as illustrated here for the degree 4 polynomials shown on the left. Courtesy of Komatitsch D, Tsuboi S, and Tromp J (2005) The spectral-element method in seismology. In: Levander A and Nolet G (eds.) *The Seismic Earth: Array Analysis of Broadband Seismograms*, pp. 205–227. Washington, DC: AGU.

$$\int_\Omega f(\mathbf{x})\mathrm{d}^3\mathbf{x} = \int_{-1}^{1}\int_{-1}^{1}\int_{-1}^{1} f(\mathbf{x}(\xi,\eta,\zeta))\mathcal{J}(\xi,\eta,\zeta)\mathrm{d}\xi\mathrm{d}\eta\mathrm{d}\zeta = \sum_{\alpha=0}^{n}\sum_{\beta=0}^{n}\sum_{\gamma=0}^{n}\omega_\alpha\omega_\beta\omega_\gamma f^{\alpha\beta\gamma}\mathcal{J}^{\alpha\beta\gamma} \quad [29]$$

where ω_α, $\alpha=0,\ldots,n$, denote the $n+1$ weights associated with the GLL points of integration and $\mathcal{J}^{\alpha\beta\gamma}=\mathcal{J}\left(\xi_\alpha,\eta_\beta,\zeta_\gamma\right)$ denotes the value of the Jacobian $\mathcal{J}$ of the mapping at a GLL point. To facilitate the integration of functions and their partial derivatives over the elements, the values of the inverse Jacobian matrix $\partial\boldsymbol{\xi}/\partial\mathbf{x}$ need to be stored at the $(n+1)^3$ GLL integration points for each element.

We illustrate the reasons for using GLL quadrature by explicitly calculating the SEM mass matrix, that is, the integral on the left-hand side of eqn [11]. First, we expand the displacement field $\mathbf{s}$ and the test vector $\mathbf{w}$ in terms of Lagrange polynomials:

$$\mathbf{s}(\mathbf{x}(\xi,\eta,\zeta),t) = \sum_{i=1}^{3}\hat{\mathbf{x}}_i\sum_{\sigma=0}^{n}\sum_{\tau=0}^{n}\sum_{\nu=0}^{n}s_i^{\sigma\tau\nu}(t)\ell_\sigma(\xi)\ell_\tau(\eta)\ell_\nu(\zeta) \quad [30]$$

$$\mathbf{w}(\mathbf{x}(\xi,\eta,\zeta)) = \sum_{i=1}^{3}\hat{\mathbf{x}}_i\sum_{\sigma=0}^{n}\sum_{\tau=0}^{n}\sum_{\nu=0}^{n}w_i^{\alpha\beta\gamma}\ell_\alpha(\xi)\ell_\beta(\eta)\ell_\gamma(\zeta) \quad [31]$$

Because we use the same basis functions to express the displacement and test vectors, the SEM is another example of a Galerkin method. Next, we substitute the interpolations [30] and [31] in the mass matrix at the elemental level, using GLL quadrature [29], to obtain

$$\int_\Omega \rho\mathbf{w}\cdot\partial_t^2\mathbf{s}\mathrm{d}^3\mathbf{x} = \int_{-1}^{1}\int_{-1}^{1}\int_{-1}^{1}\rho(\mathbf{x}(\boldsymbol{\xi}))\mathbf{w}(\mathbf{x}(\boldsymbol{\xi}))\cdot\partial_t^2\mathbf{s}(\mathbf{x}(\boldsymbol{\xi}),t)\times\mathcal{J}(\boldsymbol{\xi})\mathrm{d}^3\boldsymbol{\xi} = \sum_{\alpha=0}^{n}\sum_{\beta=0}^{n}\sum_{\gamma=0}^{n}\omega_\alpha\omega_\beta\omega_\gamma\mathcal{J}^{\alpha\beta\gamma}\rho^{\alpha\beta\gamma}\times\sum_{i=1}^{3}\omega_i^{\alpha\beta\gamma}\ddot{s}_i^{\alpha\beta\gamma} \quad [32]$$

where $\rho^{\alpha\beta\gamma}=\rho(\mathbf{x}(\xi_\alpha,\eta_\beta,\zeta_\gamma))$, and where a dot denotes differentiation with respect to time. By independently setting factors of $\omega_1^{\alpha\beta\gamma}$, $\omega_2^{\alpha\beta\gamma}$, and $\omega_3^{\alpha\beta\gamma}$ equal to zero, since the weak formulation [11] must hold for any test vector $\mathbf{w}$, we obtain independent equations for each component of acceleration $\ddot{s}_i^{\alpha\beta\gamma}(t)$ at grid point $(\xi_\alpha,\eta_\beta,\zeta_\gamma)$. One can see that the value of acceleration at each point of a given element $\ddot{s}_i^{\alpha\beta\gamma}(t)$ is simply multiplied by the factor $\omega_\alpha\omega_\beta\omega_\gamma\rho^{\alpha\beta\gamma}\mathcal{J}^{\alpha\beta\gamma}$, which means that the elemental mass matrix is exactly diagonal. This is one of the key ideas behind the SEM, and the main motivation behind the choice of Lagrange interpolation at the GLL points used in conjunction with GLL numerical integration.

In summary, the main differences between FEM and SEM are the polynomial degree of the basis functions, the choice of integration rule, and, as a consequence, the nature of the time-marching scheme. In an FEM, one tends to use low-degree basis functions and Gauss quadrature. In an SEM, one uses higher-degree basis functions and GLL quadrature to obtain better resolution as well as a diagonal mass matrix. For the SEM, this leads to simple explicit time schemes, as opposed to the numerically more expensive implicit time schemes used in FEMs. It is important to note that even under ideal circumstances, the GLL rule is exact only for integrands that are polynomials of degree $2n-1$. Since integrations in the SEM involve the product of two polynomials of degree n – the displacement and the test function – the integration of the resulting polynomial of degree $2n$ is never exact. As in an FEM, for deformed elements, there are additional errors related to curvature (Maday and Rønquist, 1990); the same is true for elements with heterogeneous material properties. Thus, in an SEM, a diagonal mass matrix is obtained by a process of subintegration. In this respect, the SEM is related to FEMs in which mass lumping is used to avoid the costly resolution of the nondiagonal system resulting from the use of Gauss quadrature (Cohen et al., 1993). Evaluating the stiffness matrix and the source term in eqn [11] is a bit more complicated (e.g., Komatitsch and Tromp, 1999; Komatitsch and Vilotte, 1998), because this involves taking first-order spatial derivatives of the displacement field and the test vector. These derivatives may be expressed in terms of Lagrange polynomials and their derivatives.

The SEM uses domain decomposition between the fluid and the solid regions of the Earth model. In the inner core, mantle, and crust, one solves the anelastic wave equation, and in the liquid outer core, one solves the acoustic wave equation. At the fluid–solid boundaries, that is, at the ICB and CMB, the

continuity in traction and the normal component of displacement may be imposed exactly (Chaljub and Valette, 2004; Komatitsch and Tromp, 2002b; Komatitsch et al., 2005), which leads to a very accurate representation of waves that interact with the fluid–solid boundary, in particular diffracted phases.

FEM and SEM meshes, for example, the mesh shown in Figure 11, are generally too large to fit in memory on a single computer. Modern parallel computers, such as clusters or grids of computers, have a distributed memory architecture. A standard, portable approach for programming parallel machines with distributed memory is to use a message-passing methodology, usually based upon the Message Passing Interface (MPI) library (e.g., Gropp et al., 1994). On such parallel machines, we need to split the mesh into as many slices as the available number of processors. Figure 13 illustrates how an SEM mesh may be split into 1944 slices for a parallel calculation on 1944 processors.

Time marching in an SEM is frequently accomplished based upon an explicit second-order Newmark scheme (e.g., Komatitsch, 1997). Therefore, the main numerical cost associated with the SEM is in small local matrix–vector products within each spectral element and not in the time scheme. This implies that the processors spend most of their time doing actual calculations, and only a small amount of time on communications.

The SEM has been extensively benchmarked against normal-mode synthetics for spherically symmetrical Earth model PREM (e.g., Komatitsch and Tromp, 2002a,b). Figure 14 shows an example of such a benchmark for the 9 June 1994 Bolivia earthquake recorded at station PAS in Pasadena, CA. The match between the SEM and mode synthetics on all three components is perfect. An even more difficult benchmark between modes and the SEM for PKP arrivals at near-antipodal distances is shown in Figure 15. Notice how one can see a weak P_{diff} arrival prior to the arrival of PKIKP in both the SEM and the normal-mode synthetics. This benchmark favorably tests the domain decomposition between the fluid and the solid regions, as well as the quality of the mesh, in particular near the CMB and in the inner core.

A snapshot of a global SEM simulation for the 3 November 2002, Denali Fault, AK, earthquake is shown in Figure 16 (Chen et al., 2005; Tsuboi et al., 2003). Because the rupture propagates in a southeasterly direction along the Denali Fault, the waves that propagate along the west coast of the United States have large amplitudes. This directivity effect due to the finite size of the earthquake fault is clearly visible in the SEM simulations. Figure 17 shows waveform comparisons between SEM synthetics and data recorded by the Global Seismographic Network. Note that the SEM synthetic seismograms for mantle model S20RTS (Ritsema et al., 1999), accurate at periods of 5 s and longer, capture the dispersion of the Rayleigh waves reasonably well.

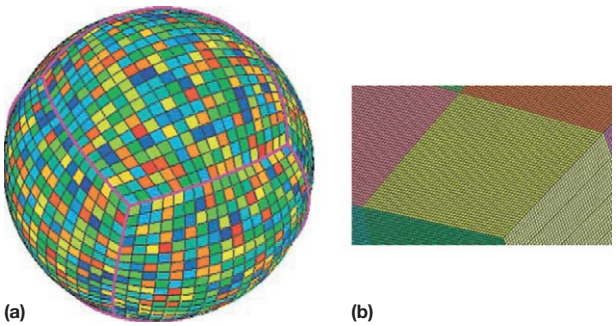

Figure 13 The SEM uses a mesh of hexahedral finite elements on which the wavefield is interpolated by high-degree Lagrange polynomials on GLL integration points. In order to perform the calculations on a parallel computer with distributed memory, the mesh is split into slices based upon a regular domain decomposition topology. Each slice is handled by a separate processor. Adjacent slices located on different processors exchange information about common faces and edges based upon a message-passing methodology. (a) A global view of the mesh at the surface, illustrating that each of the six sides of the cubed sphere mesh is divided into 18×18 slices, shown here with different colors, for a total of 1944 slices. The elements within each slice reside in memory on a single processor of the parallel machine. (b) A close-up of the mesh of 48×48 spectral elements at the surface of each slice. Within each surface spectral element, we use $5 \times 5 = 25$ GLL grid points, which translates into an average grid spacing of 2.9 km (i.e., 0.026°) on the surface of the Earth. 1.07.6 Discussion and Conclusions

We have provided an overview of the various numerical methods used in global seismology. Of these methods, currently only CMM, DSM, and the SEM are capable of simulating 3D seismic wave propagation throughout the entire globe. CMMs are quite useful for calculating the very long-period (>500 s) response of a laterally heterogeneous, rotating, self-gravitating Earth model, and DSMs accomplish the same at somewhat shorter periods. The main difficulties with both CMM and DSM have to do with a linearized treatment of boundary perturbations and, more severely, practical limitations associated with large matrix–vector operations that do not lend themselves well to calculations on parallel computers.

The only method capable of generating fully 3D synthetic seismograms at the scale of the entire globe at short periods is the SEM. On a modest PC cluster, one can now calculate global synthetics at periods of 20 s and longer that account for heterogeneity in the crust and mantle, topography, anisotropy, attenuation, fluid–solid interactions, self-gravitation, rotation, and the oceans. At the present time, on 150 processors, a 1 h long seismogram may be calculated in about 5 h. On the Earth Simulator at the Japan Agency for Marine-Earth Science and Technology, one can reach a shortest period of 3.5 s. Such a calculation involves more than 4000 processors and requires about 18 h of compute time. Interestingly, broadband normal-mode synthetics for spherically symmetrical (1D) Earth models are typically restricted to periods of 6 s and longer, so seismologists can now calculate 3D synthetics accurate at periods shorter than 1D mode synthetics.

In the context of inverse problems, the challenge now lies in harnessing these newfound forward capabilities to enhance the quality of models of Earth's interior, in conjunction with improving models of the rupture process during an

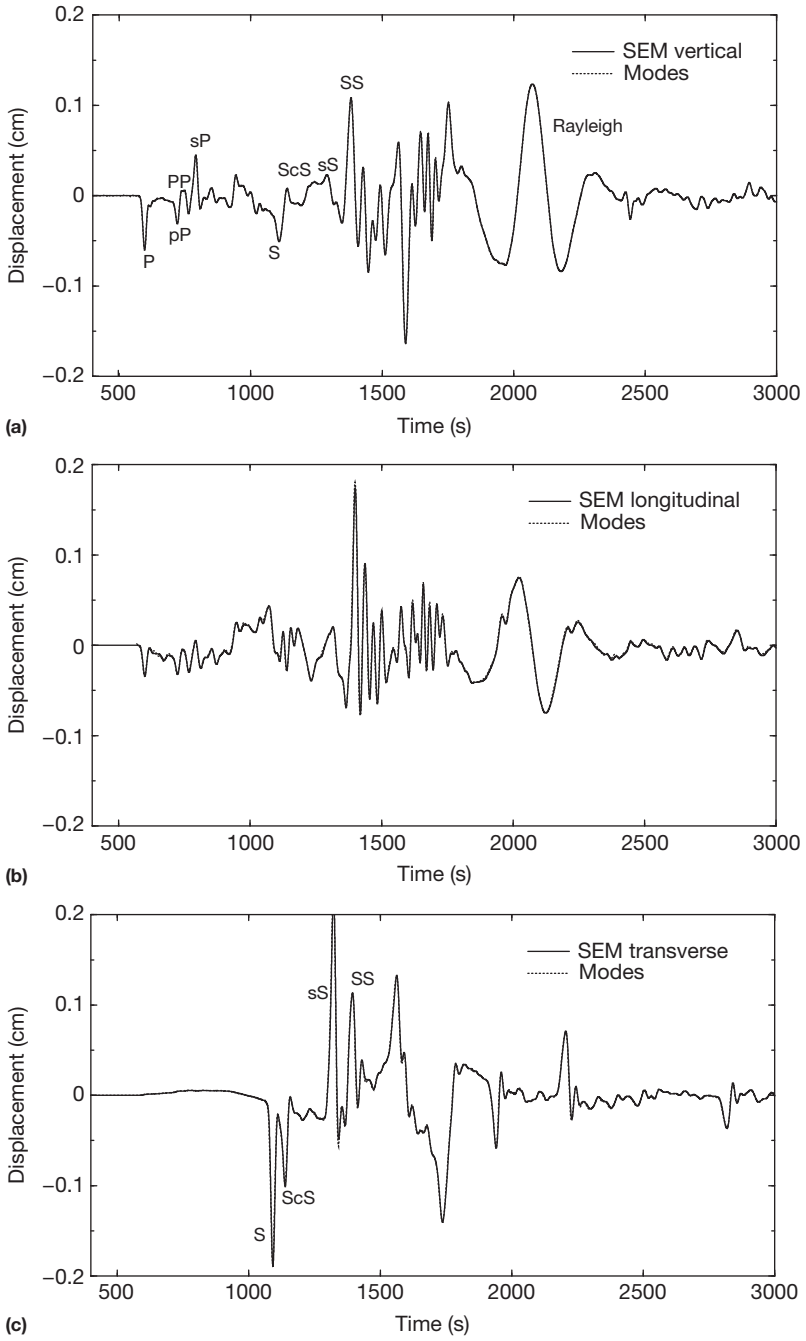

Figure 14 SEM (solid line) and mode (dotted line) synthetic seismograms in PREM for the great magnitude 8.2 Bolivia earthquake of 9 June 1994, recorded at SCSN station PAS in Pasadena, CA. The depth of the event is 647 km. Anisotropy and attenuation are both included in this simulation. (a) Vertical component, (b) longitudinal component, (c) transverse component. The synthetics are accurate at periods of 18 s and longer. Courtesy of Komatitsch D and Tromp J (2002) Spectral-element simulations of global seismic wave propagation. earthquake. On the face of it, this seems like a Herculean task because hundreds or even thousands of model parameters are involved in such inversions. In principle, the sensitivity of a seismogram with respect to the model parameters may be calculated numerically, but this would require a number of forward calculations equal to the number of model parameters (typically thousands). Tarantola (1984) demonstrated that one iteration in tomographic and source inversions may be performed based upon just two calculations for each earthquake: one calculation for the current model and a second 'adjoint' calculation that uses time-reversed signals at the receivers as simultaneous, fictitious sources. This approach has been used in global seismology based upon the DSM (e.g., Geller and Hara, 1993; Hara, 2004; Hara and Geller, 2000). Adjoint

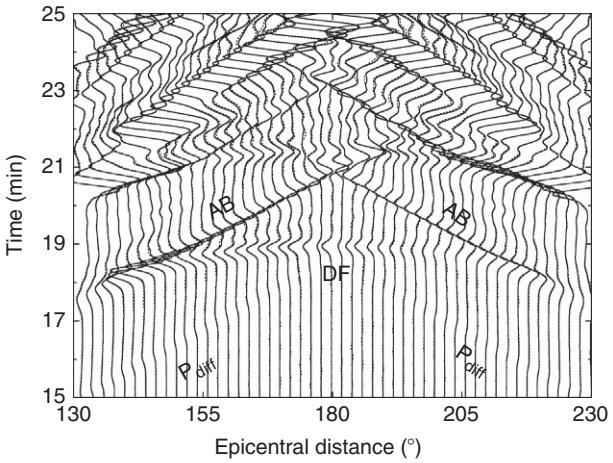

Figure 15 Record section comparison of PKP phases calculated for anelastic, anisotropic PREM based upon the SEM (solid lines) and modes (dotted lines) between 130° and 230° along the Greenwich meridian (see **Figure 11** for the source–receiver geometry). At each epicentral distance, we plot both the SEM and the mode solution. All PKP arrivals, including PKIKP, which has traveled through the central cube in the mesh, are well reproduced. Note also a very weak P_{diff} arrival in both synthetics between 130° and 170° and between 190° and 230°. The correct representation of this diffracted signal in the SEM illustrates the accuracy of the domain decomposition between the fluid outer core and the solid mantle and the effective implementation of the related fluid–solid boundary conditions. The synthetics are accurate at periods of 18 s and longer. Courtesy of Komatitsch D and Tromp J (2002) Spectral-element simulations of global seismic wave propagation. Figure 17 Comparison of transverse component data (black line) and spectral element synthetic seismograms (red line) for the 3 November 2002, Denali Fault, AK, earthquake. Both the synthetic seismograms and the data are low-pass-filtered at 5 s. The source azimuth measured clockwise from due north is indicated on the left of each trace, and the station name and epicentral distance are on the right. Records are aligned on the S wave. The 3D model includes mantle model S20RTS (Ritsema et al., 1999) and crustal model crust 2.0 (Bassin et al., 2000). Courtesy of Tsuboi S, Komatitsch D, Chen J, and Tromp J (2003) Spectral-element simulations of the November 3, 2002, Denali, Alaska earthquake on the Earth Simulator. *Physics of the Earth and Planetary Interiors* 139: 305–312.

methods (e.g., Talagrand and Courtier, 1987) have opened the door to solving the full 3D inverse problem, that is, the problem of using the remaining differences between the data and the synthetics to improve source and Earth models (e.g., Akçelik et al., 2002, 2003; Tromp et al., 2005). Recently, Capdeville et al. (2005) had proposed a spectral element approach to the inverse problem based upon a source-stacking technique that may further reduce the numerical burden.

Acknowledgments

The author would like to thank Heiner Igel, Dimitri Komatitsch, Nozomu Takeuchi, Christine Thomas, Seiji Tsuboi, and Yanbin Wang for contributing figures to this chapter. The SEM synthetics were calculated by Seiji Tsuboi on the Earth Simulator computer at the Japan Agency for Marine-Earth Science and Technology. Broadband data were obtained from the IRIS Data Management Center. This material is based in part upon work supported by

the National Science Foundation under grant EAR-0309576. This is contribution No. 9124 of the Division of Geological and Planetary Sciences, California Institute of Technology.

1.08.1 Introduction

The analysis of scattered, teleseismic body waves to characterize the receiver-side lithosphere and upper mantle spans over 4 decades, and it is now among the most widely used means of resolving fine-scale structure in these outer layers of the Earth. The first studies to harness converted teleseismic waves for investigation of deep Earth structure were undertaken in the former Soviet Bloc (Rainer Kind, pers. comm; see, e.g., Hoffmann et al., 1989). Most early studies involved single-station analyses, and the work of Phinney (1964) represents an important milestone. He recognized that one could remove the effect of the earthquake source by examining spectral ratios of radial and vertical component *P*-seismograms measured at a surface receiver and thereby gain insight into the bulk properties of the Earth's crust. His work was formulated in the frequency domain (see also Kurita, 1973) and constitutes the first application of the so-called receiver function technique. Soon thereafter, Båth and Stefánson (1966) examined recordings of teleseismic *S* and identified *S*-to-*P* precursors scattered from the crust–mantle boundary as a viable means once again of characterizing crustal structure. A full decade was to elapse before the next major development. Working independently on transition zone and crustal structure, respectively, Vinnik (1977) and Langston (1979) introduced the time-domain, *P* receiver function to characterize receiver-side *P*-to-*S* conversions present within the coda of teleseismic *P*. The time-domain receiver function, which contains information on phase, has intuitive appeal as a leading-order approximation to the Earth's Green function at early times (i.e., up until the arrival of the next major phase *PP*). In addition, Vinnik (1977) enhanced the weak scattered signals present in the receiver function by stacking multiple receiver functions from different epicentral distance ranges along theoretical move-out curves for a radial Earth model, thereby effectively approximating a 1-D, single-scattering inversion. By the mid-1980s, an increasing number of researchers had come to recognize the potential of the approach in general applications (e.g., Kind and Vinnik, 1988; Owens et al., 1984; Zandt and Owens, 1986). This recognition combined with the growing availability of three-component, broadband seismometers and high-capacity, digital acquisition systems has led to the popularity that teleseismic receiver function analysis enjoys today in regional studies of lithospheric and upper mantle structure.

In the last decade, there has been major focus on placing the empirical 'receiver function' technique on a firmer theoretical foundation and extending its application to multichannel data sets. In both respects, much has been (and may still be) learned from the vast, accumulated experience in exploration seismology. Although geometries in the global and exploration contexts are at first glance quite different (plane-wave excitation from below versus point source excitation from above), both disciplines share an important common element, namely, the interaction of near-vertically propagating waves with near-horizontal and, often, modest-contrast stratification. The recorded wave fields are thus free of postcritical interactions that lead to dispersive, guided waves and can be inverted to extract highly resolved information on subsurface material property contrasts within a single-scattering (or 'Born approximation') framework. Nonetheless, there are important distinctions between the two disciplines. Exploration seismology has, for practical reasons (source

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00008-7

generation and recording), largely ignored elastic phenomena by focusing on pure *P*-mode scattering and modeling data with acoustic theory. Global seismology, in contrast, relies primarily on conversions to resolve subsurface structure, and pure-mode reflections have, to date, played a far lesser role. It is interesting to note that the two communities have begun to forge closer links (e.g., Marfurt et al., 2003) due in part to the growing interest in exploration for the use of local, passive seismicity to monitor changes in hydrocarbon reservoirs.

In this chapter, we will provide an overview of the theory that underlies the processing of scattered teleseismic wave fields and thereby facilitates interpretation for regional lithospheric and upper mantle structure. Section 1.08.2 begins with a description of the geometric attributes of different teleseismic phases that can be considered for use in studies of the lithosphere and upper mantle, along with their merits and shortcomings. The canonical problem of structural response/source signature separation is then addressed in the teleseismic context. This discussion centers on the relationship between the classic receiver function and the more fundamental Green function that is required in formal inverse-scattering approaches. Sections 1.08.4 and 1.08.5 examine the inverse problem for one- and multidimensional heterogeneity. The focus here is on formal inverse-scattering techniques because of the insight they afford into physics of the scattering process and because they provide a framework through which more empirical schemes can be understood. In the final section, we discuss several shortcomings arising from the single-scattering or Born approximation that has, to this point, underlain most attempts to invert scattered teleseismic body waves for receiver-side structure. We then sketch out a means through which nonlinear inverse scattering could, in principle, be applied to teleseismic wave fields, based on recent theoretical developments in exploration seismology. Before proceeding, we mention several additional review sources that the reader may wish to consult in gaining a broader appreciation for the field, namely, Pavlis (2005), which discusses outstanding issues in the inversion of teleseismic *P*-wave fields for receiver-side structure; Rondenay (2009), which provides a survey of upper mantle imaging studies using scattered waves; and Kennett (2002), a more general treatise of observational seismology at regional scales that includes a chapter on teleseismic body-wave fields.

1.08.2 Geometrical Preliminaries

In this section, we sketch out the general scattering geometry to be considered for the remainder of the chapter. We shall restrict our attention to incident-wave fields representing sources located at teleseismic distances (i.e., epicentral distance $\Delta > 30^\circ$) from one or more receivers located at the Earth's surface. The term 'incident-wave field' will be defined more precisely in later sections, but for the present, it can be considered to be the signal associated with a primary body-wave phase that has reflected/converted, if at all, only at the Earth's surface and/or core–mantle boundary, for example, *P*, *pP*, *PP*, *S*, *pS*, *PKP*, *SKS*, and *ScS* (see Figure 1). This definition serves to distinguish the incident-wave field from the scattered waves generated through reflection or mode conversion at receiver-side heterogeneity that we are ultimately interested in exploiting

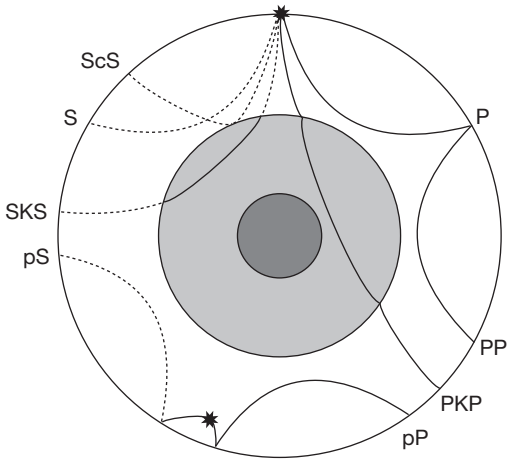

Figure 1 Ray paths of some major phases referred to in text that may serve as incident-wave fields for study of near-receiver scattering from subsurface structure (*P*-wave legs, solid; *S*-wave legs, dashed).

(Burdick and Langston, 1977). Signals originating through source-side scattering will, in contrast, be most conveniently treated as part of the source signature.

For much of what follows, we shall focus our attention on teleseismic *P* as it historically has been the most practically useful of the candidate incident-wave fields and ignore, for the moment, associated depth phases created by deep earthquakes. At lesser distances ($14^\circ < \Delta < 30^\circ$), *P* (and *S*) waves traveling through the mantle experience triplications at strong velocity gradients defining the Earth's transition zone (between $\sim$400 and 670 km depth), and consequently, the incident-wave field will comprise several superposed arrivals characterized by different horizontal slownesses that are difficult to distinguish and separate (see Figure 2 and, e.g., Kennett, 2002). In the distance range $30^\circ < \Delta < 100^\circ$, teleseismic *P* bottoms within the lower mantle, which is generally characterized by a smoothly varying and dominantly radial velocity profile. Consequently, propagation is simple and the wave field is accurately modeled by a single surface slowness that decreases monotonically from $\sim$0.08 to 0.04 s km^{-1} (or, equivalently, through ray parameters of 8.8 to 4.4 s per degreee) over this distance range. Moreover, wave front curvature is small because we are well into the far field, and it is frequently convenient in both single-station and multistation applications to approximate the incident teleseismic wave field as planar in horizontal aspect (see, e.g., Section 1.08.3.1). The small values of horizontal slowness also manifest steep angles of propagation that are, again, advantageous in that the likelihood of postcritical interactions is reduced. Complications due to depth phases can be dealt with in two ways, depending on source depth. As depth decreases, the slowness (and timing) of the depth phases approach that of the incident-wave field such that they can be considered one and the same. At greater depths, the difference in slowness may be significant, but in this case, the short duration of time functions that characterize the Wadati–Benioff sources combined with greater time separation between the incident-wave field and depth phases will usually permit the depth phases to be temporally windowed and analyzed independently. The source depth at which one

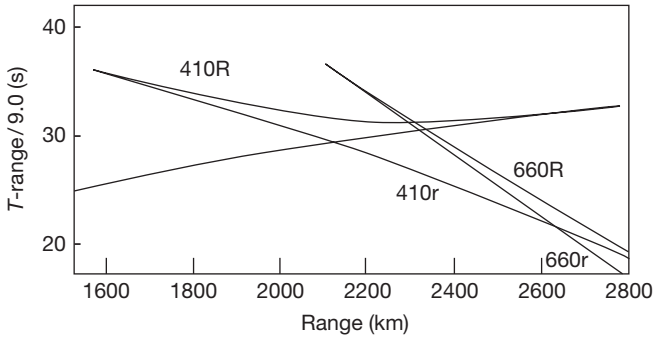

Figure 2 Travel-time curves at regional distances displaying triplications due to transition zone (410 and 660 km) discontinuities that complicate analysis of scattering from more shallow discontinuities. Individual travel-time branches are labeled by the associated discontinuity (*r*, refraction; *R* reflection).

draws the line between inclusion and separation of depth phases will depend on the application but will generally be taken to lie between 100 and 200 km.

The treatment of teleseismic *S* is somewhat more difficult than teleseismic *P* for a number of reasons. First, the distance range over which useful recordings can be procured is more limited. This is due in part to the development of postcritical *S*-to-*P* conversion from deeper (e.g., transition zone) discontinuities at larger slowness. In addition, conversion and triplication at the core–mantle boundary lead to close coincidence and interference of *S*, *SKS*, and *ScS* over the distance range 70–90°. Depending on source mechanism, all three *S* phases may possess comparable amplitudes, and their separation (and that of associated scattered fields) is difficult, especially where three-dimensional heterogeneity is expected. *SKS* extends the usable distance range well beyond 100°, but the number of high signal-to-noise ratio recordings diminishes rapidly with distance. Second, because teleseismic *S* is characterized by larger slowness than teleseismic *P* at any given epicentral distance, postcritical phenomena within the receiver-side crust occur at smaller epicentral distances (*Spdp* (Zandt and Randall, 1985) and shear-coupled *PL* (Baag and Langston, 1985; Frazer, 1977; Owens and Zandt, 1997)) that can complicate interpretation and inversion. Third, the receiver-side response to an incident *S*-wave field will generally depend on the wave field polarization as imparted by the source and modified by source-side heterogeneity/anisotropy. The incident polarization is not generally known (with the exception of *SKS* that is radially polarized due to receiver-side conversion from *P* to *S* at the core–mantle boundary), though its influence can under certain assumptions be removed (e.g., Farra and Vinnik, 2000; **Section 1.08.3.4**). Fourth, higher frequencies in teleseismic *S* (and hence its resolving power) are attenuated more severely than those in teleseismic *P* due to lower *Q* especially in the shallow upper mantle. Lastly, signal-generated noise levels are generally higher in teleseismic *S* due to the energy that has propagated some large portion of its path as *P* (Bock, 1994; Vinnik and Romanowicz, 1991; Wilson et al., 2006). Although it might be argued that free-surface multiples arriving as *S*-waves in the coda of teleseismic *P* represent a comparable form of signal-generated noise exacerbating interpretation of direct *P*-to-*S* conversions, these multiples are generated by receiver-side heterogeneity and can be exploited to leverage additional and complementary constraint on structure (see **Sections 1.08.4.3** and **1.08.5**).

Despite these complications, there has been renewed interest in recent years in teleseismic *S*-to-*P* conversions as means of characterizing the lithosphere to asthenosphere boundary (e.g., Kawakatsu et al., 2009; Kumar et al., 2005; Li et al., 2004; Oreshin et al., 2002; Rychert et al., 2007; Vinnik et al., 2005; Yuan et al., 2006). The growing waveform archive afforded by the profusion of modern digital networks has enabled stacking of large quantities of data to mitigate the low signal-to-noise ratios that characterize these phases, resulting in important new insights into this enigmatic structure (Eaton et al., 2009; Rychert et al., 2010).

The utility of most other phases is still more limited due to either interference or low signal-to-noise levels, although it is often used to augment teleseismic *P* data *PP* (e.g., Gurrola et al., 1994; Owens et al., 2000). Useful structural information has on occasion also been extracted from regional *P* (e.g., Park and Levin, 2001) and *PKP* (e.g., Park and Levin, 2000) using 'receiver function'-style approaches.

1.08.3 Source Removal

With the geometric framework just described in mind, the first task in most structural studies employing teleseismic wave fields is to characterize and remove the source. The standard model is a linear convolution of the form

$$u_{in}(\mathbf{x}, t) = S(t) \otimes G_{in}(\mathbf{x}, t; \mathbf{p}_{\perp}) \quad [1]$$

where u_{in} is the observed particle displacement/velocity in direction i at location $\mathbf{x}$ as a function of time t, $S(t)$ is an effective source time function, $\otimes$ signifies temporal convolution, and $G_{in}(\mathbf{x}, t; \mathbf{p}_{\perp})$ is a 'Green function' or, more precisely, receiver-side response to an impulsive quasi-plane-wave incident from below, which is characterized, for example, by horizontal slowness $\mathbf{p}_{\perp}$. Index n denotes the incident-wave polarization and will be omitted (or, rather, implicitly assumed) in the discussions that follow; however, it is important to acknowledge, in particular, in dealing with incident *S*-wave fields. Note that (1) is a far-field approximation that ignores finite source directivity. Early applications of receiver

functions (e.g., Langston, 1979; Phinney, 1964) implicitly approximated $S(t)$ on a teleseismic P recording by the vertical component of motion, $u_z(t)$. In the following sections, we will describe procedures whereby this approximation can be improved leading to more accurate estimates of the Green function. We begin by discussing means by which incident-wave and scattered-wave energies can be more effectively separated on different components. We will then proceed to review the minimum-phase nature of teleseismic wave fields that will allow us to simplify characterization and removal of the source. Our focus throughout this analysis will be on teleseismic P, but reference to teleseismic S will be made toward the end of the section.

1.08.3.1 Modal Decomposition

The combination of transmission geometry, precritical incidence, and modest material property gradients within the crust and upper mantle generally results in the incident-wave arrival (i.e., teleseismic P) being the most energetic feature on a seismogram windowed to exclude other principal phases, usually by at least an order of magnitude. Figure 3 demonstrates this property with synthetic seismograms for P-wave field incident upon an idealized, layer-over-a-half-space crustal model. Because the incident-wave field comprises a single-mode type that is either P or S, it is useful to decompose the observed wave field into separate modes in order to aid in source deconvolution and characterization of the scattered-wave field. In early studies, 'modal decomposition' was crudely accomplished through the identification of the vertical/radial components of displacement with dominantly P/S energy, respectively. A better isolation of energy into modes can be achieved in one of a number of ways. In principle, one could isolate P- and S-waves exactly in laterally heterogeneous, isotropic media by identifying the respective modes as the curl-free and divergence-free components of displacement. The density of recording instrumentation is rarely, if ever, sufficient, however, to accurately estimate the necessary spatial derivatives. As a practical alternative and as justified in Section 1.08.2, we may assume that the incident-wave field is dominated by a single horizontal slowness p. By further assuming that near-surface P- and S-velocities α, β are known, an approximate, 1-D, upgoing wave field separation can be used to isolate P- and S-modes (Bostock, 1998; Kennett, 1991; Reading et al., 2003), specifically,

$$\begin{pmatrix} P \\ V \\ H \end{pmatrix} = \begin{pmatrix} \frac{p\beta^2}{\alpha} & 0 & \frac{\beta^2 p^2 - 1/2}{\alpha q_\alpha} \\ \frac{1/2 - \beta^2 p^2}{\beta^2 q_\beta} & 0 & p\beta \\ 0 & 1/2 & 0 \end{pmatrix} \begin{pmatrix} u_r \\ u_t \\ u_z \end{pmatrix} \qquad [2]$$

where P, V, and H are estimates of the upgoing P-, SV-, and SH-component seismograms; u_r, u_t, and u_z are the radial, transverse, and vertical displacement seismograms; and q_α, q_β, and p are the vertical P, vertical S, and horizontal components of slowness at the surface, respectively. The modal field $[P,V,H]^{\mathrm{T}}$, deconvolved of source and transformed back to upgoing (Cartesian) displacement $[\hat{u}_r, \hat{u}_t, \hat{u}_z]^{\mathrm{T}}$ as

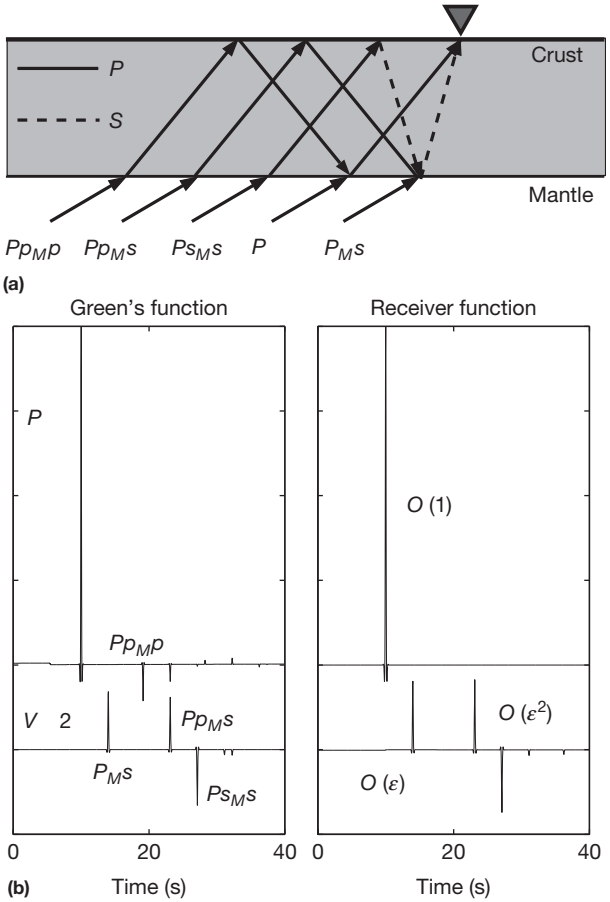

Figure 3 Synthetic seismograms for a layer-over-a-half-space, crustal model. (a) Ray paths of largest amplitude phases (P_MS, Pp_MP, Pp_MS, and Ps_MS) scattered crustal phases from the crust–mantle boundary resulting from an incident P-wave field (P-wave legs, solid; S-wave legs, dashed). See Figure 4 for examples of these phases on observed seismograms. (b) Left panel shows the Green function P and (SV) seismograms with phases labeled, and right panel comprises the corresponding time series in the receiver function approximation. Note that the direct P arrival dominates the Green function and that the receiver function is a leading-order approximation to the Green function correct to $O(1)$ on the P-component and to $O(\varepsilon)$ on the SV-component where $\varepsilon \ll 1$ measures the amplitude of the first-order scattered field relative to the incident wave.

$$\begin{pmatrix} \hat{u}_r \\ \hat{u}_t \\ \hat{u}_z \end{pmatrix} = \begin{pmatrix} \alpha p & \beta q_\beta & 0 \\ 0 & 0 & 1 \\ \alpha q_\alpha & -\beta p & 0 \end{pmatrix} \begin{pmatrix} P \\ V \\ H \end{pmatrix} \qquad [3]$$

(vs. the original displacement field $[u_r, u_t, u_z]^{\mathrm{T}}$ that contains both upgoing and downgoing waves), is generally the quantity that will be required in the inverse-scattering analysis of subsequent sections. Note that the near-surface velocities α, β can be determined from the data (assuming known slowness) from measurements of first-motion amplitudes on seismograms representing individual, incident P- and S-waves (Bostock and Rondenay, 1999; Helmberger, 1968) or, equivalently, from the zero-lag amplitudes of radial/vertical receiver functions (Ammon, 1991).

This approach can be generalized to the treatment of ocean-bottom recordings where the reverberatory effect of the ocean column is to be mitigated. Isolation of the upgoing wave field at the top of the solid medium (i.e., oceanic crust) is once more desirable since the ocean column reverberations are downgoing at this location. Several formulations are possible within a 1-D context. If pressure gauge recordings are available in addition to ocean-bottom displacement, then the decomposition can be accomplished along with the knowledge of material properties at the ocean bottom (e.g., Amundsen and Reitan, 1995; Thorwart and Dahm, 2005). Alternatively, if water depth is known together with ocean-bottom displacement and material properties, then recovery of the upgoing wave field is also possible (Bostock and Tréhu, 2012).

An alternative approach to modal decomposition for land observations involves rotation of the particle displacement field to a coordinate system where maximum energy is transferred to a single component. The angle of rotation can be determined by diagonalizing the displacement covariance matrix C (Vinnik, 1977) defined as

$$\mathbf{C} = \begin{pmatrix} \int_{t_1}^{t_2} \mathrm{d}t\, u_r^2(t) & \int_{t_1}^{t_2} \mathrm{d}t\, u_r(t) u_z(t) \\ \int_{t_1}^{t_2} \mathrm{d}t\, u_r(t) u_z(t) & \int_{t_1}^{t_2} \mathrm{d}t\, u_z^2(t) \end{pmatrix} \qquad [4]$$

where $[t_1, t_2]$ is a time window that encompasses the energy associated with the primary phase. The latter approach fails to acknowledge the presence of the free surface (and, more specifically, the generation of downgoing waves therefrom) but may be used where the incident slowness is unknown or the wave field is distorted by strong, laterally heterogeneous structure. A more detailed comparison of the two approaches is made by Svenningsen and Jacobsen (2004).

1.08.3.2 Receiver Functions and the Property of Minimum Phase

Once modal decomposition has been accomplished, we shall (either implicitly or explicitly) draw upon an important property of teleseismic body-wave fields to remove the effects of the source, namely, that the underlying Green function component in the incident mode (i.e., the *P*-component of teleseismic *P*) is minimum phase. To provide intuitive justification for the minimum-phase assertion, we consider the seismograms in Figure 3(b) and note that the incident *P*-wave at $t=0$ clearly dominates other arrivals in amplitude. In particular, let us normalize the amplitude of this arrival to unity, such that the amplitudes of the first-order scattered phases (i.e., those phases that have reflected/converted once from heterogeneity, not including the free surface) are of order ε. Because material property contrasts are small and scattering interactions occur at near-normal incidence, we have in general that $\varepsilon \ll 1$. Multiply scattered-wave fields (i.e., two or more reflection/conversion interactions with subsurface heterogeneity) attenuate as ε^n where n is the order of scattering and can be safely neglected in most applications. Accordingly, we may characterize the modal component of the Green function in the incident mode as, for example, $G^P(t) \sim \delta(t) + s(t)$, where $\delta(t)$ is the delta-function direct arrival and $s(t)$ represents the scattered field and is $O(\varepsilon)$ in amplitude. Following Claerbout (1976), we shall examine the properties of the $G^P(t)$ in the frequency domain, that is, $G^P(\omega)$. As shown in Figure 4, the delta-function makes a purely real contribution to the spectrum that is constant, say, 1, for all frequencies. Moreover, if the amplitude spectrum of $s(t)$, that is, $s(\omega)$, is <1 for all frequencies, we note that it is impossible for the phase of $G^P(\omega) = 1 + s(\omega)$ to wrap around the origin. This scenario thus constitutes a sufficient condition for $G^P(t)$ to be minimum phase. If a signal is minimum phase, it is by definition that signal, among all signals sharing the same amplitude spectrum, which possesses maximum possible energy concentrated near its onset (Robinson and Treitel, 1980). Bostock (2004) provided a more detailed justification and examination of the conditions under which the minimum-phase assumption is likely to apply to teleseismic wave fields (see also, Li and Nabelek, 1999; Sherwood and Trorey, 1965). We note at this juncture that an effective modal decomposition, as outlined in the previous section, is important in this regard as it improves the likelihood that the estimated *P*-component impulse response is minimum phase by ensuring that the delta-function $\delta(t)$ in the definition of $G^P(t)$ is of maximum possible amplitude relative to the scattered waves $s(t)$.

The minimum-phase property is important in at least two respects. First, it implies that energy is strongly concentrated at early times within the time series. In particular, the *P*-component, teleseismic *P* Green function is to leading

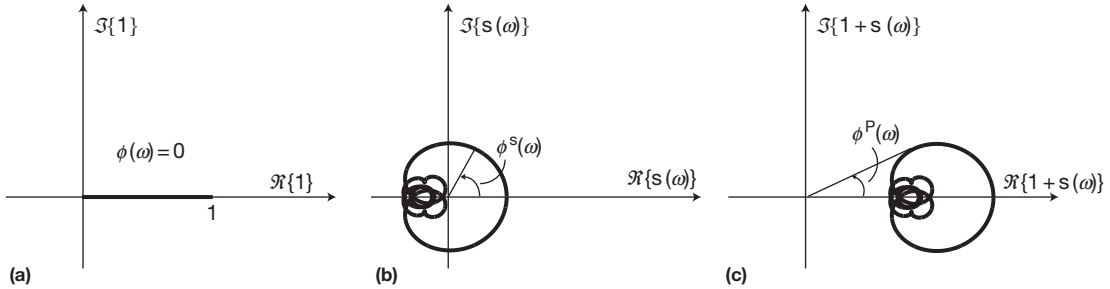

Figure 4 Frequency-domain description of $G^P(t) = \delta(t) + s(t)$. (a) Direct wave. The direct wave is represented by a delta-function at time 0 and is thus pure real, constant (amplitude 1) with phase $\phi(\omega) = 0$ for all frequencies ω. (b) Scattered waves. The scattered-wave spectrum $s(\omega)$ is characterized by an amplitude spectrum $|s(\omega)| < 1$ and a more general phase spectrum $\phi^s(\omega)$. (c) $G^P(\omega)$. The total spectrum is characterized by a real component that is positive for all ω, thereby ensuring that $G_P(t)$ is minimum phase. Reproduced from Claerbout JF (1976) *Fundamentals of Geophysical Data Processing*. New York, NY: McGraw-Hill.

order $O(1)$ a delta-function. Consequently, an observed P-component seismogram can be taken to be an estimate of the earthquake source time function that is accurate to leading order. Moreover, deconvolution of the corresponding S-component with the P-component will result in an estimate of the S-component Green function that is correct to leading order, that is, $O(\varepsilon)$, since the S-component of teleseismic P comprises only scattered (converted) waves. The foregoing argument provides justification for the validity of the classic receiver function as a leading-order estimate of the S-component of the teleseismic P Green function. Indeed, interpretation of the receiver function as a series of discrete, scattered arrivals from subsurface discontinuities relies intrinsically on this observation. In situations where the minimum-phase assumption is questionable, for example, at regional distances where several incident arrivals with comparable magnitudes and different slownesses originate from triplication at transition zone discontinuities (cf. Park and Levin, 2001), interpretation must proceed with caution. In such cases, the receiver function (i.e., spectral ratio of different modal components) can no longer be considered as good an approximation to the Green function, although it may still possess utility as a source-independent transfer function.

A second point of importance is that the minimum-phase property affords insight into how more accurate estimates of the Earth's true Green function can be recovered. Improved knowledge of the P-component Green function is particularly desirable because this component is a simple delta-function (i.e., the direct wave) within the receiver function approximation. That is, it contains no information on pure P (i.e., P-to-P) scattering whatsoever. The P-to-P scattering mode is important because its amplitude provides constraints on short-wavelength variations in subsurface compressional moduli (e.g., P-impedance, P-velocity, and bulk modulus). Amplitudes of conversions and pure S reflections, in contrast, have first-order sensitivity only to shear properties (e.g., S-impedance and S-velocity) (see, e.g., Aki and Richards, 2002). Numerous authors (e.g., Bostock and Rondenay, 1999; Bostock and Sacchi, 1997; Clayton and Wiggins, 1976; Langston and Hammer, 2001; Li and Nabelek, 1999; Paulssen et al, 1993; Revenaugh, 1995; Zhu and Kanamori, 2000) have exploited the minimum-phase property within a multichannel context to procure better estimates of the teleseismic P Green function. In these studies, P-component time series from a number of stations recording the same earthquake are time-normalized and averaged in some fashion to approximate the source. Weaker ($O(\varepsilon)$ in amplitude) scattered-wave contributions at different stations are assumed to be incoherent in time and thus sum destructively, whereas the incident wave, $O(1)$ in amplitude and fixed at time 0 on all traces, adds constructively to produce a scaled estimate of the true source time function. The teleseismic P Green function is then recovered by deconvolving this source estimate from both P- and S-component seismograms recorded at all stations. The main drawback to this approach is that the signal from structure that exhibits little or no lateral variation (e.g., the continental Moho in many instances) is identified with the source and, consequently, is not represented in the deconvolved Green function estimates. We shall describe an alternative to this approach in the succeeding text that also relies on the minimum-phase property but does not suffer from this last shortcoming.

1.08.3.3 Improved Teleseismic *P* Green Functions

The minimum-phase property implies that knowledge of the P-component amplitude spectrum alone is sufficient to define the time-domain function, since its phase, ϕ^P, is simply related to amplitude A^P through

$$\phi^P(\omega) = \mathcal{H}\{\log(A^P)\} \qquad [5]$$

where $\mathcal{H}\{\ \}$ denotes Hilbert transform (e.g., Claerbout, 1976). In fact, the phase of all three components of motion (or, more specifically, upgoing P, SV, and SH), as well as the source, need not be considered until their respective amplitude spectra have been recovered. As explained by Baig et al. (2005) and Mercier et al. (2006), estimation of, for example, the source amplitude spectrum can be accomplished by considering the cross spectrum of two seismograms sharing that source. As an example, consider two components P and SV of the same three-component recording represented in the frequency domain as $P(\omega)$, $V(\omega)$. Their cross spectrum can be written as

$$P(\omega)V^*(\omega) = |S(\omega)|^2 |G^P(\omega)||G^V(\omega)|e^{i(\phi^P - \phi^V)} \qquad [6]$$

where $|G^P(\omega)|$, $|G^V(\omega)|$, and $|S(\omega)|$ are amplitude spectra of the Green function components and the source, respectively, and * denotes complex conjugate. Note that the source enters the cross spectrum as a common convolutional element and that, accordingly, it does not contribute to the cross spectrum phase, $\phi^P - \phi^V$. We can say, therefore, that the source makes a zero-phase contribution to the cross spectrum $P(\omega)V^*(\omega)$. There are several algorithms that can, in principle, be utilized to isolate the zero-phase component of a signal (Hayes et al., 1980) and thus to form an estimate of $|S(\omega)|$ under the assumption that the cross spectrum of the two Green function components, that is, $G^P(\omega)GV^*(\omega)$, contains no zero-phase component. Moreover, by appealing to causality and a propagation model that includes a dominantly 1-D lower mantle, the duration of the two components $P(t)$ and $V(t)$ in the time domain will determine the maximum depth to which scattered energy is mapped to the Green function cross spectrum. All scattered signals generated in advance of this depth will either arrive outside the recording interval (in the case of conversions) or be mapped to $|S(\omega)|$ (in the case of same mode interactions). The latter result is a beneficial consequence for studies of receiver-side structure.

The procedures for zero-phase signal extraction tend, unfortunately, to be highly sensitive to noise, and Baig et al. (2005) discussed modifications based on spectral smoothing that tend to improve recovery on synthetic examples. Nonetheless, it is advantageous, when possible, to further improve upon estimates by making use of multichannel measurements. Even a single, three-component seismogram will afford three independent estimates of a common source, and when multiple stations and events are available, this number can increase dramatically. Consider, for example, a data set comprising J stations recording I three-component seismograms. By casting the convolution relation in the log-spectral domain such that a single recording representing source i and impulse response j is represented as, for example,

$$\log(|P_{ij}(\omega)|) = \log(|S_i(\omega)|) + \left(\left|G_j^P(\omega)\right|\right) \qquad [7]$$

we may generate a large linear system of equations (see Andrews, 1986) that includes $3IJ$ equations in $I + 3J$ unknowns.

This system, when augmented with equations that include source estimates $|S_i(\omega)| \approx |\widetilde{S}_i(\omega)|$ determined as outlined in the preceding text, becomes highly redundant and can be solved via least squares to recover the improved amplitude spectra $|G_j^P(\omega)|$, $|G_j^V(\omega)|$, $|G_j^H(\omega)|$, and $|S_i(\omega)|$. The phase of $G_j^P(\omega)$ is readily determined directly through eqn [5], whereas the phase of the two remaining quantities can be recovered through a slightly more involved procedure described by Mercier et al. (2006). An example showing the teleseismic *P* Green function estimates as a function of horizontal slowness for station HYB at Hyderabad, India, is shown in Figure 5. The *P*-image clearly reveals the pure *P* surface–Moho reflection that cannot be recovered through conventional receiver function analysis.

The approach outlined in this section can in principle be applied to *P* phases other than teleseismic *P* (e.g., *PP* and *PKP*) provided that these recordings are free of other primary phases. We consider its relevance and application to *S* phases in the succeeding text.

1.08.3.4 The Teleseismic *S* Green Functions

There are two principal complications that arise when seeking to extend the approach of the previous section to *S* phases, both of which concern the applicability of the minimum-phase assumption. The first complication is primarily theoretical in nature and is easily qualified. The second issue pertains to the polarization of *S*-waves and poses more practical difficulty. We discuss each in turn.

We have already alluded to the increased tendency for multiply interfering phases (e.g., teleseismic *S*, *ScS*, and *SKS*) within the teleseismic *S*-wave field in some circumstances but will assume that these complications have been dealt with and that our observations represent a single, direct phase with known slowness. Strictly speaking, the *S*-component of the impulse response (i.e., the *S*-component of the teleseismic *S* Green function) cannot be minimum phase in the presence of heterogeneity owing to the generation of acausal, for example, *S*-to-*P*-to-*S* scattering interactions that arrive as *S*-waves in advance of the incident *S*-wave field. These early arrivals are, however, of order $O(\varepsilon^2)$ in amplitude and so can be ignored within the single-scattering formulations that dominate inversion practice (see Sections 1.08.4 and 1.08.5).

The next issue, then, is to determine to which component of *S* the minimum-phase assumption should apply. In 1-D, isotropic (or transversely isotropic) media, this question is easily addressed since *P*/*SV* and *SH* interactions are decoupled and the minimum-phase assumption can be made independently for both the *SV*- and *SH*-components of motion. A number of earlier studies (Båth and Stefánson, 1966; Baumgardt and Alexander, 1984; Bock, 1991; Faber and Müller, 1980; Jordan and Frazer, 1975; Sacks et al., 1979) have avoided source deconvolution by employing deep focus events to examine *SV*-to-*P* conversions. More recently, the teleseismic *SV* Green/receiver functions have been generated in a manner directly analogous to teleseismic *P* by simply interchanging the roles of the *P*- and *SV*-components (e.g., Kumar et al., 2005; Li et al., 2004; Vinnik et al., 2005) or by using teleseismic *P* as a source estimate (Zhou et al., 2000). Considerably less attention has been paid to *SH* due to the lack of conversions in isotropic, 1-D media, although multichannel stacking has been used in at least one study to recover *SH* reflections from dipping structures (Li, 1996).

In more realistic circumstances, particularly those involving azimuthal anisotropy, we recognize, however, that *S*-waves with different polarizations will couple such that the impulse response becomes a more complex function of the incident *S*-polarization (Farra et al., 1991). Our objective in this class of study is thus to extract an azimuth-dependent and polarization-dependent impulse response (Farra and Vinnik, 2000; Frederiksen and Bostock, 2000). Because (quasi-)*S*-modes propagate at different velocities in anisotropic media, situations will

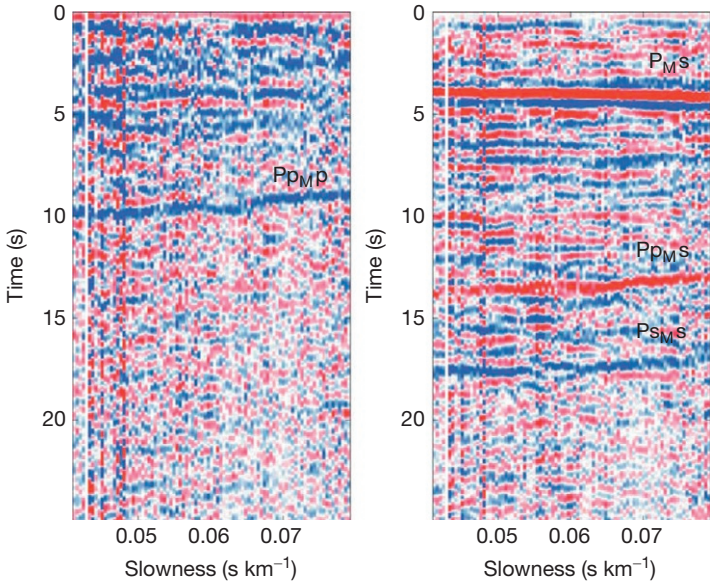

Figure 5 The teleseismic *P* and *SV* Green function estimates for station HYB, India, as function of horizontal slowness $\sqrt{p_x p_\alpha}$ (reproduced from Kumar MR and Bostock MG (2006) Transmission to reflection transformation of teleseismic wavefields. *Journal of Geophysical Research* 111: B08306). Note the clear definition of the main first-order scattered phases from the continental Moho on both components, as defined in Figure 3.

frequently arise where at least one component of *S*-motion recorded at the surface is decidedly non-minimum phase.

To address this issue, we write the upgoing wave field (which contains both direct- and scattered-wave contributions) recorded at the surface $[P, V, H]^{\mathrm{T}}$ in terms of a purely *S*-wave field $[0, V_0, H_0]^{\mathrm{T}}$ incident at the base of laterally homogeneous, generally anisotropic, receiver-side stratification,

$$\begin{pmatrix} P \\ V \\ H \end{pmatrix} = \begin{pmatrix} U^{PP} & U^{PV} & U^{PH} \\ U^{VP} & U^{VV} & U^{VH} \\ U^{HP} & U^{HV} & U^{HH} \end{pmatrix} \begin{pmatrix} 0 \\ V_0 \\ H_0 \end{pmatrix} \qquad [8]$$

where the various elements of the transmission matrix for upgoing waves $\mathrm{U} = \mathrm{U}(\omega, \mathbf{p}_\perp)$ are functions of frequency and horizontal slowness p_α, $\alpha = 1, 2$. Note that the matrix U can be related to the transmission matrix T_U for upward incidence in the absence of a free surface as $\mathsf{U} = \left(\mathsf{I} - \mathsf{R}_D\widetilde{\mathsf{R}}\right)^{-1}\mathsf{T}_U$ (Kennett, 1983) where the effects of reverberation are expressed through the free-surface reflection matrix $\widetilde{\mathsf{R}}$ and reflection matrix R_D for the stratification in the absence of free surface. We will further assume that the incident-wave field $[0, V_0, H_0]^{\mathrm{T}}$ is linearly polarized as would be the case for a simple, for example, double-couple, point source within an isotropic source-side structure. Upon arrival at the surface, the *V*,*H*-components can combine to produce an elliptically polarized wave field characterized by low eccentricity that is the manifestation of shear-wave splitting (e.g., Silver and Chan, 1991; Vinnik et al., 1989). This observation indicates that the elements U^{HV} and U^{VH} can be comparable in magnitude to the diagonal elements of U for structures representing the real Earth.

An obvious way to proceed is thus to follow standard practice for shear-wave splitting analysis and search for the combination of fast-polarization direction and delay time that most nearly corrects for shear-wave splitting to produce a linearly polarized estimate of V_0 and H_0. Although this downward continuation (i.e., simulation of U^{-1}) is only approximate in that internal reverberations/reflections are neglected, our main concern is with the dominant, incident *S*-arrival. In particular, the component of the resulting time series in the polarization direction, say, $\mathbf{s}_0$, will then be minimum phase under the condition that the incident wave has been reduced to a single impulse on one component and is more energetic than all remaining signals. Accordingly, the source can be removed following the approach taken in **Section 1.08.3.3** for *P*-waves. Once the source is removed, we may reverse the downward continuation (including errors therein) by applying the forward-splitting operator to produce the corresponding source-deconvolved surface wave field $[P, V, H]^{\mathrm{T}}$. To create the Green function, it remains to distinguish between the impulse responses produced by individual V_0 and H_0. We may exploit multichannel measurements taken at the same horizontal slowness $p_\alpha = [p_1, p_2]$ (i.e., seismograms representing different source mechanisms but the same geographical source–receiver combinations) to this end, by taking appropriate linear combinations of the deconvolved $[P, V, H]^{\mathrm{T}}$ as dictated by independent values of $\mathbf{s}_0$.

The approach outlined in the preceding text may break down where source-side anisotropy has contributed to splitting or where a single fast-polarization direction and delay time do not adequately characterize the transmission response. This latter situation may arise where multiple, strongly anisotropic layers exist. In these cases, a single measured $\mathbf{s}_0$ may not accurately represent the polarization state of the wave field incident on receiver-side heterogeneity (e.g., Silver and Savage, 1994). Farra and Vinnik (2000) described an alternate procedure, also using multichannel measurements, for computing the *S*-receiver function by deconvolving the *P*-component with the projection of the *S*-wave in the direction of the strongest polarization. The interpretation of this quantity faces the same restrictions identified in the preceding text and is based on a linearization, which limits allowable relative magnitudes of off-diagonal elements in U.

1.08.3.5 Deconvolution, Stacking, and Array Processing

Our focus throughout the majority of this section has been to establish the physical basis for the classical receiver function and extensions that allow us to recover a more fundamental quantity, namely, the Green function, which is required in the inverse-scattering approaches to be described in **Sections 1.08.4.3** and **1.08.5**. In so doing, we have paid little attention to a significant body of work that has been devoted to a more general topic of signal processing as applied to teleseismic wave fields, specifically deconvolution. In the main, this work is concerned with estimating a transfer function (i.e., either receiver function or the Green function) such that the effect of noise is mitigated, usually under the assumption that the source wavelet is perfectly known. We provide, in the succeeding text, a brief overview of deconvolution applications to receiver-side scattering of teleseismic wave fields.

Among the first attempts to extract an impulse response from teleseismic body waves, Ulrych and coworkers (Ulrych, 1971; Ulrych et al., 1972) employed filtering in the cepstral domain to separate source from structural signal. The cepstrum of a signal is computed by inverse Fourier transformation of the logarithm of its Fourier transform. That and eqn [7] are therefore termed homomorphic decompositions since they transform the convolutional operation to an additive one (see, e.g., Oppenheim and Schafer, 1975). The difficulty in applying such homomorphic decompositions to non-zero-phase signals (vs. autocorrelations) resides in the necessity for phase unwrapping, which effectively renders the approach intractable for many practical purposes. This shortcoming was noted by Clayton and Wiggins (1976) who proposed an alternative 'water-level' method that has subsequently found widespread use. The receiver function $R(t)$ is thereby computed as

$$R(t) = \mathcal{F}^{-1}\left\{\frac{P^*(\omega)S(\omega)}{\max\left(P^*(\omega)P(\omega), cP_{\max}{}^*P_{\max}\right)}\right\} \qquad [9]$$

where $\mathcal{F}^{-1}\{\}$ denotes inverse Fourier transformation, $P_{\max}$ is the spectral value for which $P(\omega)$ achieves maximum absolute value, and c is a user-specified water-level parameter that regularizes the deconvolution by damping contributions at frequencies where signal levels are low and thus more likely to be corrupted by noise. Note that when $c = 0$, eqn [9] reduces to simple spectral division, whereas large values of c produce a receiver function that is a scaled cross correlation of the *P*- and *S*-components. In the latter case, the *P*-component acts as a matched filter (Kind and Vinnik, 1988). Variations on this

same theme include the standard damped least-squares deconvolution solution

$$R(t) = \mathcal{F}^{-1}\left\{\frac{P^*(\omega)S(\omega)}{P^*(\omega)P(\omega)+\delta}\right\} \quad [10]$$

where δ is a constant Tichonov regularization parameter determined by standard (e.g., L-curve, generalized cross validation (Golub et al., 1979)) means and Wiener deconvolution (e.g., Press et al., 1986) where δ in eqn [10] becomes frequency-dependent and proportional to the pre-event noise spectrum. When multichannel measurements representing the same $R(t)$ are available, it is advisable to compute a simultaneous estimate (Gurrola et al., 1995) as

$$R(t) = \mathcal{F}^{-1}\left\{\frac{\sum_i P_i^*(\omega)S_i(\omega)}{\sum_i P_i^*(\omega)P_i(\omega)+\delta}\right\} \quad [11]$$

rather than stacking individual estimates computed by, for example, eqn [10] because only one value of δ needs to be chosen and that value is likely to be small since different seismograms will, in general, exhibit spectra with different signal-to-noise characteristics. Park and Levin (2000) advocated using multitaper spectral estimates (Thomson, 1982) to help stabilize receiver function deconvolution, where the individual multichannel recordings within the sums in eqn [11] are replaced by the tapered spectral estimates for a single seismogram.

While quadratic misfit and model norms are being considered, Parseval's theorem ensures that the results of deconvolution in the time domain and frequency domain will be equivalent, and it is therefore expedient to perform computations in the frequency domain to take advantage of the fast Fourier transform. Time-domain deconvolution may be desirable, however, where time-domain-specific regularization of $R(t)$ such as sparseness is required (Gurrola et al., 1995; Ligorria and Ammon, 1999).

In addition to deconvolution, nonlinear stacking and array processing methods are often used to improve signal-to-noise levels on teleseismic body-wave recordings and, in particular, for emphasizing discrete, weak arrivals. Popular nonlinear stacking techniques include the Nth root stack (Muirhead and Datt, 1976) and the phase-weighted stack (Schimmel and Paulssen, 1997); Kennett (2000) discussed the application of these approaches to multicomponent teleseismic wave fields. In the next two sections, we will examine multichannel processing of scattered teleseismic wave fields in the context of structural inversion for which (weighted but linear) stacking enters naturally through surface integration. For a summary of more general array processing techniques applied to teleseismic wave fields, the reader is referred to Rost and Thomas (2002).

1.08.4 1-D Inversion

The use of single-station data in early receiver function studies forced practitioners to focus attention on delineation of strictly 1-D structures. In fact, this practice is still commonplace today because, in many circumstances, the target discontinuities are expected to be locally horizontal or to vary slowly in lateral coordinates. Thus, for example, in studies of the continental crust (e.g., Owens et al., 1984; Zandt and Ammon, 1995) and transition zone discontinuities (e.g., Chevrot et al., 1999; Kind and Vinnik, 1988; Vinnik, 1977), the 1-D analysis has proved to be quite adequate and has yielded valuable information on the characteristics of these structures in different tectonic regimes. The more recent documentation of near-horizontal, anisotropic discontinuities within the continental lithosphere (Asencio et al., 2003; Bostock, 1997, 1998; Leidig and Zandt, 2003; Levin and Park, 1997, 1998; Saul et al., 2000) has opened new avenues for study with regard to both inverse modeling and complementary new information that anisotropy can potentially deliver on subsurface structures and dynamics.

Methods employed to invert receiver functions for 1-D variations in material properties can be classified into three categories: optimization based on least squares, Monte Carlo methods, and inverse scattering. We discuss each category in turn but pay special attention to the last method because it is most closely tied to the physics of scattering and provides formal justification for the 'delay-and-sum' and 'squeezing and stretching' approaches that have dominated 1-D studies of lithospheric and upper mantle discontinuities to date.

1.08.4.1 Least-Squares Optimization

Optimization by least squares is the most widely used and generic method for solving geophysical inverse problems (Menke, 1984; Parker, 1994). It is less expensive than Monte Carlo inversion and, in the context of teleseismic body waveforms, makes less stringent demands on data than inverse-scattering methods. More specifically to the latter point, data insufficiency (in the form, say, of limited frequency and/or slowness content) can be readily compensated for through model regularization, and there is no formal requirement that data be supplied in the form of the Green functions. That is, model matching by least-squares techniques can be directly undertaken using transfer functions, for example, the receiver function, without concern for the proximity of this quantity to the true Green function. All that is required is a means of performing receiver function forward modeling.

Implementation is straightforward (see, e.g., Ammon et al. (1990) for a more detailed account). A receiver function or series of receiver functions strung end to end and represented in either the time or frequency domain is assembled within a vector d, with individual elements d_i. For consistency with later notation, we shall define c to be a vector containing the elasticities and densities of a sequence of horizontal layers bounded by a free surface above and half-space below, thereby representing a 1-D Earth model. The forward-modeling operator is represented by a (nonlinear) functional $\mathcal{D}$ that operates on c to produce synthetic data, that is,

$$\mathbf{d} = \mathcal{D}\{\mathbf{c}\} \quad [12]$$

In the 1-D context, both exact layer-matrix methods (Ammon et al., 1990; Haskell, 1962; Kennett, 1983; Kind et al., 1995; Kosarev et al., 1993) and approximate ray methods (e.g., Langston, 1977; Owens et al., 1984) are feasible means of representing $\mathcal{D}$. Ray methods are more economical in time-domain implementations where only a limited number of low-order scattering interactions are to be modeled, whereas layer-matrix methods provide a complete representation wherein economies

may be gained by restricting computation to the range of frequencies and slowness that characterize the data.

Nonlinearity is addressed in the inverse problem by expanding the receiver function vector as a Taylor series about a starting model $\mathbf{c}_0$, such that

$$d_i = \mathcal{D}_i(\mathbf{c}) = \mathcal{D}_i\{\mathbf{c}_0\} + \frac{\partial \mathcal{D}_i}{\partial c_j}\{\mathbf{c}_0\}\Delta c_j + O\left(||\Delta \mathbf{c}||^2\right) \qquad [13]$$

Rearranging eqn [13], discarding nonlinear terms, and writing in matrix form yield

$$\mathbf{W}\Delta\mathbf{c} = \mathbf{f} \qquad [14]$$

where the data residual vector is $\mathbf{f} = \mathbf{d} - \mathcal{D}(\mathbf{c}_0)$ and the elements of the sensitivity matrix W are defined by $W_{ij} = \partial \mathcal{D}_i / \partial c_j$. Randall (1989) described a particularly economical means to compute W_{ij} for receiver function inversions that exploits Kennett's (1983) reflection/transmission layer-matrix formalism. Alternatively, this quantity can be determined numerically. Since receiver functions are sensitive primarily to short-wavelength structure, $\mathbf{c}_0$ is generally taken to represent a slowly varying velocity model on which the unknown short-wavelength perturbation $\Delta\mathbf{c}$ is superposed.

The solution of the linear system [14] can be accomplished in a number of ways, although minimization of the quadratic norm of f leading to solution of the normal equations is the standard approach. Depending on the form of model parameterization (e.g., layer thicknesses), the system in eqn [14] may be rank-deficient in which case regularization via, for example, damping can be implemented. Further accommodation of nonlinearity can, in principle, be accomplished by Newton iteration on eqn [13].

1.08.4.2 Monte Carlo Inversion

The advent of high-performance computing and the relatively few model parameters that characterize 1-D problems have led to investigation of Monte Carlo methods for performing receiver function inversions. These methods require only a forward-modeling engine without need for calculation of derivatives (i.e., W_{ij}), since the sole criterion for model selection is an arbitrary measure of fit. They hold the distinct advantage over least-squares optimization that they are global in nature and less apt to identify incorrect, local misfit minima as solutions. Although the number of unknowns is relatively small, a purely random sampling of the model space is still computationally demanding and, at best, inefficient. Consequently, preference has been given to 'directed search' algorithms that exploit information from past computations to guide future sampling. Two examples of directed search algorithms that have been applied to receiver function inversion are the genetic algorithm (Clitheroe et al., 2000; Goldberg, 1989; Lawrence and Wiens, 2004; Shibutani et al., 1996) and the recently introduced nearest-neighbor algorithm (Frederiksen et al., 2004; Lucente et al., 2005; Nicholson et al., 2005; Sambridge, 1999a). Both algorithms begin with a population of models generated through an initial (uniform or random) sampling of model space. Genetic algorithms employ an evolutionary analogy wherein model parameters are encoded within binary strings or 'chromosomes.' The model population is allowed to evolve through iterations (or 'generations') by stochastic selection of models based on goodness of fit, by recombination of models (through chromosomal splicing), and by random 'mutation.' The natural neighborhood algorithm employs an adaptive Voronoi cellular network to drive the parameter search, where each successive iteration randomly samples the model space within cells occupied by the fittest models of the previous iteration. The algorithm thereby focuses increasingly on regions in model space that produce models that come closer to satisfying the data. Another important advantage of these directed search approaches lies in the output of model populations that afford the opportunity for either qualitative or quantitative (Sambridge, 1999b) appraisal of the model space.

1.08.4.3 Born Inversion and Classic (Delay and Sum) Studies

Unlike the two methods just described, inverse-scattering approaches to the receiver function inversion problem rely fundamentally on an explicit description of the scattering process. Accordingly, the starting point is the Lippman–Schwinger equation that we shall write in the frequency domain as (see Hudson and Heritage, 1981)

$$\Delta u_n(\mathbf{x}', \omega) = \int_V \mathrm{d}\mathbf{x}\left(-\Delta c_{ijkl}(\mathbf{x})\partial_k u_l(\mathbf{x}, \omega)\partial_j G^0_{in}(\mathbf{x}, \mathbf{x}', \omega) + \Delta\rho(\mathbf{x})\omega^2 u_i(\mathbf{x}, \omega) G^0_{in}(\mathbf{x}, \mathbf{x}', \omega)\right) \qquad [15]$$

This equation is cast in terms of field quantities and perturbations in material properties whose support is the volume V. The material properties of the medium are described by the stiffness tensor c_{ijkl} and density ρ through

$$c_{ijkl}(\mathbf{x}) = c^0_{ijkl}(\mathbf{x}) + \Delta c_{ijkl}(\mathbf{x}), \quad \rho(\mathbf{x}) = \rho^0(\mathbf{x}) + \Delta\rho(\mathbf{x}) \qquad [16]$$

where quantities with superscript '0' denote those of a background reference medium and the 'Δ' quantities are perturbations. Although not strictly required at this stage, we shall assume that short-wavelength heterogeneity is represented within $\Delta c_{ijkl}(\mathbf{x})$, $\Delta\rho(\mathbf{x})$ and ascribe the smoothly varying component of the material property perturbations to $c^0_{ijkl}(\mathbf{x})$, $\rho^0(\mathbf{x})$. The total wave field u_i is defined as

$$u_i(\mathbf{x}, \omega) = u^0_i(\mathbf{x}, \omega) + \Delta u_i(\mathbf{x}, \omega) \qquad [17]$$

where $u^0_i(\mathbf{x}, \omega)$ is the incident (or 'reference') wave field, created by a source with $\delta(t)$ time dependence, that would propagate independently in a medium with properties $c^0_{ijkl}(\mathbf{x})$, $\rho^0(\mathbf{x})$. Note that this definition is consistent with our earlier designation of the incident-wave field as a primary phase such as teleseismic P or S propagating through a smoothly varying mantle. The scattered (or 'perturbed') wave field $\Delta u_i(\mathbf{x}, \omega)$ arises through the interaction of $u^0_i(\mathbf{x}, \omega)$ with short-wavelength structure $\Delta c_{ijkl}(\mathbf{x})$, $\Delta\rho(\mathbf{x})$. We will assume that an accurate representation of $\Delta u_i(\mathbf{x}', \omega)$ has been secured using methods described in **Section 1.08.3** where $\mathbf{x}' = [x'_1, x'_2, 0]^{\mathrm{T}}$ shall be taken in this and the following sections to parameterize the Earth's surface. The quantity $G^0_{in}(\mathbf{x}, \mathbf{x}', \omega)$ represents the Green function for the reference medium and will be determined analytically. We now make the customary 'single-scattering' or 'Born' approximation by assuming that $\Delta u_i(\mathbf{x})$ is small relative to $u^0_i(\mathbf{x}, \omega)$ such that we may rewrite eqn [15] as

$$\Delta u_n(\mathbf{x}',\omega) \approx \int_V \mathrm{d}\mathbf{x}\big(-\Delta c_{ijkl}(\mathbf{x})\partial_k u_l^0(\mathbf{x},\omega)\partial_j G_{in}^0(\mathbf{x},\mathbf{x}',\omega) + \Delta\rho(\mathbf{x})\omega^2 u_i^0(\mathbf{x},\omega)G_{in}^0(\mathbf{x},\mathbf{x}',\omega)\big) \quad [18]$$

(see Chapter 1.05 for an account of the Born approximation in an acoustic context). Note that this step is analogous to the linearization of eqn [13] where the forward-modeling operator (or, more specifically, $\mathcal{D}_i\{\mathsf{c}\}-\mathcal{D}_i(\{\mathsf{c}_0\})$) is given by eqn [15].

To set the problem in a form that is appropriate for plane-wave propagation in a 1-D Earth, we recognize that plane waves (or, more precisely, wave fields with constant horizontal slowness p_α, $\alpha=1, 2$) propagate independently in media exhibiting strictly vertical variations in material properties, that is, $\Delta c_{ijkl}(x_3)$, $\Delta\rho(x_3)$. Since propagation takes place in the reference medium, we will make use of plane-wave, modal expansions for $u^0(\mathbf{x},\omega)$ and $G_{in}^0(\mathbf{x},\mathbf{x}',\omega)$ that also employ the high-frequency or WKBJ approximation. Following Bostock (2003) (and correcting an error in eqn [32] therein), we write

$$u_i^0(\mathbf{x},\omega) = \sum_r A^r(x_3)s_i^r(x_3)\mathrm{e}^{\mathrm{i}\omega(\tau^r(x_3)+p_\alpha x_\alpha)} \quad [19]$$

$$G_{in}^0(\mathbf{x},\mathbf{x}',\omega) = \sum_s \frac{-\mathrm{i}s_n^s(0)s_i^s(x_3)\mathrm{e}^{\mathrm{i}\omega\left(\tau^s(x_3,0)+p_\alpha\left(x'_\alpha-x_\alpha\right)\right)}}{2\omega\sqrt{\rho^0(0)\rho^0(x_3)\left|U_3^s(0)\right|\left|U_3^s(x_3)\right|}} \quad [20]$$

where the subscript α follows the repeated index summation convention; the superscripts r,s index the incident- and scattered-wave modes (i.e., P, SV, SH, or their analogs in anisotropic media); s_i^r and s_n^s are corresponding depth-dependent, unit polarization vectors; $A^r(x_3)$ is the source amplitude, $U_3^r(x_3), U_3^s(x_3)$ are the vertical components of group velocity; and $\tau^r(x_3)$ and $\tau^s(x_3)$ are delay times of the incident and scattered modes, respectively.

The modal expansion allows us to isolate and describe individual scattering interactions; for example, we set $A^r(x_3)=1/\sqrt{\rho(x_3)\left|U_3^r(x_3)\right|}$ for direct P-to-S scattering (say, $r=1$ and $s=2$), and the corresponding delay time functions are written as

$$\tau^r(x_3) = -\int_0^{x_3}\mathrm{d}\gamma_3 p_3^P(\gamma_3), \quad \tau^s(x_3,0) = \int_0^{x_3}\mathrm{d}\gamma_3 p_3^S(\gamma_3) \quad [21]$$

where $p_3^P(x_3)$ and $p_3^S(x_3)$ are the vertical components of phase slowness for P- and S-waves, respectively. The choice of $\tau^r(x_3)$ in the preceding text implies a time normalization where the direct P-wave ($r=1$) arrives at the Earth's surface at $\tau^r=0$ consistent with the output of most deconvolution schemes described in Sections 1.08.3.3–1.08.3.5. Back scattering that involves free-surface reflection of the upgoing incident wave can be described through an alternate set of amplitude and delay time functions. For example, pure P-mode reflection (say, $r=2$ and $s=1$) is characterized by $A^r(x_3)=\widetilde{R}^{PP}/\sqrt{\rho(x_3)\left|U_3^r(x_3)\right|}$ where $\widetilde{R}^{PP}$ is the free-surface P-to-P reflection coefficient and the delay time functions are

$$\tau^r(x_3) = \int_0^{x_3}\mathrm{d}\gamma_3 p_3^P(\gamma_3), \quad \tau^s(x_3,0) = \int_0^{x_3}\mathrm{d}\gamma_3 p_3^P(\gamma_3) \quad [22]$$

(note that for an anisotropic reference medium that does not exhibit mirror symmetry, we would have to employ different values for up- and downgoing phase slowness in eqns [22]).

Inserting expressions [19] and [20] into [18] and retaining only the leading-order terms in frequency, one obtains

$$\Delta u_n(\mathbf{x}',\omega) \approx \sum_r\sum_s s_n^s(0)\mathrm{e}^{\mathrm{i}\omega p_\alpha x'_\alpha}\int \mathrm{d}x_3 B^{rs}(x_3,\omega) \left[\frac{\Delta c_{ijkl}}{\rho^0}s_l^r p_k^r s_i^s p_j^s + \frac{\Delta\rho}{\rho^0}s_i^r s_i^s\right]\mathrm{e}^{\mathrm{i}\omega(\tau^r(x_3)+\tau^s(x_3,0))} \quad [23]$$

where, for brevity, we have suppressed the x_3 dependence in all quantities within the square brackets, p_i^r, p_i^s are the phase slowness vectors of the incident- and scattered-wave fields at depth x_3, and the factor $B^{rs}(x_3,\omega)$ is defined by

$$B^{rs}(x_3,\omega) = -\frac{\mathrm{i}\omega A^r(x_3)\sqrt{\rho^0(x_3)}}{2\sqrt{\rho^0(0)\left|U_3^s(0)\right|\left|U_3^r(x_3)\right|}} \quad [24]$$

Equation [23] represents an asymptotic, linearized relation between the scattered field $\Delta u_n(0)$ measured at the Earth's surface and the unknown material parameters $\Delta c_{ijkl}(x_3)$ and $\Delta\rho(x_3)$. To simplify the extraction of these parameters, we follow Burridge et al. (1998) and define a fourth rank tensor a_{ijkl} that possesses the same symmetry properties as Δc_{ijkl} and satisfies

$$\frac{\Delta c_{ijkl}}{V^r V^s}a_{ijkl} = \Delta c_{ijkl}s_l^r p_k^r s_i^s p_j^s \quad [25]$$

where V^r and V^s represent the phase velocities of incident and scattered modes, respectively, averaged over all angles, that is

$$a_{ijkl} = \frac{V^r V^s}{8}\left[\left(s_i^s p_j^s + s_j^s p_i^s\right)\left(s_k^r p_l^r + s_l^r p_k^r\right) + \left(s_k^s p_l^s + s_l^s p_k^s\right)\left(s_i^r p_j^r + s_j^r p_i^r\right)\right] \quad [26]$$

This construction allows us to adopt a more compact notation and rewrite eqn [23] as

$$\Delta u_n(0,\omega) \approx \sum_r\sum_s s_n^s(0)\mathrm{e}^{\mathrm{i}\omega p_\alpha x'_\alpha}\int \mathrm{d}x_3 B^{rs}(x_3,\omega)\mathrm{e}^{\mathrm{i}\omega(\tau^r(x_3)+\tau^s(x_3,0))}\mathsf{w}^{\mathrm{T}}\Delta\mathsf{c} \quad [27]$$

The radiation patterns and material property perturbations are now contained within 22-element vectors, w and Δc, whose entries correspond to the 21 independent elastic constants and density as

$$\mathsf{w} \leftrightarrow \left[a_{ijkl}, s_i^s s_i^r\right], \quad \Delta\mathsf{c} \leftrightarrow \left[\frac{\Delta c_{ijkl}}{\rho^0}, \frac{\Delta\rho}{\rho^0}\right] \quad [28]$$

Equation [27] takes a form that may be readily discretized and solved for Δc. It is common practice, however, to consider the contribution of each scattering mode $\Delta u_i^{rs}(0,\omega)$ (where $\Delta u_i(\mathbf{x},\omega)=\sum_r\sum_s\Delta u_i^{rs}(\mathbf{x},\omega)$), independently. Assuming that the individual $\Delta u_i^{rs}(\mathbf{x},\omega)$ can be approximately isolated (see Section 1.08.6 for further discussion on this assumption), we define the scalar, time-domain quantity

$$f^{rs}(t) = \mathcal{F}^{-1}\left\{\frac{\Delta u_i^{rs}(0,\omega)s_i^s(0)\mathrm{e}^{-\mathrm{i}\omega p_\alpha x'_\alpha}}{B^{rs}(x_3,\omega)}\right\}\left[p_3^s(x_3)+p_3^r(x_3)\right] \quad [29]$$

where $\mathcal{F}^{-1}$ denotes, as before, inverse Fourier transformation. Note that contraction with $s_i^s(0)$ rotates the data into the

anticipated polarization direction of the upgoing scattered mode s. In practice, we accomplish this operation using eqn [2] since the effect of the free surface on polarization of the recorded wave field is not explicitly accounted for in the treatment of this section. Multiplication by $e^{-i\omega p_z x'_z}$ in eqn [29] removes the time shift associated with horizontal coordinate such that the arrival of the direct wave (P for $r=1$ and S for $r=2, 3$) corresponds to time 0. By inserting the expression for $\Delta u_i^{rs}(0,\omega)$ in eqns [27] into [29] and evaluating both integrals in ω and x_3 (with the aid of Leibniz' rule), we arrive at

$$f^{rs}(t=\tau^r(x_3)+\tau^s(x_3,0))=\mathbf{w}^{\mathrm{T}}(x_3)\Delta\mathbf{c}(x_3) \qquad [30]$$

that is, a one-to-one relation between material property perturbations at depth x_3 and the value of $f^{rs}(t)$ evaluated at time $t=\tau^r(x_3)+\tau^s(x_3,0)$. If we now assemble a large number of data $u_i^{rs}(0,\omega)$ representing different scattering interactions r, s and geometries (as reflected in p_i^r and p_i^s), normalize as in eqn [29], and arrange these data in a column vector f, a system of equations can be written as

$$\mathbf{f}(x_3)=\mathbf{W}(x_3)\Delta\mathbf{c}(x_3) \qquad [31]$$

where the transposed vectors $\mathbf{w}^{\mathrm{T}}$ form the rows of W. The solution to this system of equations amounts to an amplitude versus slowness analysis of the scattering coefficient corresponding to depth x_3. Normalization of the upgoing wave field by $[p_3^s+p_3^r]/B^{rs}(x_3,\omega)$ in eqn [29] ensures that it is appropriately scaled and filtered such that the perturbation profile $\Delta c(x_3)$ is, to within the single-scattering and high-frequency approximations, correctly recovered. If, instead, we wish to recover a profile of reflectivity (or, more precisely, the singular function of the discontinuity surface scaled to the amplitude of the perturbation; e.g., Bleistein, 1987), we must remove the factor $i\omega$ in eqn [24]. In so doing, the solution of eqn [31] is seen to be simply a weighted diffraction stack of the data along move-out curves corresponding to the various scattering interactions r,s within the 1-D reference medium.

In the case of isotropic stratification, the reflectivity inversion affords a formal justification for the delay-and-sum approach introduced by Vinnik in his analysis of P-to-S conversions from the mantle transition zone in 1977 and adopted subsequently by numerous workers (e.g., Bostock, 1996; Chevrot et al., 1999; Dueker and Sheehan, 1998; Kind and Vinnik, 1988; Stammler et al., 1992). In these studies, data are stacked along move-out curves computed for a 1-D Earth model and corresponding to a range of trial depths, to produce a map of stacked amplitude as a function of delay time and discontinuity depth. If amplitude extrema are observed at delay times consistent with a trial depth, a discontinuity is tentatively identified (see **Figure 6**). An approximate reflectivity (or 'convertibility') depth profile can be recovered by slicing through the amplitude map along the appropriate travel-time curve (see **Figure 7**). This empirical approach is equivalent to migrating (or 'squeezing and stretching') traces to depth prior to stacking (e.g., Fee and Dueker, 2004; Gilbert et al., 2003). It handles kinematics in precisely the same way as the solution of eqn [31]. The dynamics are of secondary importance, and their neglect in empirical migration approaches only means that the stacked waveforms are less directly interpretable in terms of perturbations in the Earth's material properties. The creation of an amplitude map has the advantage of permitting visual assessment of the veracity of a potential structural signal on the basis of whether its amplitude maximum occurs at or near the expected travel time. In this sense, Vinnik's approach has much in common with the velocity spectrum stack developed for exploration applications and also applied to teleseismic wave fields by Gurrola et al. (1994). In this case, amplitude maxima of delayed and stacked waveforms are used to provide improved velocity (or in the case of teleseismic P-to-S conversions, Poisson's ratio) model information for structural imaging.

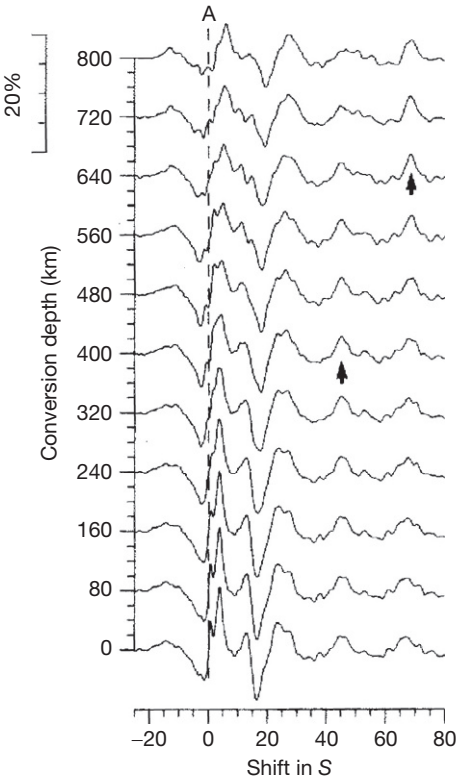

Figure 6 Delayed and summed *SV*-components of source-normalized teleseismic *P* recorded at the Gräfenberg array, Germany. Each trace represents a sum of seismograms, from events at different epicentral distances, delayed by a time interval corresponding to the expected arrival of a conversion from a given trial depth. Arrows point to amplitude maxima that occur for trial depths of 400 and 640 km and that are therefore consistent with the origin of *P*-to-*S* conversions from the two major transition zone discontinuities. Reproduced from Kind R and Vinnik LP (1988) The upper-mantle discontinuities underneath the GRF array from *P*-to-*SV* converted phases. *Journal of Geophysics* 62: 138–147.

The method of Zhu and Kanamori (2000); following on Zandt and Ammon (1995) employs a similar approach to more tightly constrain crustal properties beneath a single three-component station, namely, depth of Moho and crustal Poisson's ratio, under the assumption that the latter is constant. This approach is commonly used for reconnaissance work (e.g., Darbyshire et al., 2007; Finotello et al., 2011; Phillips et al., 2012; Wei et al., 2011) and involves stacking of multiple-scattering modes r, s (consistent with the formulation in eqn [31]) along predicted travel-time trajectories for a grid of Moho depths and Poisson's ratios, to recover an

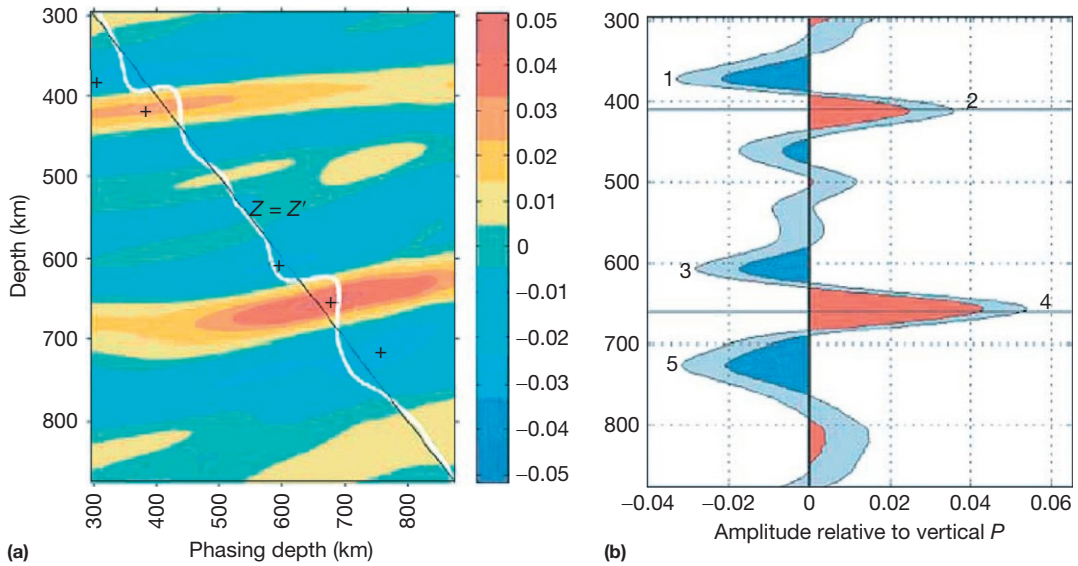

Figure 7 1-D migration (reproduced from Fee D and Dueker K (2004) Mantle transition zone topography and structure beneath the Yellowstone hotspot. *Geophysical Research Letters* 31: L18603. http://dx.doi.org/10.1029/2004GL020636). (a) Left panel shows amplitude map that results from stacking data along move-out curves corresponding to a range of conversion (phasing) depths. The vertical depth axis is proportional to time as mapped through a 1-D velocity model. (b) Right panel plots a slice through the 45° line shown in (a) and accomplishes a 1-D migrated depth profile of 'convertibility' below the Yellowstone hotspot.

optimal model under an assumed *P*-velocity. Extensions include applications to other layered regimes (e.g., subducting oceanic crust (Audet et al., 2009), lower crustal eclogites (Wittlinger et al., 2009), mantle transition zone (Schaeffer and Bostock, 2010), and the base of ice sheets (Wittlinger and Farra, 2012); the retrieval of absolute velocity information (e.g., Bostock and Kumar, 2010; Kumar and Bostock, 2008; Wittlinger et al., 2009); and the extraction of Poisson's ratio without prior knowledge of *P*-velocity (Helffrich and Thompson, 2010)).

Previous empirical studies of anisotropic stratification using scattered teleseismic wave fields can also be related to the linearized, 1-D inverse-scattering solution in eqn [31]. In this case, the Earth's response not only is simply a function of epicentral distance (or, more precisely, the magnitude of horizontal slowness, $\sqrt{p_\alpha p_\alpha}$) but also depends on back azimuth. Various authors (Bostock, 1997, 1998; Farra and Vinnik, 2000; Farra et al., 1991; Kosarev et al., 1984; Levin and Park, 1997, 1998; Vinnik and Montagner, 1996; Wilson et al., 2004) have noted that the back-azimuthal response of a stratified medium exhibiting different classes of anisotropic symmetry and orientation can be represented in simple trigonometric terms. Consequently, several schemes involving stacking with trigonometric weights have been proposed to investigate anisotropic stratigraphy. These schemes can be related to eqn [31] by noting that the linear system, for general Δc and typical teleseismic data sets, will be rank-deficient. It will thus be necessary to solve eqn [31] via a pseudoinverse (e.g., Bank and Bostock, 2003) with singular value decomposition being an obvious and tractable choice. These latter authors noted that only five- to seven-parameter combinations of Δc are likely to be resolvable using teleseismic *P* and that these parameter combinations can be identified with different harmonic orders of response in back azimuth θ, notably 1θ, 2θ, and 3θ. Recovery of Δc through eqn [31] thus amounts once more to a weighted diffraction stack and holds the advantage over more empirical schemes that the full data sensitivity to the elastic stiffness tensor is exploited without having to resort to simplified a priori model representations (e.g., hexagonal symmetry).

Finally, we remark that, in practice, it is difficult to isolate the individual scattering-mode contributions, $\Delta u^{rs}(\mathbf{x}, \omega)$, and in general, we will approximate these quantities by the observed wave field, $\Delta u(\mathbf{x}, \omega)$, for each scattering-mode interaction. The main drawback with this course of action is that we interpret a superposition of several different styles of scattering interaction *r*, *s* as that due to a single one with the result that artificial structures appear in the solution. The most commonplace example is the misinterpretation of the free-surface-reflected, back-scattered waves from shallow interfaces for direct, forward-scattered conversions from deeper interfaces. This shortcoming afflicts both 1-D and multidimensional analyses of teleseismic waves, and we shall comment on a potential remedy in **Section 1.08.6**.

1.08.5 Multidimensional Inversion

There are several approaches to consider in moving from 1-D to multiple dimensions. The first and simplest strategy is to assume that the Earth's structure varies slowly in the horizontal coordinates in which case a 2-D or 3-D profile can be assembled as a cascade of local 1-D models determined from individual, adjacent stations (e.g., Kumar et al., 2005). If stations are sufficiently closely spaced that the (1-D) ray paths of scattered phases intersect below the profile, it becomes advantageous to consider a 2-D model where scattered energy on seismogram is mapped to common conversion points (CCP) assuming a locally horizontal, plane-layer scattering geometry

(e.g., Dueker and Sheehan, 1998; Ferris et al., 2003; Knapmeyer and Harjes, 2000; Kosarev et al., 1999; Niu et al., 2005; Schulte-Pelkum et al., 2005; Simmons and Gurrola, 2000; Zandt et al., 2004). Travel-time and polarity corrections to account for layer dip where structures remain quasiplanar, for example, in subduction zones, provide further improvement in imaging (e.g., Kawakatsu and Watada, 2007; Kawakatsu and Yoshioka, 2011; **Figure 8**). Such CCP stacking techniques are commonly employed because they place less stringent requirements on spatial sampling than formal multidimensional inversion schemes, but of course, their accuracy deteriorates as departures from one-dimensionality or assumed planar structure become more pronounced.

Unlike the strictly 1-D case, the multidimensional inverse problem has not lent itself so readily to treatment using optimization via least squares because of the large increase in model parameters and concomitant rise in computations. It is likely, however, that in the near future, computational tractability will become less of a concern. Indeed, two recent studies (Frederiksen and Revenaugh, 2004; Wilson and Aster, 2005) have explored different least-squares formulations for solving multidimensional receiver function inversions, a trend that is likely to continue. Much of the essential machinery for this task has already been developed for exploration applications; we note, in particular, the work of Tarantola (1984, 1986).

The 1-D, high-frequency, Born-approximate inverse solution described in the previous section can, however, be efficiently extended to multiple dimensions so as to be computationally tractable on standard desktop computers. In this extension, there are no conceptual difficulties in dealing with 2-D versus 3-D problems, although there are practical limitations, in particular, for data from temporary, portable deployments. More specifically, it is difficult at the current time to assemble numbers of instruments sufficient to ensure that the teleseismic wave field is sampled with sufficient areal density (and aperture) to avoid aliasing most of its useful spectrum. Two approaches may be taken to remedy this difficulty. One may seek to interpolate data to a finer spacing over an areal grid followed by 3-D inversion (Neal and Pavlis, 1999, 2001; Poppeliers and Pavlis, 2003a,b) or follow the lead of early exploration practice and adopt a 2-D inverse strategy under the assumption that a dominant geologic strike direction can be identified (Bostock et al., 2001). In the following, we summarize the approach taken by the latter authors, which can be regarded as a 2-D, isotropic extension of the 1-D treatment outlined in **Section 1.08.4.3**.

We begin with the linearized integral equation [18]. In the 1-D case, the invariance of material properties in horizontal coordinates together with the far-field (quasiplanar) nature of the incident-wave field $u_i^0(\mathbf{x}, \omega)$ allowed us to adopt plane-wave expansions for the incident and scattered modes as in

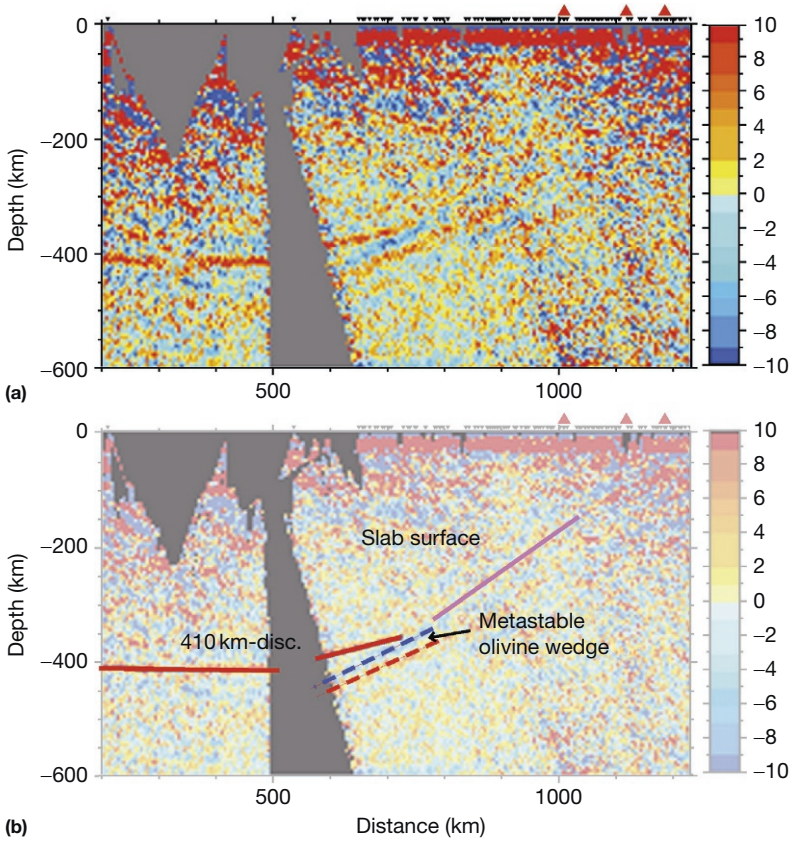

Figure 8 Common conversion point image (a) below southwest Japan with allowance made for assumed nonhorizontal geometry (reproduced from Kawakatsu H and Yoshioka S (2011) Metastable olivine wedge and deep dry cold slab beneath southwest Japan. *Earth and Planetary Science Letters* 303: 1–10). Image in (b) identifies structures associated with subducting Pacific Plate, metastable olivine wedge, and 400 km discontinuity.

eqns [19] and [20]. This choice is effectively equivalent to Fourier transforming over the horizontal plane. Accordingly, for a 2-D inversion where there is only one coordinate of spatial invariance, say, the strike coordinate x_2, we Fourier transform over this coordinate. We thereby assume that, for an incident (e.g., planar) wave field characterized by a single value of slowness p_2 in the strike direction, all resulting scattering interactions will be characterized by this same component of horizontal slowness, and so, we may parameterize the wave fields by this variable. Although not required, it will be computationally and practically expedient to assume that the reference medium is both 1-D and isotropic, so that the reference medium description is reduced from $c^0_{ijkl}(x_1, x_3), \rho^0(x_1, x_3)$ to, for example, $\alpha^0(x_3)$, $\beta^0(x_3)$, $\rho^0(x_3)$. Consequently, we may adopt the same 1-D form for the incident-wave field $u^0_i(\mathbf{x}, \omega)$, that is, eqn [19], whereas for the Green function, we adopt a form that allows for interaction with 2-D (i.e., line) scatterers:

$$G^0_{in}(\mathbf{x}, 0, \omega) = \sum_s \frac{1}{\sqrt{-i\omega}} A^s(\mathbf{x}_\perp, \mathbf{x}'_\perp, p_2) \, e^{i\omega\left[p^s_1 |x_1 - x'_1| - p_2 x_2 + \tau^s(\mathbf{x}_\perp, \mathbf{x}'_\perp)\right]} s^s_i(\mathbf{x}_\perp) s^s_n(\mathbf{x}'_\perp) \quad [32]$$

where, as before, $s = 1, 2, 3$ correspond to *P*, *SV*, and *SH* waves, respectively, and the 2-D amplitude functions A^s are defined, for example, for $s = 1$, as

$$A^s(\mathbf{x}_\perp, \mathbf{x}'_\perp, p_2) = \frac{1}{4\alpha^0(0)} \sqrt{\frac{2}{\pi \rho^0(x_3)\alpha^0(x_3)\rho^0(0)[J^P(\mathbf{x}_\perp, \mathbf{x}'_\perp, p_2)]^2 \sqrt{1 - p_2^2[\alpha^0(0)]^2}}} \quad [33]$$

with a comparable expression holding for the *S*-modes (i.e., $s = 2, 3$). We employ $\mathbf{x}_\perp = (x_1, x_3)$ to represent observation coordinates within the plane of 2-D spatial variations and evaluate source coordinates $\mathbf{x}_\perp{}'$ along the Earth's surface, that is, $\mathbf{x}_\perp{}' = (x_1', 0)$. The travel-time functions $\tau^s(\mathbf{x}_\perp, \mathbf{x}_\perp{}')$ are computed as in eqn [21], but now, we recognize that p^s_1 is no longer constant but depends on $x_1 - x_1'$. A similar consideration also applies in the definition of the unit polarization vectors $s^s_n(\mathbf{x}_\perp)$. The 2-D geometric spreading functions $J^s(\mathbf{x}_\perp, \mathbf{x}_\perp{}', p_2)$ $(= J^P(\mathbf{x}_\perp, \mathbf{x}_\perp{}', p_2)$, for $s = 1$, see, e.g., Hudson, 1980), depend on the divergence of the rays in the x_1, x_3 plane. Note that we have permitted an oblique component of incidence through dependence on x_2, p_2, which bears important practical implications as it will allow us to employ a full range of earthquake sources that need not align with the 2-D model geometry. If forms eqns [19] and [32] are inserted within the isotropic equivalent of eqn [18], we may construct 2-D, high-frequency, single-scattering, forward-modeling equations for various incident-/scattering-mode combinations *r*, *s* of the form

$$\Delta u_n(\mathbf{x}'_\perp, p_2, \omega) = \sum_r \sum_s s^s_n(\mathbf{x}'_\perp) \int d\mathbf{x}_\perp F^{rs}(\mathbf{x}_\perp, \theta) A^r(x_3) A^s(\mathbf{x}_\perp, \mathbf{x}'_\perp, p_2) e^{i\omega\left(\tau^r(x_3) + \tau^s(\mathbf{x}_\perp, \mathbf{x}'_\perp)\right)} \quad [34]$$

The 2-D 'scattering potential,' $F^{rs}(\mathbf{x}_\perp, \theta)$, is derived from contractions of the stiffness tensor (expressed in terms of, e.g., velocities and density) and the local polarization and slowness vectors of the incident and scattered waves. It is expressed as a function of the scattering angle, $\theta = \theta^{rs}(\mathbf{x}_\perp, \mathbf{x}_\perp{}')$, between the slowness vectors of these two wave fields (see Figure 9), and the material property perturbations such that for, for example, forward *P*-to-*S* conversions $(r = 1, s = 2)$

$$F^{rs}(\mathbf{x}_\perp, \theta) = \rho^0 \left[\frac{\Delta\beta}{\beta^0} \left(2\frac{\beta^0}{\alpha^0} \sin 2\theta \right) + \frac{\Delta\rho}{\rho^0} \left(\sin\theta + \frac{\beta^0}{\alpha^0} \sin 2\theta \right) \right] \quad [35]$$

where the dependence of the material property perturbations is, for example, $\Delta\beta = \Delta\beta(\mathbf{x}_\perp)$. Similar relations can be written for other combinations of scattering interaction *r*, *s* (see, e.g., Bostock et al., 2001).

The inverse problem can be tackled by applying an inverse Fourier transform to eqn [34], that is,

$$\Delta u_n(\mathbf{x}'_\perp, p_2, t) = \frac{1}{2\pi} \sum_r \sum_s s^s_n(\mathbf{x}'_\perp) \int d\mathbf{x}_\perp F^{rs}(\mathbf{x}_\perp, \theta) A^r(x_3) A^s(\mathbf{x}_\perp, \mathbf{x}'_\perp, p_2) \delta\left(t - \tau^r(x_3) - \tau^s(\mathbf{x}_\perp, \mathbf{x}'_\perp)\right) \quad [36]$$

and noting that the result bears a close resemblance to the definition of the 2-D Radon transform $F(\mathbf{n}, t)$ of a function $f(\mathbf{x}_\perp)$ (Deans, 1983; Miller et al., 1987)

$$F(\mathbf{n}, t) = \int d\mathbf{x}_\perp f(\mathbf{x}_\perp) \delta(t - \mathbf{n} \cdot \mathbf{x}_\perp) \quad [37]$$

where $\mathbf{n}$ is a unit vector in the 2-D plane defined by $\mathbf{x}_\perp$, especially if we restrict attention to a single-scattering mode $\Delta u^{rs}_n(\mathbf{x}_\perp{}', p_2, t)$. Here, we identify the scattered field $\Delta u_n(\mathbf{x}_\perp{}', p_2, t)$ with $F(\mathbf{n}, t)$ and the scattering potential $F^{rs}(\mathbf{x}_\perp, \theta)$ with $f(\mathbf{x}_\perp)$. The primary differences between the two equations are that the integrand in eqn [36] contains additional factors in the form $A^r(x_3)A^s(\mathbf{x}_\perp, \mathbf{x}_\perp{}', p_2)$ and that the arguments of the delta-function are not straight lines but, rather, isochronal curves along which the sum $\tau^r(x_3) + \tau^s(\mathbf{x}_\perp, \mathbf{x}_\perp{}')$ is constant. The correspondence can be made closer still by recognizing that the product of geometric amplitudes will, in general, be slowly varying and that, in keeping with the asymptotic forms adopted in eqns [19] and [32], the isochronal curves can be approximated

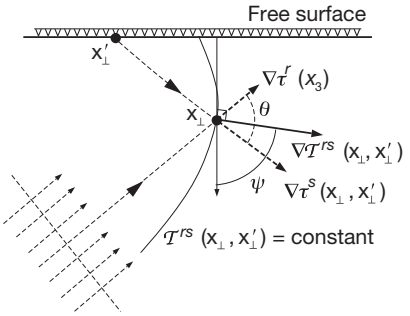

Figure 9 Geometric quantities relevant to high-frequency, inverse scattering of teleseismic wave fields for 2-D structure. The vectors $\nabla\tau_r$ and $\nabla\tau^s$ are the slowness vectors for the incident and scattered waves, respectively, whereas θ is the 'scattering' angle between them. The total slowness vector $\nabla T^{rs} = \nabla\tau^r + \nabla\tau^s$, characterized by angle ψ, plays an important role in controlling spatial resolution within the generalized Radon transform.

locally as planar. We may then draw upon the formal inverse Radon transform (Beylkin, 1985; Beylkin and Burridge, 1990; Deans, 1983; Miller et al., 1987):

$$\begin{aligned} f(\mathbf{x}'_\perp) &= -\frac{1}{4\pi}\int d\mathbf{n}\mathcal{H}\left\{\frac{\partial}{\partial t}F(\mathbf{n},t)\right\}\Big|_{t=\mathbf{n}\cdot\mathbf{x}'} \\ &= -\frac{1}{4\pi}\int d\mathbf{n}\int d\mathbf{x}_\perp f(\mathbf{x})\mathcal{H}\{\delta'(\mathbf{n}\cdot(\mathbf{x}'_\perp-\mathbf{x}_\perp))\} \\ &= -\frac{1}{4\pi}\int d\psi\int d\mathbf{x}_\perp f(\mathbf{x})\mathcal{H}\{\delta'(\mathbf{n}\cdot(\mathbf{x}'_\perp-\mathbf{x}_\perp))\} \end{aligned} \quad [38]$$

where ψ is the angle of $\mathbf{n}$, $\mathcal{H}\{\ \}$ denotes Hilbert transform, and $\delta'(x)$ is the derivative of $\delta(x)$, to devise a formal back-projection operator for the recovery of $F^{rs}(\mathbf{x}_\perp, \theta)$, namely,

$$F^{rs}(\mathbf{x}_\perp,\theta)\approx\frac{1}{4\pi}\int d\psi\frac{|\nabla\mathcal{T}^{rs}|^2}{\sum_n\mathcal{A}_n^{rs}\mathcal{A}_n^{rs}}\sum_n\mathcal{A}_n^{rs}v_n^{rs}(\mathbf{x}'_\perp,p_2,t=\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)) \quad [39]$$

Here, we have, for brevity, defined the composite quantities

$$\begin{aligned} \mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp) &= \tau^r(x_3)+\tau^s(\mathbf{x}_\perp,\mathbf{x}'_\perp)\quad \mathcal{A}_n^{rs} \\ &= A^r(x_3)A^s(\mathbf{x}_\perp,\mathbf{x}'_\perp,p_2)s_n^s(\mathbf{x}'_\perp) \end{aligned} \quad [40]$$

and have identified $\nabla\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)/|\nabla\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)|$ with $\mathbf{n}$. Thus, the integration variable ψ is the angle of $\nabla\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)$, that is,

$$\psi = a\tan\frac{\partial_3\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)}{\partial_1\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)} \quad [41]$$

and the scattered-wave field is represented through the time series

$$v_n^{rs}(\mathbf{x}'_\perp,p_2,t)=\mathcal{F}^{-1}\left\{\Delta u_n^{rs}(\mathbf{x}'_\perp,p_2,\omega)\frac{-\mathrm{isgn}(\omega)}{\sqrt{-\mathrm{i}\omega}}\right\} \quad [42]$$

The geometric relationships among the various quantities defined in the preceding text are illustrated in Figure 9. As for the 1-D case, we have assumed that we are able to separate the recorded wave field into its individual scattering mode (r, s) contributions $\Delta u_n^{rs}(\mathbf{x}'_\perp,p_2,\omega)$. From eqn [39], we note that the scattering potential can be approximately recovered as a weighted diffraction stack of filtered data $v_n^{rs}(\mathbf{x}'_\perp,p_2,t)$ over the isochronal travel-time curves. The form of filter $-\mathrm{isgn}(\omega)/\sqrt{-\mathrm{i}\omega}$ applied to the scattered-wave field data in eqn [42] stems from the plane-wave/2-D geometry and ensures that, for example, a step function perturbation is recovered in the case of a discontinuity in material properties. Recovery of $F^{rs}(\mathbf{x}_\perp, \theta)$ is, of course, an intermediate result from which we wish to resolve the individual material property perturbations $\Delta\mathsf{c}(\mathbf{x}_\perp)=[\Delta\alpha/\alpha\ \Delta\beta/\beta^0,\Delta\rho/\rho^0]^{\mathrm{T}}$. Exploiting the linear relation in eqn [35], this task is readily accomplished by assembling measurements of $F^{rs}(\mathbf{x}_\perp, \theta)$ for all available scattering interactions at a given model point within a column vector $\mathsf{f}(\mathbf{x}_\perp, \theta)$ and solving the trivial 3×3 system

$$\mathsf{f}(\mathbf{x}_\perp,\theta)=\mathsf{W}(\theta)\Delta\mathsf{c}(\mathbf{x}_\perp) \quad [43]$$

where, as in eqn [31], the row vectors constituting the matrix W represent radiation patterns for the various scattering-mode combinations r, s.

The main computational effort in this approach is expended in computing the weighted diffraction stack in eqn [39]. The appearance of $|\nabla\mathcal{T}^{rs}|^2$ as a weight in that equation corresponds to the factor $[p_3^s(x_3)+p_3^r(x_3)]$ in eqn [29] for the 1-D case. It represents the sensitivity of travel time to scatterer position and, as a product with frequency ω, governs the scale of resolution. For example, back-scattered modes, for which $|\nabla\mathcal{T}^{rs}|^2$ is in general large, possess better resolving capability than forward-scattered waves since a given change in scatterer position has a larger effect on timing of the scattered arrival (see, e.g., Rondenay et al., 2005). The direction of $\nabla\mathcal{T}^{rs}$, as quantified by dip angle ψ, controls the degree to which different structural dips can be resolved at a given model point. In contrast, material property resolution depends on the range of scattering angle θ afforded by the data and the different modal scattering sensitivities as represented through the radiation patterns (e.g., eqn [35]). Material property resolution may be analyzed through eigenvector decomposition of the matrix $\mathsf{W}^{\mathrm{T}}\mathsf{W}$ (e.g., Bostock and Rondenay, 1999; Forgues and Lambaré, 1992). Since teleseismic data are characterized by a limited range of θ, the simultaneous inversion of different scattering modes r, s affords the best prospects for discrimination of material properties.

In addition to the plane-wave, isotropic, 2-D oblique incidence geometry described in the preceding text, the generalized Radon transform treatment of the inverse-scattering problem has also been developed with point sources for acoustic waves (Miller et al., 1987), elastic waves in 3-D isotropic (Beylkin and Burridge, 1990), and anisotropic (Burridge et al., 1998) media. Like the 1-D case, these algorithms can be recast to recover singular functions of discontinuity surfaces (vs. Born-approximate perturbations), thereby accomplishing Kirchhoff-approximate inversion (Beylkin and Burridge, 1990; Bleistein, 1987; Bostock, 2002; de Hoop and Bleistein, 1997). In the teleseismic context, generalized Radon transform inversions have been strictly applied in a limited number of studies on subduction zones (Nicholson et al., 2005; Rondenay et al., 2001), Precambrian mobile belts (Poppeliers and Pavlis, 2003b; Rondenay et al., 2005), and the mantle transition zone (Liu and Pavlis, 2013).

If the weights in eqn [39] are ignored and otherwise normalized seismograms are simply stacked along move-out curves $t=\mathcal{T}^{rs}(\mathbf{x}_\perp,\mathbf{x}'_\perp)$, the formal parameter inversion is reduced to migration. Variants include migration via the Kirchhoff scattering integral (French, 1974; Schneider, 1978), which has been applied to the receiver (versus Green) functions with the aim of imaging (rather than inverting for) structure (e.g., Kind et al., 2002; Levander et al., 2005; Niu et al., 2005; Revenaugh, 1995; Sheehan et al., 2000; Wilson et al., 2005). All of the approaches mentioned in the preceding text can be classified as 'prestack' in that they deal directly with the individual Green function or receiver function data. Ryberg and Weber (2000) had described a teleseismic analogy to active source 'poststack' migration. This procedure involves normalizing teleseismic data to vertical incidence and stacking to produce a reduced data set, which can be readily processed using seismic reflection algorithms. Chen et al. (2005a) had built upon this poststack framework to develop a wave equation migration method that back propagates CCP stacked receiver functions into structural models and that has been applied to image the Japanese subduction zones (Chen et al., 2005b).

1.08.6 Beyond the Born Approximation

As argued in Sections 1.08.4 and 1.08.5, the tools of inverse scattering provide a framework for understanding many of the empirical approaches developed and employed over the past four decades to analyze scattered teleseismic wave fields in terms of lithospheric and upper mantle structure. In addition, the application of these techniques in recent years to multichannel data sets collected over, for example, plate boundaries, has led to new insights into the structures and dynamics of these complex regions that would have been difficult to achieve through a less complete analysis. As access to large numbers of instruments improves, it is possible that sampling of teleseismic wave fields may begin to approach that in exploration practice, allowing and prompting still more ambitious and complete treatments. Clearly, one approach is to employ fully numerical solutions (see Chapter 1.07) to model receiver-side scattering of teleseismic waves, and a number of authors have begun to investigate this route. Roecker et al. (2010) presented a spectral, finite-difference scheme to model plane-wave scattering in 2-D and demonstrated its incorporation within a waveform inversion using synthetic data. Monteiller et al. (2013) coupled 1-D global simulations with the spectral element method on a 3-D regional domain to compare numerical simulations with receiver function observations from the Pyrenees. As computational resources improve, regional waveform tomography employing, for example, adjoint methods (Tromp et al., 2005) will eventually become practical on a routine basis. An alternative approach to fully numerical treatments of the forward problem involves higher-order, nonlinear inverse scattering. We shall conclude this chapter by sketching out such a formulation, based on recent theoretical developments in reflection seismology, that would permit a nonlinear treatment of inverse scattering for teleseismic wave fields.

1.08.6.1 Shortcomings of the Born Approximation

Perhaps the most serious shortcomings of the methodologies heretofore described in Sections 1.08.4 and 1.08.5 lie in the linearization or 'Born approximation' made in eqn [18]. There are several negative consequences that follow from the Born approximation. First, as is widely appreciated, the reference medium must be sufficiently close to the real Earth to ensure that the phase of the wave fields is accurately represented. If not, images may become seriously distorted, usually through blurring, leading to reduced resolution and, worse, misinterpretation (see, e.g., Yilmaz, 2001). As researchers attempt to exploit higher frequencies in the teleseismic wave field (up to 10 Hz for teleseismic P generated by deep earthquakes), there will be increased need to improve reference velocity estimates.

A second drawback of the Born approximation is its failure to account for higher-order scattering in the form of multiple reflection/conversion. In reflection seismology, the most serious manifestation of multiple scattering is present in the form of free-surface multiples, which are order $O(\varepsilon^2)$ in amplitude. In the teleseismic context, the free-surface multiples are still larger ($O(\varepsilon)$) due to the transmission geometry as explained in Section 1.08.3.2 and have presented that a major impediment to lithospheric imaging due to the arrival of multiple signals from the Moho during the same time interval that directs conversions from the shallow mantle (say, 100–250 km depth) would be expected. Using formal inversion approaches, the multiples can be accommodated to varying degrees through the simultaneous inclusion of both direct and free-surface-reflected waves within the incident-wave field $u_i^0(\mathbf{x},\omega)$ as in eqn [19]. If, however, as we have advocated in coming to solutions for eqns [31] and [43], the approximation $\Delta u^{rs}(\mathbf{x},\ \omega)\approx\Delta u(\mathbf{x},\ \omega)$ is made for each mode combination r,s, this accommodation is incomplete and artificial structures resulting from misidentification of one scattering mode for another will occur (e.g., Shragge et al., 2001). Most studies based on diffraction stacking have implicitly adopted the $\Delta u^{rs}(\mathbf{x},\ \omega)\approx\Delta u(\mathbf{x},\ \omega)$ assumption for computational expedience. The advantage, as exemplified in the generalized Radon transform approach of the previous section (cf. eqn [43]), is that the matrix $\mathbf{W}^{\mathrm{T}}\mathbf{W}$ is block-diagonal in structure leading to solution of a small (rank equivalent to number of material parameters considered) linear system for each spatial location within the model. If we choose, instead, to include both forward- and back-scattered (multiples) waves simultaneously and avoid the latter approximation, the Hessian becomes block-band-diagonal and computational expense increases dramatically. This latter approach is feasible using sparse matrix techniques, especially in 2-D, but to our knowledge has yet to be applied.

Notwithstanding the viability of simultaneously including the direct-wave and free-surface reflections within the definition of $u_i^0(\mathbf{x},\omega)$, there is reason to consider a formal decomposition of the observed field, $\Delta u_i(\mathbf{x},\ \omega)$, into individual scattering modes, $\Delta u_i^{rs}(\mathbf{x},\omega)$. Motivation for this line of thought stems from recent progress in reflection seismology by Weglein and coworkers (Matson, 1997; Weglein et al., 1997, 2003) and Wapenaar et al. (2004). Weglein's group has demonstrated that a sequential, task-driven approach, which includes isolation and removal of free-surface reflections, results in a better-posed, nonlinear treatment of the inverse-scattering problem within the seismic reflection context. Moreover, Wapenaar et al. had developed a theoretical framework based on correlational reciprocity (Bojarski, 1983) that allows the transformation of transmission (earthquake) data into reflection data, thereby effectively accomplishing the scattering-mode decomposition and allowing, in principle, the inversion of transmission data with reflection algorithms. In the following two subsections, we shall outline these procedures in more detail.

1.08.6.2 The Inverse-Scattering Series

Weglein and coworkers adopt operator-series representations to address both the forward- and inverse-scattering problems. The operator notation is convenient because it is largely independent of geometry and model type and affords a succinct summary of the main arguments. For further detail and background, the reader is referred to Weglein et al. (2003).

We begin with the operator form of the Lippman–Schwinger equation [15]:

$$\mathcal{U}=\mathcal{G}-\mathcal{G}^0=\mathcal{G}^0\mathcal{V}\mathcal{G} \qquad [44]$$

where we define $\mathcal{U}$ to be the data generation operator and $\mathcal{G}$ and $\mathcal{G}^0$ are the Green operators for the true Earth and reference

medium, respectively, that act on a given force distribution $f_i(\mathbf{x}, \omega)$ to produce a vector wave field. For example, in the teleseismic context, the scattered-wave field (cf. eqn [15]) can be written

$$\begin{aligned}\Delta u_i(\mathbf{x}, \omega) &= \mathcal{U}\{f_i\} = \mathcal{G}\{f_i\} - \mathcal{G}^0\{f_i\} \\ &= \int d\mathbf{y} \left[G_{ij}(\mathbf{x}, \mathbf{y}, \omega) - G^0_{ij}(\mathbf{x}, \mathbf{y}, \omega)\right] f_j(\mathbf{y}, \omega) \end{aligned} \quad [45]$$

where, as before, $G^0_{ij}(\mathbf{x}, \mathbf{y}, \omega)$ is the Green function for the reference medium (e.g., eqns [20] and [32] for laterally homogeneous reference media with 1-D and 2-D source geometries, respectively, in the high-frequency approximation); $G_{ij}(\mathbf{x}, \mathbf{y}, \omega)$ is the unknown Green function of the true Earth; and f_i then represents the force distribution that gives rise to upgoing, planar *P*- or *S*-wave fields in the absence of heterogeneity. The differential operator $\mathcal{V}$ includes the action of the material property perturbations and can be written as

$$\mathcal{V} = \partial_j \Delta c_{ijkl} \partial_k + \Delta \rho \omega^2 \delta_{il} \quad [46]$$

Note that eqn [44] implies $\mathcal{G} = \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V} \mathcal{G}$ and so by successive insertion, we recover the forward-scattering series:

$$\mathcal{U} = \mathcal{G}^0 \mathcal{V} \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V} \mathcal{G}^0 \mathcal{V} \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V} \mathcal{G}^0 \mathcal{V} \mathcal{G}^0 \mathcal{V} \mathcal{G}^0 + \cdots \quad [47]$$

From the RHS of eqn [47], we note that $\mathcal{G}$ is not required to solve the forward problem; that is, knowledge of $\mathcal{G}^0\{f_i\}$ is sufficient to recover $\mathcal{U}\{f_i\}$, if $\mathcal{V}$ is given.

The goal of the inverse problem is to isolate the scattering operator $\mathcal{V}$ (and from it Δc_{ijkl}, $\Delta\rho$) from the data generation operator $\mathcal{U}$ as represented by the data $\Delta u_i(\mathbf{x}, \omega)$ in eqn [45] using, again, knowledge of $\mathcal{G}^0$ alone. The inverse-scattering series solution represents $\mathcal{V}$ in series form as

$$\mathcal{V} = \mathcal{V}_1 + \mathcal{V}_2 + \mathcal{V}_3 + \mathcal{V}_4 + \cdots \quad [48]$$

where the individual terms are organized in orders of the data $\mathcal{U}$. Inserting eqn [48] within [47] allows one to solve for these terms explicitly. For example, the first three equations are

$$\begin{aligned}\mathcal{U} &= \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \\ 0 &= \mathcal{G}^0 \mathcal{V}_2 \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \\ 0 &= \mathcal{G}^0 \mathcal{V}_3 \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V}_2 \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \mathcal{V}_2 \mathcal{G}^0 + \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \mathcal{V}_1 \mathcal{G}^0 \end{aligned} \quad [49]$$

where we have used the fact that $\mathcal{U}$ is, by definition, first order in itself. In principle, these equations can be solved sequentially, first for $\mathcal{V}_1$, then for $\mathcal{V}_2$, and so on. Note that $\mathcal{V}_1$ is just the Born-approximate solution to the inverse problem, which may or may not accurately represent the true Earth (i.e., $\mathcal{V}$) depending on the proximity of $\mathcal{G}^0$ to $\mathcal{G}$.

Blind application of the series solution to raw data is marred by poor convergence properties and thus does not afford a practical solution to the inverse-scattering problem. Rather, Weglein et al. advocated that a 'subseries' approach be taken whereby sets of terms in the inverse series are identified with specific tasks and a sequential application is performed. This sequence of tasks is, namely, (i) removal of free-surface multiples, (ii) removal of internal multiples, (iii) imaging of scatterer location, and (iv) material property recovery. It has been noted that tasks (i) and (ii) can be effectively performed with absolutely no knowledge of the underlying velocity structure and with excellent convergence properties. Tasks (iii) and (iv) are the topic of current research and early results show promise (Weglein et al., 2002).

The relevance of the latter work to the teleseismic problem is twofold. First, it indicates that a sequential treatment that proceeds from multiple removal through material property inversion is likely to be better-posed than simultaneous solution. Second, as we sketch out in the succeeding text, it is possible, at least in principle, to transform the teleseismic transmission problem directly into a reflection problem such that the inverse-scattering series, as developed for exploration purposes, is then directly applicable.

1.08.6.3 Transmission to Reflection

Perhaps the most direct way of isolating individual scattering modes $\Delta u_i^{ts}(\mathbf{x}, \omega)$ is to consider reformulating the transmission problem as a reflection problem. Motivation for this concept stems from early work of Claerbout (1968) who demonstrated a relationship between the transmission response of a layered acoustic half-space and its reflection response. For precritical, energy flux-normalized elastic waves in 1-D media, this relation can be written

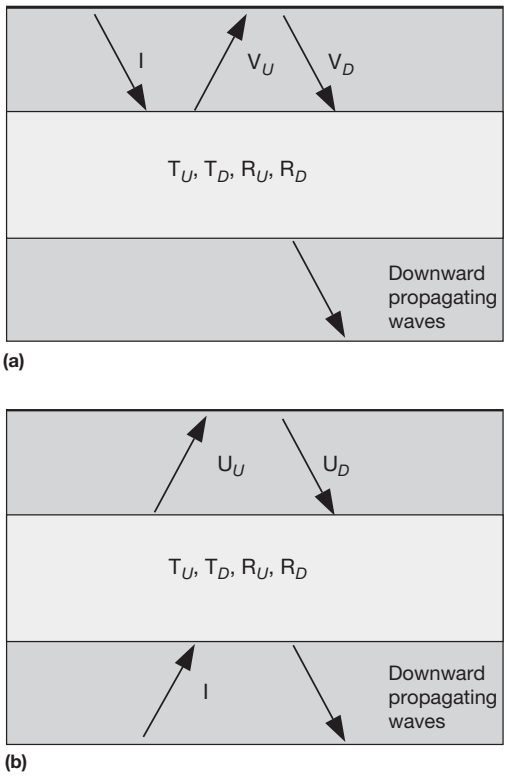

Figure 10 Geometric definition of quantities relevant to the transformation of transmission wave fields to reflection wave fields. (a) Reflection experiment: An incident-wave field (I) interacts with stratification from the preceding text to produce an upgoing wave field V_U and a downgoing wave field V_D at the Earth's free surface. (b) Transmission experiment: In this case, direct wave (I) is incident on stratification from below and produces upgoing (U_U) and downgoing (U_D) wave fields at the free surface.

$$\mathbf{U}^{*}\mathbf{U}^{\mathrm{T}} = \mathbf{I} + \mathbf{R}\mathbf{V} + \mathbf{V}^{\mathrm{H}}\mathbf{R}^{\mathrm{H}} \qquad [50]$$

where $\mathbf{U} = \mathbf{U}(\omega, \mathbf{p}_{\perp})$ is the 3×3 matrix of eqn [8] containing the transmission response for different modes incident upon the base of a stratified half-space bounded in the preceding text by free surface, $\mathbf{V} = \mathbf{V}(\omega, \mathbf{p}_{\perp})$ represents the corresponding reflection response for the same medium to different modes incident from earlier, $\tilde{\mathbf{R}} = \tilde{\mathbf{R}}(\mathbf{p}_{\perp})$ is the free-surface reflection matrix, I is the identity matrix, and $^{\mathrm{H}}$ denotes conjugate transpose. The two geometric configurations are illustrated in **Figure 10**.

Recall that complex conjugation in the frequency domain is equivalent to time reversal and that the inverse Fourier transforms of the elements of U and V are causal functions. Accordingly, each element on the left-hand side of eqn [50] represents, in the time domain, a sum of cross correlations and equates to the sum of a causal function $\left(\mathcal{F}^{-1}\left\{\tilde{\mathbf{R}}\mathbf{V}\right\}\right)$, an acausal function $\left(\mathcal{F}^{-1}\left\{\mathbf{V}^{\mathrm{H}}\tilde{\mathbf{R}}^{\mathrm{H}}\right\}\right)$ and, for diagonal elements, an impulse $\left(\mathcal{F}^{-1}\{\mathbf{I}\}\right)$ at zero lag. The time-domain reflection response $\mathcal{F}^{-1}\{\mathbf{V}\}$ can therefore be recovered by applying $\tilde{\mathbf{R}}^{-1}$ to $\mathcal{F}^{-1}\{\mathbf{U}^{*}\mathbf{U}^{\mathrm{T}}\}$ upon zeroing negative lags where, as in eqn [2], we have assumed that the near-surface material properties (and hence $\tilde{\mathbf{R}}$) are known. Since the individual elements of $\mathcal{F}^{-1}\{\mathbf{V}\}$ represent the reflection response of the stratified half-space to a separate incident mode, an isolation of different, first-order ($O(\varepsilon)$) modal interactions to individual components has therefore been achieved. **Figure 11** shows the result of this procedure applied to data from station HYB by Kumar and Bostock (2006) who outline a practical recipe for its implementation.

Note that the effect of the free surface is still included within V in as far as $O(\varepsilon^2)$ and higher-order, free-surface-related multiples are contained therein. The first step of the inverse-scattering series scheme involves removing these multiples. For 1-D, we accomplish this task by writing

$$\mathbf{V} = \mathbf{R}_D\left(\mathbf{I} - \tilde{\mathbf{R}}\mathbf{R}_D\right)^{-1} \qquad [51]$$

where we have, once more, employed the notation of Kennett (1983) and used $\mathbf{R}_D$ to denote the reflection matrix for the stratification alone (no free surface included). Reorganizing and solving for $\mathbf{R}_D$ using successive insertion leads to the series solution:

$$\mathbf{R}_D = \mathbf{V} - \mathbf{V}\tilde{\mathbf{R}}\mathbf{V} + \mathbf{V}\tilde{\mathbf{R}}\mathbf{V}\tilde{\mathbf{R}}\mathbf{V} - \mathbf{V}\tilde{\mathbf{R}}\mathbf{V}\tilde{\mathbf{R}}\mathbf{V}\tilde{\mathbf{R}}\mathbf{V} + \cdots \qquad [52]$$

Subsequent steps, including multiple elimination, spatial imaging, and material property recovery, are more involved, and the reader is referred to Weglein et al. (2003) for details and discussion.

The theory describing extension of the transmission-to-reflection transformation to multiple dimensions has recently been developed by Wapenaar et al. (2004) by exploiting correlational and convolutional reciprocity. Accordingly, the 3-D extension to eqn [50] expressed in the spatial (vs. slowness) domain becomes

$$\int_{Z} \mathrm{d}\mathbf{x}\,\mathbf{U}^{*}\left(\mathbf{x}'_A, \mathbf{x}, \omega\right)\mathbf{U}^{\mathrm{T}}\left(\mathbf{x}'_B, \mathbf{x}, \omega\right) = \mathbf{I}\delta\left(\mathbf{x}'_A - \mathbf{x}'_B\right) + \tilde{\mathbf{R}}\mathbf{V}\left(\mathbf{x}'_A, \mathbf{x}'_B, \omega\right) + \mathbf{V}^{\mathrm{H}}\left(\mathbf{x}'_A, \mathbf{x}'_B, \omega\right)\tilde{\mathbf{R}}^{\mathrm{H}} \qquad [53]$$

where, as before, the primed coordinates are located at the free surface, the surface integral over horizontal coordinate $\mathbf{x}$ is

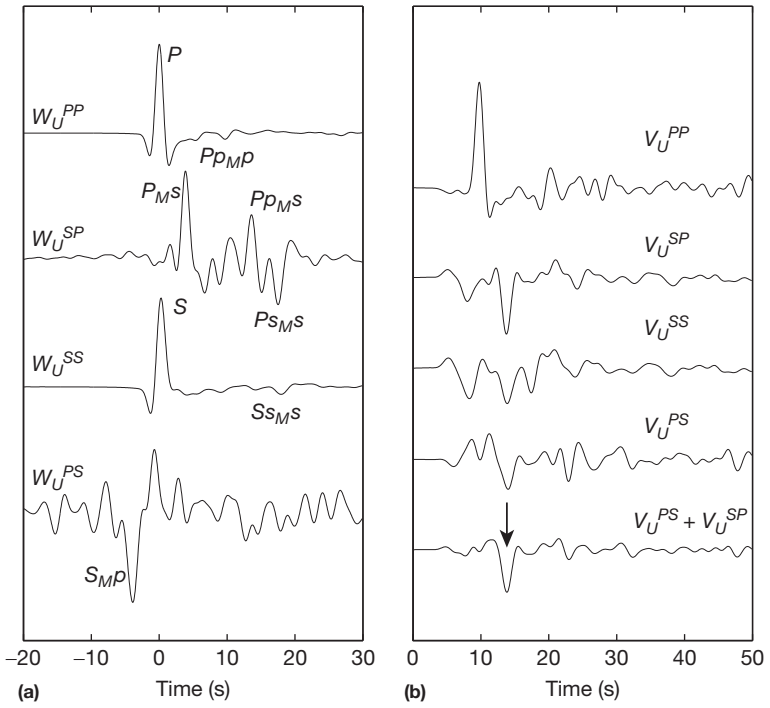

Figure 11 Transmission to reflection transformation of data from HYB (reproduced from Kumar MR and Bostock MG (2006) Transmission to reflection transformation of teleseismic wavefields. *Journal of Geophysical Research* 111: B08306). (a) Input transmission data. Components W_U^{PP} and W_U^{SP} were computed from teleseismic *P* data shown in **Figure 5** over the slowness range 0.04–0.0575 s km^{-1}, whereas components W_U^{PS} and W_U^{SS} were computed from *SKS* recordings over the same range. (b) Transformed reflection response. Note that bottom trace is computed as sum of $V_U^{PS} + V_U^{SP}$ since these two traces should, by reciprocity, be equivalent. Arrow indicates the reflection–conversion from the continental Moho.

evaluated at some depth Z below the heterogeneity, and the dependencies indicate that, for example, $\mathbf{V}(\mathbf{x}_A', \mathbf{x}_B', \omega)$ is the upgoing wave field recorded at surface location $\mathbf{x}_A'$ due to a source at surface location $\mathbf{x}_B'$, at frequency ω. Likewise, the multidimensional equivalent of eqn [51] can be written as

$$\mathbf{V}(\mathbf{x}_A', \mathbf{x}_B', \omega) = \mathbf{R}_D(\mathbf{x}_A', \mathbf{x}_B', \omega) + \int d\mathbf{x}' \mathbf{R}_D(\mathbf{x}_A', \mathbf{x}', \omega) \widetilde{\mathbf{R}} \mathbf{V}(\mathbf{x}', \mathbf{x}_B', \omega) \quad [54]$$

The extension to multiple dimensions thus places greater demands on data by requiring the evaluation of surface integrals within certain depth ranges. It remains to be seen whether these demands can be accommodated through data interpolation/extrapolation in the teleseismic context where seismicity is sparse and irregularly distributed.

1.08.7 Conclusions

Over the past few decades, scattered teleseismic body waves have contributed greatly to our understanding of crust and mantle structure (see, e.g., **Chapters 1.16**, **1.21** and **1.24**). They possess higher resolving capability for small-scale structure than other elements of the global seismic wave train and do not suffer from the shallow depth sampling that limits active source seismic surveys. In this chapter, we have provided an overview of methodologies used to extract receiver-side structural information from the scattered teleseismic wave fields. These methodologies address two fundamental issues: (1) the isolation of structural signal from earthquake source signature and (2) the translation of structural signals into Earth models. The identification, in early practice, of source-free transfer functions formed by simple ratios of vector component waveforms has gradually given way in more recent work to better approximations to the true Earth 'Green function,' thereby extending sensitivity to the Earth's material parameters. In a like manner, the processing of these structural signals using empirical delay-and-sum approaches has progressed in the last few years to formal inversion where quantitative material property separation is, at least in principle, possible. These technological advances have brought analysis of scattered teleseismic waveforms in line with modern reflection seismic signal processing. In fact, as we have attempted to illustrate in the previous section, it is now possible to contemplate unified reflection/transmission approaches to the inverse-scattering problem. An important future challenge in application to global seismology will be to overcome the sparse sampling imposed by earthquake source distributions and current inventories of instrumentation.

1.09.1 Introduction

Elastic anisotropy occurs when the relationship between stress and strain in a material depends on its orientation. Rotate an applied stress, and the strain response will differ. Seismic anisotropy is how elastic anisotropy influences propagating seismic waves. Wave speed and scattering will depend on the azimuth of propagation. Intrinsic anisotropy characterizes many common minerals in Earth rocks, by virtue of atomic structure. Cubic-lattice minerals, such as garnet, often exhibit little or no elastic anisotropy. Sheet-silicate minerals, such as mica, can exhibit extreme anisotropy, with directional differences in shear and compressional response of 20% or more. Despite the extreme anisotropy of individual minerals, the bulk anisotropy of a rock will vanish if its minerals are randomly oriented. Bulk anisotropy can develop as a rock either forms or deforms, if its minerals orient preferentially (Hansen et al., 2011; Jung and Karato, 2001; Ribe, 1989), cracks or melt pockets develop within the rock and become mutually aligned (Holtzman et al., 2003; Siegesmund et al., 1991b), or other mechanisms break the rock's internal symmetry (Nowacki et al., 2011).

An anisotropic material has physical properties that depend on direction, whereas a heterogeneous material has properties that depend on location. Whether Earth's subsurface appears heterogeneous or anisotropic is often a matter of the scale at which we analyze its properties. At small scale, alternating layers of isotropic stiff and soft material would be observed as a heterogeneous medium. At large scale, seismic waves respond to thin layers as a homogeneous anisotropic material (Backus, 1962). If seismic waves exert a unidirectional compression on such a stack, the deformation will be different if the compression is perpendicular to the layering or in the plane of the layering. A medium that is isotropic at the scale of a hand sample of rock but exhibits an ordered texture within a seismic wavelength (>100 m) is an 'effective' anisotropic medium.

By themselves, seismic observations cannot distinguish between 'intrinsic,' 'bulk,' and 'effective' anisotropies. A correct description at large scale of any heterogeneous structure that is not randomly heterogeneous in an isotropic way should include anisotropy (Capdeville and Marigo, 2007). What we infer from seismic observations is large-scale anisotropy. A range of structures can, in principle and at first order, explain this anisotropy. A priori information from mineral physics, geodynamics, or surface lithology is necessary to narrow our interpretation.

Layering and preferred orientations of anisotropic minerals are common in the Earth's interior (see Mainprice, **Chapter 2.20**). Seismic anisotropy is therefore present at different scales and in many different settings. Excellent reviews of seismic anisotropy in exploration and reservoir seismics can be found in Tsvankin et al. (2010) and Helbig and Thomsen (2005), the latter offering a historical perspective. Teleseismic earthquake waves have lower frequency and longer wavelength than waves generated for resource exploration and are more likely to respond to the effective anisotropy of fine-layering and similar

heterogeneities. We review here the basic theoretical tools available in seismology to analyze wave propagation in anisotropic structures, earthquake observations sensitive to anisotropy, and their geodynamic implications.

1.09.2 Basic Theory of Seismic Anisotropy

1.09.2.1 Basic General Theory

The fundamentals of seismic-wave propagation in anisotropic media have been described in several papers and books, and we will only highlight them here. For more details, we refer to Crampin (1981), Garmany (1989), Babuska and Cara (1991), and Chapman (2004), for example.

In anisotropic media, seismic wave speed varies with propagation direction and S waves split into two shear waves with different velocities, a behavior called birefringence. A more subtle anisotropic behavior is that wave polarizations do not align parallel or perpendicular to the propagation direction and that phase and group velocities are not parallel, aside from exceptional cases.

Let us see briefly how these behaviors arise in a linear elastic medium. The elastic tensor c_{ijkl} relates the stress tensor elements τ_{ij} to the strain tensor elements e_{kl} linearly:

$$\tau_{ij} = c_{ijkl} e_{kl} \qquad [1]$$

An alternative to the elastic tensor is the compliance tensor s_{ijkl}, which computes the strain tensor e_{ij} as a linear function of the stress tensor τ_{kl}.

The equation of motion for a plane wave $\vec{u}\left(\vec{x},t\right) = \vec{a}\, f\left(\vec{n}\cdot\vec{x} - ct\right)$ propagating with velocity c in direction $\vec{n}$ in a uniform medium of density ρ can be written as

$$\frac{c_{ijkl}}{\rho} n_j n_k a_l = c^2 a_i \qquad [2]$$

The term $(c_{ijkl}/\rho)n_j n_k$ on the LHS is the 3×3 Christoffel matrix, which plays a central role in anisotropic wave propagation. Solving [2] for $\vec{a}$ and c is equivalent to finding the three eigenvalues and eigenvectors of the Christoffel matrix. In the general case, the three eigenvalues are distinct, leading to three waves with three different velocities in the propagation direction $\vec{n}$. The polarizations of the three waves, given by the eigenvectors, are perpendicular to each other, but are in directions that, unlike the isotropic case, may deviate from ray-based coordinates. In strongly anisotropic media, the three waves' polarizations may hybridize so that one cannot label them confidently as P or S wave.

For weak anisotropy, the waves separate into one quasi-P wave, with the highest velocity and a polarization near-parallel to the propagation direction $\vec{n}$, and two quasi-S waves. Aside from singular cases, the quasi-S waves have distinct velocities and polarization directions perpendicular to each other in a plane near perpendicular to the propagation direction $\vec{n}$. Shear-wave splitting occurs because any S wave entering the anisotropic medium sees its particle motion projected onto the polarization directions of the two quasi-S waves, which then propagate at different velocities (**Figure 1**). Once splitting has occurred, it is carried along by the S wave even after leaving the anisotropic region.

Since the Christoffel matrix depends on the components of $\vec{n}$, the waves' speeds and polarizations vary with propagation plunge and azimuth. Due to this angular dependence, wavefronts are not spherical in homogeneous anisotropic media. The vector $\vec{n}$ defines the direction of the phase propagation and is perpendicular to the wavefront. Wave energy follows another direction, defined by the group velocity direction $\vec{V}$. In homogeneous media, the group velocity follows a straight path from the wave's origin to the wavefront, as shown in **Figure 2**. The difference between the phase and group velocities depends on the curvature of the wavefront through the relation

$$\vec{V} = \vec{C} + \partial\vec{C}/\partial\theta \qquad [3]$$

where θ is the azimuth angle and $\vec{C} = c\,\vec{n}$.

Depending on the elastic tensor and on the strength of the anisotropy, wavefronts can get quite complicated. Shear waves in particular can get folds and cusps, as those shown in **Figure 3**, which displays the wavefield at three different propagation times for an ultrasonic S wave propagating through a silicon crystal. Details about the experiment and other examples can be found in Wolfe (1998).

These characteristics of wave propagation in uniform anisotropic media also occur in more complex structures. All the classical modeling methods in nonuniform structures like ray theory, WKBJ, and reflectivity have been extended to account

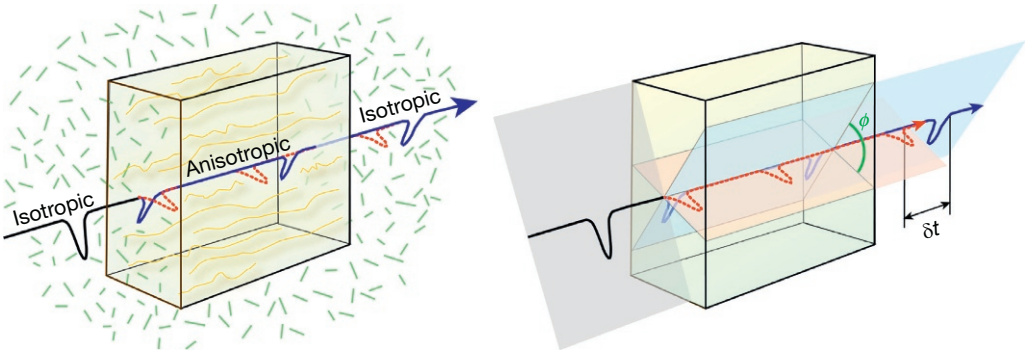

Figure 1 Principle of shear-wave birefringence. The leftmost figure shows the evolution with time of the polarization of an S wave (in black) that traverses a block of anisotropic medium. When the wave enters the anisotropic part, it splits into a fast S wave (in blue) and a slow one (in red). When the fast and slow waves leave the anisotropic regions, they are separated by a time delay. The rightmost figure shows how the initial polarization of the S wave is projected onto the planes of the fast and slow waves in the anisotropic structure. Figure courtesy of Ed Garnero.

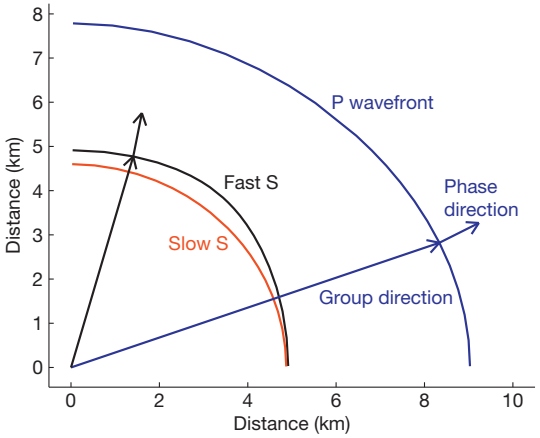

Figure 2 Wavefronts of the P wave (blue), the fast S wave (black), and the slow S wave (red) in pyrolytic material with 59% olivine (Estey and Douglas, 1986), after 1 s of propagation from a source located at the origin. The *a*-axis of the olivine is oriented along the horizontal direction and the *c*-axis along the vertical direction. The directions of the phase velocity (perpendicular to the wavefront) and of the group velocity (from the origin) are indicated at two locations of the wavefronts.

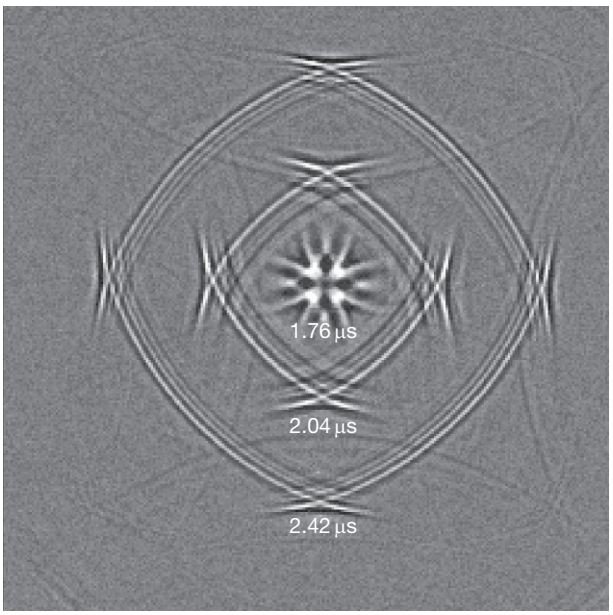

Figure 3 Snapshot of the wavefield of an ultrasonic shear wave that has propagated through a silicon crystal, recorded at three times after excitation on the other side of the crystal. Details can be found in Wolfe (1998). Photo is courtesy of J.P. Wolfe.

for anisotropy and its distinctive features (Cerveny, 1972; Fryer and Fraser, 1984; Garmany, 1988). Recent work focuses on improving the efficiency of the methods and their domains of applications, as we shall see later in the text. The elastic tensor describes the properties of any anisotropic material and we need first to analyze it in more detail.

1.09.2.2 Different Parameterizations of the Elastic Coefficients

The elastic tensor has the following symmetries:

$$c_{ijkl} = c_{jikl} = c_{ijlk} = c_{klij} \qquad [4]$$

resulting in 21 independent coefficients in the fully anisotropic case. These symmetries can be exploited to define a more convenient symmetrical 6×6 matrix, called Voigt notation, derived from c_{ijkl} using the following correspondence between ij and m and between kl and n:

$$(11):1 \quad (22):2 \quad (33):3 \quad (23) \text{ or } (32):4$$
$$(13) \text{ or } (31):5 \quad (12) \text{ or } (21):6 \qquad [5]$$

It should be noted that C_{mn} is not a tensor but that, as explained by Chapman (2004), it is possible to rotate it to a different coordinate system using a 6×6 Bond-transformation matrix without having to go back to the physical c_{ijkl} tensor (Auld, 1973).

In a laboratory, the elasticity of minerals and rocks can be measured in all orientations and all 21 coefficients determined (see Stixrude and Jeanloz, **Chapter 1.26**). Our resolution of the Earth's anisotropy is limited, and seismic-wave observations do not feasibly constrain all 21 independent elastic coefficients. Symmetry in the elastic tensor reduces the number of independent coefficients to a number that can be more easily estimated with seismic waves, at least in theory. Materials with orthorhombic symmetry, such as olivine, have nine independent coefficients, three of which specify the principal coordinate axes of the material. $9-3=6$ Parameters remain to specify the strength and the 'shape' of the elastic tensor c_{ijkl} or of the Voigt notation matrix C_{mn}. A further simplification of the anisotropy posits an axis of cylindrical symmetry (equivalent to hexagonal symmetry). Several realistic models for the Earth's anisotropy, such as fine layering and uniformly aligned penny-shaped or elongated cracks, predict this kind of symmetry. In addition, olivine crystals, which are a dominant contributor to anisotropy in the upper mantle, often undergo lattice-preferred orientation (LPO) within deforming rocks that favors aggregate anisotropy with hexagonal symmetry. Anisotropy with a cylindrical axis of symmetry is also called transverse isotropy (TI) because the solid is isotropic with respect to rotations about the symmetry axis. A general TI medium can of course have the symmetry axis in any direction and uses five free parameters to specify the strength and shape of the elastic tensor. In many applications, the axis is assumed to be either horizontal TI (HTI) or vertical TI (VTI). A tilted TI (TTI) symmetry axis perturbs seismic waveforms more strongly than HTI or VTI anisotropy, but its effects are harder to interpret.

Different notations are used to characterize anisotropic solids, and the diversity can suggest that anisotropy is more complicated than it actually is. It is impossible here to review all the notations, but we introduce the principal conventions and their relation to each other. The simplest notation for a TI medium is the so-called Love notation, where the five independent elastic coefficients are noted A, C, F, L, and N, leading to the following C_{mn} when the symmetry axis is along axis 3:

$$\begin{pmatrix} A & (A-2N) & F & 0 & 0 & 0 \\ (A-2N) & A & F & 0 & 0 & 0 \\ F & F & C & 0 & 0 & 0 \\ 0 & 0 & 0 & L & 0 & 0 \\ 0 & 0 & 0 & 0 & L & 0 \\ 0 & 0 & 0 & 0 & 0 & N \end{pmatrix} \quad [6]$$

In the isotropic case with Lamé parameters λ and μ, A and C reduce to $\lambda+2\mu$, F reduces to λ, and L and N reduce to μ.

Instead of the elastic coefficients themselves, some authors use velocities, exploiting the simple expressions for P- and S-wave velocities along symmetry axes:

$$\alpha_{\perp} = \sqrt{A/\rho} \quad [7]$$

$$\alpha_{\parallel} = \sqrt{C/\rho} \quad [8]$$

$$\beta_{\parallel} = \sqrt{L/\rho} \quad [9]$$

$$\beta_{\perp} = \sqrt{N/\rho} \quad [10]$$

For P waves, the subscripts $\parallel$ and $\perp$ refer to the propagation direction with respect to the symmetry axis, but for S waves, have a slightly more complex meaning (see **Figure 4**). $\beta_{\parallel}$ is the velocity of waves that propagate along the symmetry axis or in the plane normal to it and polarized parallel to the symmetry axis. $\beta_{\perp}$ is the velocity of waves propagating and polarized in the plane perpendicular to the symmetry axis. When the symmetry axis is vertical, $\parallel$ reduces to v, for *vertical*, and $\perp$ to H, for *horizontal*. F has no direct relation to a simple velocity expression. It is common to substitute $\eta = F/(A-2L)$ as the fifth parameter, in place of F.

A more direct measure of anisotropic strength can be achieved by using A and L as references. The two reference velocities are then $\beta = \sqrt{L/\rho}$ and $\alpha = \sqrt{A/\rho}$. Note that β and α are not the mean velocities of the structure. The degree of anisotropy appears explicitly in the deviation from 1.0 of $\xi = N/L$, $\phi = C/A$, and $\eta = F/(A-2L)$. This definition of the three coefficients is by the far the most common one, but one should be aware that some authors use other definitions of these parameters. For example, Beghein and Trampert (2003) defined $\xi = 1 - N/L$ and similarly for ϕ and η.

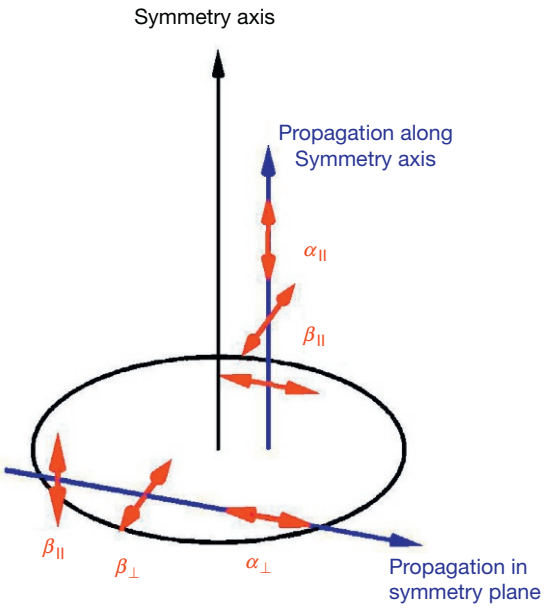

Figure 4 Velocities of P and S waves along the symmetry axis and in the symmetry plane of a transverse isotropic medium. The medium is depicted in black. The wave-propagation directions are in blue and the polarizations corresponding to the different velocities in red.

Seismic-exploration geophysicists use some variants of the coefficients as defined by Thomsen (1986). In seismic exploration, the dominant wave-propagation direction is vertical. Assuming a vertical axis of symmetry, Thomsen (1986) defined the reference-wave velocities as those of vertically traveling waves $\beta_0 = \sqrt{L/\rho}$ and $\alpha_0 = \sqrt{C/\rho}$ and the three coefficients measuring anisotropy as

$$\varepsilon = (1/\phi - 1)/2 \quad [11]$$

$$\gamma = (\xi - 1)/2 \quad [12]$$

$$\delta = (F+L)^2 - (F+L)^2/2C(C-L) \quad [13]$$

He showed that ε and γ, respectively, measure the difference in velocity between horizontally and vertically propagating P and SH waves, respectively. The parameter δ is a combination of ϕ and η from the previous notation. In weakly anisotropic media, δ controls the deviation from sphericity of the P wavefronts close to vertical propagation. Despite its subtle impact, δ is an important quantity in exploration geophysics.

Rocks are aggregates of different crystals. How different anisotropic crystals combine to produce a large-scale anisotropic material is not simple, and the exact result depends in particular on the shape of the crystals and not only on their elastic coefficients. For practical purposes, one evaluates the elastic coefficients of composite materials without knowledge of their detailed geometry. The simplest algorithm is a linear average of the elastic coefficients of the material components. This is called the Voigt average, which corresponds to the effective stiffness if all crystals undergo identical strain. Alternatively, a composite elastic tensor based on a linear average of crystal compliances is called the Reuss average, which would be accurate if all crystals experience identical stress. The mean of these two extreme averages is the Voigt–Reuss–Hill average, which typically is more accurate. Mechanical engineers have derived the so-called Hashin–Shtrikman bounds on the elastic properties of composite materials with two, three, or more components with known elastic properties (Watt and Peselnick, 1980), and these can be applied to the elasticity of rocks on scales from a hand sample to a layered intrusion.

Defining the isotropic-average properties of an anisotropic material also depends on the way the averaging is done. The Voigt averaging method takes a linear average of the elastic coefficients over all rotations in space. A TI material has the following isotropic-mean values in the Voigt average:

$$\mu = (A + C - 2F + 6L + 5N)/15 \quad [14]$$

$$\lambda + 2\mu = (8A + 3C + 4F + 8L)/15 \quad [15]$$

This implies that the isotropic-mean S wave speed depends partly on the P-wave speed parameters A and C. Since the Voigt average is an approximation based on geometric simplicity rather than physics, it is defensible to use simpler expressions for the mean velocities. The two common expressions for S waves are $(V_{SH} + V_{SV})/2$ and $(V_{SH} + 2V_{SV})/3$. Which formula

is used is not critical as long as one compares consistent quantities. Ekstrom and Dziewonski (1998) showed how discrepancies among global models have arisen because their S wave speeds were based on different datasets, shifting the weighting of SH and SV waves.

In seismology, the term TI is sometimes restricted to VTI models with a vertical axis of symmetry, but the term applies to more general orientations of the symmetry axis. Any elastic tensor can be separated into a transverse isotropic component, in the form of expression [6], corresponding to the azimuthal average of the model, plus deviations from this transverse isotropic mean, which are directly related to the azimuthal variations of the wave's velocities. This notation is particularly useful for surface-wave analysis, where the vertical direction singles out quite naturally, or for body waves propagating in the horizontal plane. Crampin (1981) showed that, in structures with a horizontal plane of symmetry, the azimuthal velocity variations of body waves propagating in the horizontal plane depend on the following combinations of elastic coefficients:

$$B_c = (C_{11} - C_{22})/2 \quad [16]$$

$$B_s = C_{16} + C_{26} \quad [17]$$

$$G_c = (C_{55} - C_{44})/2 \quad [18]$$

$$G_s = C_{54} \quad [19]$$

$$H_c = (C_{13} - C_{23})/2 \quad [20]$$

$$H_s = C_{36} \quad [21]$$

$$C_c = (C_{11} + C_{22} - 2C_{12} - 4C_{66})/8 \quad [22]$$

$$C_s = (C_{16} - C_{26})/2 \quad [23]$$

with a *c*-index for the coefficients associated with $\cos 2\theta$ and $\cos 4\theta$ velocity variations and an *s*-index for those associated with $\sin 2\theta$ and $\sin 4\theta$ variations. At first order in anisotropy, these combinations are also those that control the azimuthal variations of the body waves propagating horizontally in more general anisotropic structures (Leveque et al., 1998) and the variations of surface-wave phase velocities (Montagner and Nataf, 1986), as we shall see later in the text.

To provide a full description of the elastic tensor, eight additional elastic coefficients complement those given in the preceding text. They are given here in the notation of Chen and Tromp (2007):

$$D_c = (C_{15} - C_{25} - 2C_{46})/4 \quad [24]$$

$$D_s = (C_{14} - C_{24} - 2C_{56})/4 \quad [25]$$

$$J_c = (3C_{15} + C_{25} + 2C_{46})/8 \quad [26]$$

$$J_s = (3C_{14} - C_{24} + 2C_{56})/8 \quad [27]$$

$$K_c = (3C_{15} + C_{25} + 2C_{46} - 4C_{35})/8 \quad [28]$$

$$K_s = (3C_{14} + C_{24} + 2C_{56} - 4C_{34})/8 \quad [29]$$

$$M_c = (C_{15} - C_{25} + 2C_{46})/4 \quad [30]$$

$$M_s = (C_{14} - C_{24} + 2C_{56})/4 \quad [31]$$

At first order in anisotropy, they contribute to the velocity variation of body waves with nonhorizontal propagation, but not to the velocity variation of surface waves (Chen and Tromp, 2007).

Data averaged over azimuth will give access only to the five coefficients of the VTI component of the elastic tensor. Any global mean model, like PREM (Dziewonski and Anderson, 1981), cannot contain more elastic coefficients than these 5.

1.09.2.3 Weak Anisotropy Approximation

The exact solution of eqn [2] is a nonlinear procedure. When averaging the volume of rock typically sampled by a seismic wave, linearized solutions are a good approximation and illustrate well the first-order influence of each elastic coefficient on the wavefield. A complete treatment by the application of perturbation theory to the Christoffel equation at first order in anisotropy is presented in Jech and Psencik (1989), including perturbation of the polarization vectors.

For P waves, the perturbation in phase velocity has the simple form

$$\Delta V_P = \frac{1}{2V_P}\frac{\Delta c_{ijkl}}{\rho} n_i n_l g_j g_k \quad [32]$$

where $\vec{g}$ is the unit vector in the direction of polarization in the unperturbed medium, which is equal to $\vec{n}$ for P waves in isotropic structures. Summation should be made over repeated indexes. The azimuth angle θ appears in the vectors $\vec{n}$ and $\vec{g}$, yielding an azimuthal dependence of the velocities with a maximum order of 4. Equivalently, the well-known expressions for the velocity variations of body waves at first order in anisotropy, derived by Backus (1965), showed that ΔV_P has an azimuthal dependence in 2θ and 4θ in HTI media. In TTI media, the wave velocity also exhibits θ and 3θ azimuthal variation (Chen and Tromp, 2007).

The first-order perturbation of the P-wave polarization is normal to the unperturbed polarization. The work of Thomsen (1986), used extensively in seismic exploration and extended to more general anisotropy by Mensch and Rasolofosaon (1997), is also based on first-order approximations of the wave velocities.

The procedure to calculate the perturbations of the velocities and polarizations of S waves is more complicated than for P waves, due to the degeneracy of the Christoffel matrix for S waves in isotropic structures (Jech and Psencik, 1989). Results obtained from degenerate perturbation theory are valid even in strongly anisotropic structures with over 20% of anisotropy (Jech and Psencik, 1989). However, as opposed to the expression for P waves, the expressions for S waves are not linear in the perturbation of the elastic coefficients, and one cannot derive analytically a simple expression for the azimuthal dependence of their velocities in the general case. In practice, the velocities of quasi-S waves also show 2θ and 4θ azimuthal variations in many cases (Mensch and Rasolofosaon, 1997). Chen and Tromp (2007) showed that traveltimes of body waves and surface waves at global and regional scale are estimated well by the 'weak' expressions for anisotropies $\leq 5\%$.

1.09.2.4 Ray Theory

Body waves are commonly interpreted in terms of single phases that follow raypaths, making ray theory an important tool in seismology. Ray theory in anisotropic and in isotropic

structures is summarized by Cerveny (2001), Chapman (2004) and Virieux and Lambare (**Chapter 1.05**). In anisotropic media, some of the simple intuitive aspects of ray theory in isotropic media are lost. This is especially true for shear waves, because ray theory intertwines with the frequency-dependent coupling of the two quasi-S waves.

Ray theory is a high-frequency approximation of the equation of motion in heterogeneous structures. Following Cerveny (1972) and Cerveny (2001), the ray-tracing equations are

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = \frac{c_{ijkl}}{\rho} p_j g_j g_k = V_i \qquad [33]$$

$$\frac{\mathrm{d}p_i}{\mathrm{d}t} = -\frac{1}{2}\frac{\partial}{\partial x_i}\frac{c_{jklm}}{\rho} p_j p_m g_k g_l \qquad [34]$$

where $\vec{x}$ is a location along the ray and $\vec{p}$ is the ray's slowness, perpendicular to the wavefront and parallel to $\vec{n}$ from the previous section. $\vec{g}$ is one of the normalized eigenvectors of the Christoffel matrix, which defines the polarization of a wave that travels along the ray. The Christoffel matrix in ray theory is usually normalized by replacing the components of propagation direction $\vec{n}$ in eqn [2] by the components of the slowness $\vec{p}$, since the expressions are then better suited for the Hamiltonian formalism of the ray theory (Cerveny, 2001).

The group velocity $\vec{V}$ in eqn [33] defines the direction followed by the ray and is equivalent to the group velocity defined in eqn [3] for uniform media. The group velocity $\vec{V}$ is not generally parallel to the phase slowness $\vec{p}$, but the two vectors are related by the following dot product:

$$\vec{V} \cdot \vec{p} = 1 \qquad [35]$$

As in isotropic structures, eqn [34] controls the deviation of the ray, which depends on the lateral derivatives of the density-normalized elastic coefficients. A significant difference with the isotropic case is that the polarization vectors $\vec{g}$ appear explicitly in the ray equation in anisotropic media, whereas they do not appear explicitly (but implicitly in the choice of the wave type) in the isotropic case. The equations can be rewritten without this explicit dependence by expressing the eigenvector dot products in eqns [33] and [34] in terms of selected elements of the Christoffel matrix and its eigenvalues (Cerveny, 2001).

At leading order, the polarization of wave motion follows the polarization vector $\vec{g}$, and the rays are traced independently for the three waves. These results can be used readily for P waves in most cases. The situation is however more complex for S waves: in addition to *shear-wave splitting*, we have *shear-wave coupling* in anisotropic media with lateral variations (Chapman and Shearer, 1989). In the same way as long-period P and S waves couple when they propagate through strong gradients in elastic properties (Richards and Frasier, 1976), split S waves couple to each other in gradient regions. The closer the velocities of the two shear waves, the smaller the gradient needed to produce a significant coupling. Such coupling is therefore a critical aspect of shear-wave propagation in weakly anisotropic media (Coates and Chapman, 1990) and in strongly anisotropic media in the vicinity of singular points. At singular points, the two quasi-S wave speeds approach each other and the polarizations of the two quasi-S waves rotate rapidly around the ray (Chapman and Shearer, 1989). Quasi-S-wave coupling is stronger at low frequencies and leads therefore to frequency-dependent polarizations. Coupling partly compensates for splitting, as illustrated in **Figure 5**, and makes quasi-S-wave propagation converge toward the isotropic-media solution as the anisotropy goes to zero.

The nature of shear-wave coupling can be understood intuitively by considering cases where the theoretically determined polarization of a given quasi-S wave changes abruptly. The physical energy in the S wavefield will only partly follow the rotation of polarization and will partly transfer onto the other quasi-S wave, leaving the overall particle motion weakly perturbed. Observable birefringence in the S wave as a result of this energy transfer develops as the wave propagates. Chapman and Shearer (1989) gave an expression to connect the quasi-S rays across the gradient region where coupling occurs, which can be useful when coupling occurs only in a limited portion of the model. In cases of extended coupling through the whole model, such as with weakly anisotropic media, a possible approach is based on the perturbation of the isotropic case. In the so-called quasi-isotropic approximation (Psencik, 1998), the quasi-S waves do not appear explicitly, and observed S waves are calculated through a system of two coupled frequency-dependent differential equations. For weak anisotropy or close to singularities, this gives a regular solution in which splitting and coupling are naturally taken into account together and that naturally converges to the solution in the isotropic structure as anisotropy goes to zero. For strong anisotropy, the coupled equations transform to two decoupled equations for the two quasi-S waves.

An alternative approach based on higher-order perturbations and on an appropriate choice of coordinate system along the ray allows either for separate ray tracing of the two quasi-S waves in weakly anisotropic media (Farra, 2005; Farra and Psencik, 2003) or for coupling the two waves along a common ray traced using the average velocities of the two waves in the ray direction, avoiding the isotropic average (Farra and Psencik, 2008). Traveltime errors related to different approaches of the shear-wave coupling problem are estimated by Klimes and Bulant (2006). Similar to ray theory, a quasi-isotropic WKBJ perturbation approach with the Langer approximation has been proposed by Maupin (1994) for layered structures.

1.09.2.5 Reflection and Transmission Coefficients

Anisotropy distorts the stress–strain relation for plane waves and perturbs the orientations of particle motion and traction exerted

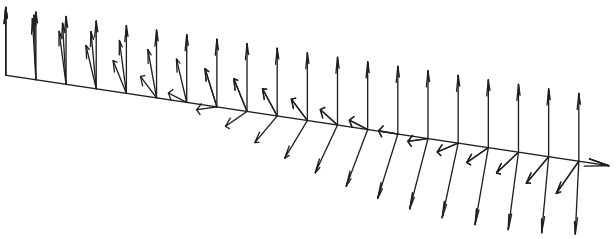

Figure 5 S-wave polarization vector along a ray: Isotropic ray theory polarization points upward. Anisotropic ray theory polarization points downward on the right-hand side. Coupling ray theory polarization vector points between the two previous ones. At longer period, it would point closer to the isotropic ray theory polarization. At shorter period, it would point closer to the anisotropic ray theory polarization. Figure courtesy of Ludek Klimes.

at an interface between two layers. Because displacements and tractions must remain continuous across solid–solid interfaces, anisotropic distortions lead to a more complicated pattern of reflected and refracted waves than in isotropic media. Basically, anisotropy removes the separation of SH waves and P-to-SV waves that occurs in isotropic horizontally layered structures (Crampin, 1981; Fryer and Fraser, 1984). The coupling means, for example, that a P wave in an isotropic layer impinging on an anisotropic layer will yield a transmitted quasi-P wave, two transmitted quasi-S waves, reflected P and SV waves, and a reflected SH wave. The conversion of a P wave to an SH wave is a characteristic of anisotropy. The exact anisotropic reflection and transmission coefficients can be readily calculated (Keith and Crampin, 1977), but useful first-order expressions have also been derived for weak anisotropy (Farra and Psencik, 2010), for weak contrast across the interface (Klimes, 2003), and for weak contrast and weak anisotropy (Vavrycuk, 1999).

Seismic observations of wave conversions at buried interfaces, such as those retrieved from teleseismic receiver functions (Farra and Vinnik, 2000; Park and Levin, 2000), can inform us about the depth dependence of anisotropy. A primary indicator of anisotropy in receiver-function studies is the conversion of P- to SH-polarized shear waves. Levin and Park (1998) showed that, for hexagonal symmetry, P-to-SH converted waves follow a two-lobed or four-lobed radiation pattern with back azimuth, depending on the combination of symmetry-axis orientation and the relative strength of anisotropy in V_P and V_S. P-to-SV converted waves vary with back azimuth as well, perturbing the converted-wave amplitude associated with discontinuities in isotropic wave speed. Anisotropy with a vertical axis of symmetry does not induce P-to-SH converted phases and does not introduce back-azimuth variation in the amplitude of P-to-SV converted waves. Four-lobed and two-lobed P-to-SH radiation are favored by a horizontal and a tilted symmetry axis, respectively. The scattered-wave amplitude vanishes for P waves whose back azimuth parallels the strike of the anisotropic symmetry axis, and the SH wave has opposite polarity for impinging waves that approach from opposing sides of the symmetry axis. The P-to-SH scattered wave also vanishes for incoming P wave whose azimuth is normal to the strike of a horizontal symmetry axis.

A 2-lobed P-to-SH radiation pattern is predicted to occur as a result of P-to-S conversion at a dipping interface in the absence of anisotropy (Levin and Park, 1997a; Savage, 1998), suggesting that anisotropy and deviations from layered structure can be confused. Moreover, at a dipping interface, there are P-to-SV amplitude variations (**Figure 6**), which are associated with the variation of the perturbed P-incidence angle on the dipping interface: updip and downdip teleseismic P arrivals impinge at angles that differ by twice the dip angle, which leads to a variation in P-to-SV conversion amplitude. Discrimination between flat-layered anisotropic media and dipping isotropic media is difficult, because the mutual variation of the P-to-SH and P-to-SV converted waves with back azimuth is quite similar. Other information, such as an independent constraint on interface geometry, is useful. There can be a strong trade-off when the dipping interface borders an anisotropic region with a tilted symmetry axis. The anisotropic effect on wave conversion also depends on the P-incidence angle. Park et al. (2004) and Savage et al. (2007) found that the dip effect in the Cascadia (the United States) and Hikurangi (New Zealand)

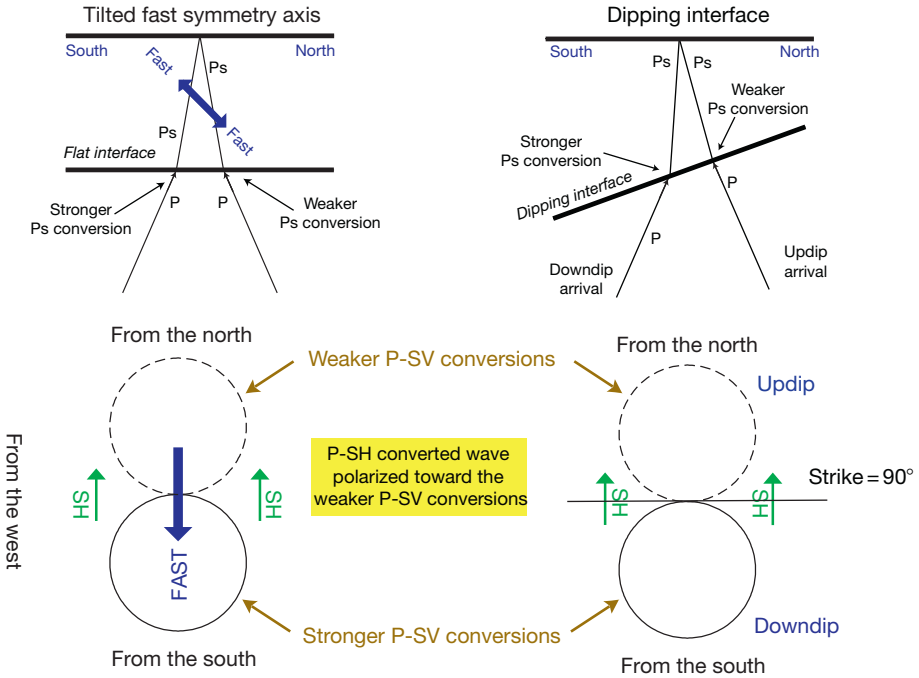

Figure 6 Schematic of S-to-P converted waves associated with anisotropy with a tilted fast symmetry axis (left) and a dipping interface between isotropic media (right). The back-azimuth variation of converted-wave amplitude follows a simple two-lobed harmonic pattern (to leading order) in both cases. The upper panels diagram the geometry of P-to-S conversion in side view. The lower panels indicate the amplitude and polarity patterns predicted for the two cases. The relationship of P-to-SV and P-to-SH conversions is similar for tilted-axis anisotropy and a dipping interface in isotropic media, suggesting that additional constraints are necessary to discriminate the two cases.

subduction zones, respectively, enabled the P-to-SH conversion amplitudes to be fit with far less anisotropy (7% vs. 10% in the case of Cascadia).

1.09.2.6 Surface Waves and Normal Modes

In anisotropic-layered media, the coupling between P, SV, and SH waves implies the loss of distinct Love and Rayleigh surface waves, to be replaced by generalized modes that are polarized in three directions. This is an essential difference between surface waves in isotropic and anisotropic media, together with azimuthal variation of their velocities and other characteristics, and that phase and group velocities are not aligned (Crampin, 1970). Anisotropy perturbs the frequencies and oscillation patterns of seismic free oscillations in a manner similar to isotropic lateral structure, especially for transversely isotropic media with a vertical axis of symmetry. Anisotropy with a nonvertical symmetry axis, or with no symmetry axis, causes more extensive waveform perturbations.

An anisotropic stress–strain relation encourages the coupling and hybridization of spheroidal (${}_nS_l$) and toroidal (${}_nT_l$) oscillation types. (The subscripts n and l refer to the overtone number and angular degree of the free oscillation, respectively. Each ${}_nS_l$ and ${}_nT_l$ is a 'multiplet,' a collection of $2l+1$ distinct 'singlet' vibrations that share a common n, l, and oscillation frequency for a standard spherical Earth reference model.) Spheroidal and toroidal free oscillations with low overtone number combine to form Rayleigh and Love surface waves with particle motions that are mutually orthogonal. Smoothly varying isotropic velocity heterogeneity causes the spheroidal and toroidal oscillation types to interact weakly at best. Anisotropic structure induces mixed-type interaction far more effectively. Similar coupling efficiency arises from the deflection of seismic particle motion by the Earth's Coriolis force, but laterally variable anisotropy perturbs the seismic wavefield more extensively, facilitating many more coupling interactions.

As for body waves, first-order perturbations can be used to describe surface-wave propagation in anisotropic Earth models. Smith and Dahlen (1973) showed that the phase velocities vary in 2θ and 4θ at first order in anisotropy and depend on a set of 13 elastic coefficients. These expressions, rewritten by Montagner and Nataf (1986), are the basis for most of the tomographic inversions made with surface-wave phase velocities. For Love waves, perturbation in phase velocity depends on the elastic parameters through two kernels only:

$$\begin{aligned}\delta V_L = &\frac{\partial V_L}{\partial L}(\delta L - G_C\cos 2\theta - G_S\sin 2\theta)\\ &+\frac{\partial V_L}{\partial N}(\delta N - C_C\cos 4\theta - C_S\sin 4\theta)\end{aligned} \quad [36]$$

Similarly for Rayleigh waves, this depends on the elastic parameters through four kernels:

$$\begin{aligned}\delta V_R = &\frac{\partial V_R}{\partial A}(\delta A + B_C\cos 2\theta + B_S\sin 2\theta + C_C\cos 4\theta + C_S\sin 4\theta)\\ &+\frac{\partial V_R}{\partial C}\delta C + \frac{\partial V_R}{\partial F}(\delta F + H_C\cos 2\theta + H_S\sin 2\theta)\\ &+\frac{\partial V_R}{\partial L}(\delta L + G_C\cos 2\theta + G_S\sin 2\theta)\end{aligned} \quad [37]$$

The sensitivity kernels of these equations are plotted in Figures 7 and 8 for Rayleigh and Love waves at different periods. $\frac{\partial V_L}{\partial N}$ dominates for Love waves and $\frac{\partial V_R}{\partial L}$ dominates for Rayleigh waves, at least for the deeper layers. As a result, Rayleigh-wave phase velocities are more strongly influenced by the distribution with depth of L, G_C, and G_S, whereas Love-wave phase velocities depend more strongly on N. C_C and C_S should also contribute significantly to Love-wave phase velocities, but the difficulty in measuring 4θ variations in Love velocities makes these parameters hard to constrain.

The sensitivity kernels in the preceding text express the sensitivity of the surface-wave velocities at first order in different anisotropic parameters as a function of depth assuming no

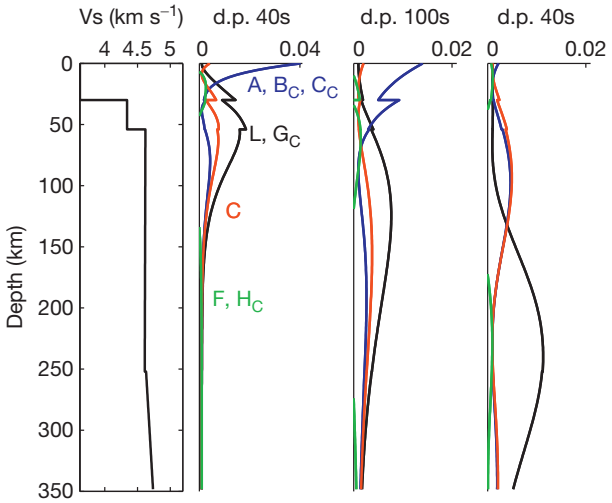

Figure 7 Sensitivity kernels of the Rayleigh-wave phase velocities to different parameters as a function of depth. The S-wave velocity of the model in which the kernels have been calculated is shown to the left. The sensitivity kernels with respect to different elastic coefficients are shown in the subsequent plots for the fundamental mode at a period of 40 and 100 s and for the first overtone at a period of 40 s.

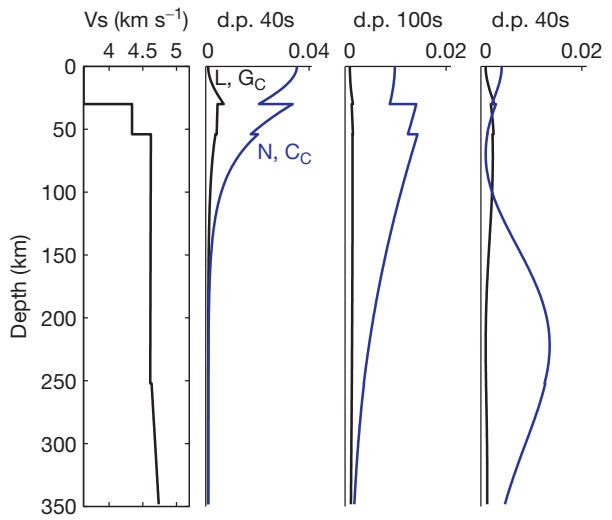

Figure 8 The same as Figure 7 for Love waves.

lateral variation of the structure. Beyond this approximation, finite-frequency kernels can be calculated (Sieminski et al., 2007). As in the isotropic case, they reveal that the width of the sensitivity zone is significant, broadening to, for example, a third of the epicentral distance for surface waves at 140 s period and 120° epicentral distance. Finite-frequency kernels confirm the role of the parameters identified earlier in the text as the main contributors to phase-velocity variations in the vicinity of the source–receiver great circle but suggest the off-path influence of other parameters, for example, N, C_C, and C_S, through Rayleigh–Love coupling.

The dominance of the 2θ phase-velocity azimuthal variation for Rayleigh waves and of the 4θ for Love waves can be seen in **Figure 9**. A 2–3% peak-to-peak azimuthal variation is observed at 40 s period in this model with anisotropy in the form of 35% oriented olivine crystals in the upper 80 km of the mantle. The surface-wave velocities have been calculated here with the reflectivity method of Thomson (1997) and are not first-order approximations based on the equations in the preceding text. The olivine a-axis is either horizontal, dipping at 45°, or vertical. We see that Rayleigh waves have maximum velocity in the azimuth of the a-axis and minimum in the azimuth of the c-axis and that a 45° dip of the a-axis modifies the average velocity but not the amplitude of the azimuthal variation. When the a-axis is close to the horizontal plane, the Rayleigh waves have average phase velocities that are lower than the isotropic reference. The average phase velocity is higher than the isotropic reference for large dips of the symmetry axis. The opposite is true for Love waves, which causes the apparent Love–Rayleigh discrepancy (Anderson, 1961), which is positive for horizontal a-axis and negative for vertical a-axis. The azimuthal variation is shown here for the fundamental mode at one period, but very similar curves are obtained at other periods and for the overtones (Maupin, 1985).

The 3-D nature of surface-wave polarization in anisotropic media brings information on the nature of the Earth's anisotropy that is complementary to the information we get from the analysis of their velocities. Coupling between fundamental Rayleigh and Love waves due to lateral gradients in anisotropy along the path of the surface waves produces wavetrains with arrival times between the direct Love and Rayleigh waves (Park and Yu, 1993). The timing can be understood in terms of the difference in group velocity between Love and Rayleigh waves. Similarly, a fundamental Rayleigh wave that scatters some energy to a fundamental Love wave is outpaced by the scattered phase, which is observed to arrive ahead of it. Overtone Love and Rayleigh waves have similar group velocities at long period, leading to a near-simultaneous arrival of direct and scattered overtone waves. In addition, anisotropy close to the station distorts the polarizations of the direct waves.

Surface waves with polarization anomalies related to anisotropy have been called 'quasi-Love' waves or 'quasi-Rayleigh' waves in the literature, but the terms have been used slightly differently in the contexts of polarization–distortion or of scattering. In the context of polarization–distortion, the usage is similar to that of quasi-P and quasi-S body waves: A 'quasi-Rayleigh' wave is mainly P-to-SV-polarized with some transverse motion (Crampin, 1970), and a 'quasi-Love' wave is mainly transverse-polarized with some P-to-SV motion. For surface-wave scattering, the term 'quasi-Love' applies to the anomalous P-to-SV-polarized wave that scatters from the main Love wave. Conversely, the 'quasi-Rayleigh' term applies to the anomalous transverse-polarized wave that scatters from the main Rayleigh wave. The quasi-Love wave is a Rayleigh-polarized wave whose energy propagates with Love-wave phase velocity before scattering and with Rayleigh-wave velocity after scattering, observed as a distinct wave that requires a name. If scattering occurs close to the station, the quasi-Love wave arrives as an apparent precursor to the Love wave, hence its name. Similarly, the 'quasi-Rayleigh' wave is a Love-polarized wave that trails the Rayleigh wave closely if scattering occurs close to the station.

The surface polarization of the quasi-Rayleigh waves whose phase velocities were shown in **Figure 9** is presented in **Figures 10** and **11**. For a horizontal a-axis (**Figure 10**), the polarization remains linear, but deviates up to 8° from the phase-velocity direction. For an olivine a-axis dipping at 45°, the polarization anomaly is much more pronounced (**Figure 11**) with a distinctive elliptical motion. Generally speaking, coupling and polarization anomalies have maximum amplitude in propagation directions far from the symmetry axes and symmetry planes of the anisotropy. Polarization anomalies are therefore better suited than velocities to detect a plunge in the anisotropy symmetry axes (Maupin, 2001).

The polarization anomalies can be analyzed at first order in anisotropy using perturbation procedures (Park, 1997; Tanimoto, 2004). It should be noted that the usual procedure,

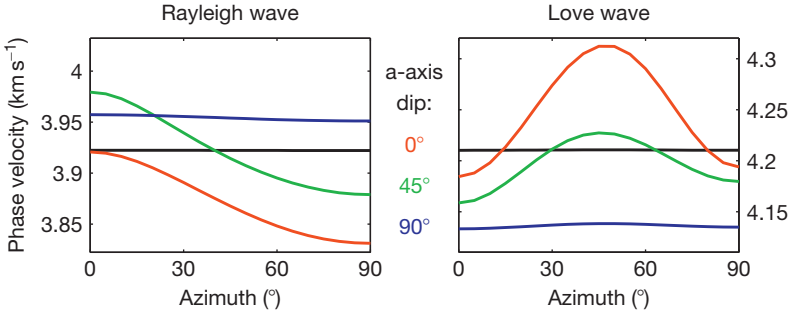

Figure 9 Azimuthal variation of the phase velocities of Rayleigh- and Love-wave fundamental modes at 40 s period in a model with 35% oriented olivine crystals (Kumazawa and Anderson, 1969) in the upper 80 km of the mantle. The olivine a-axis is in the vertical plane at azimuth 0° and dipping at either 0° (in red), 45° (in green), or 90° (in blue), and the c-axis is in the azimuth 90°. The background isotropic Voigt average model is model iasp95, and the phase velocities in this model are shown as solid black lines.

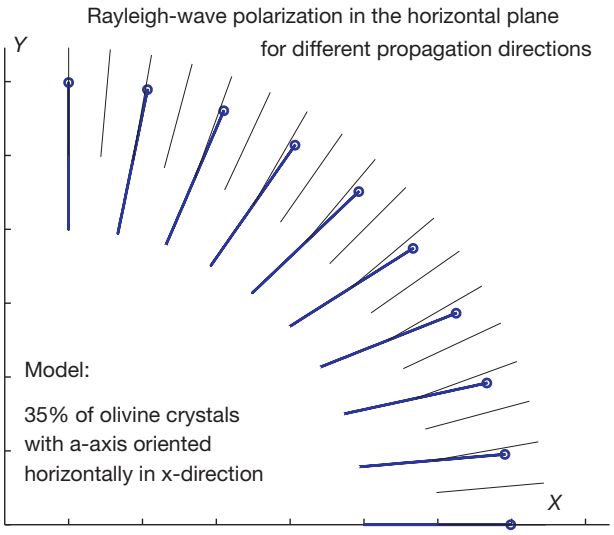

Figure 10 Polarization of a 40 s Rayleigh wave in the horizontal plane in different azimuths. The model is the same as in **Figure 9**. The olivine *a*-axis is in the *x*-direction and the *c*-axis is in the *y*-direction. Thin lines show the direction of the phase velocity and thicker blue ellipses (flat in the present case) show the surface polarizations.

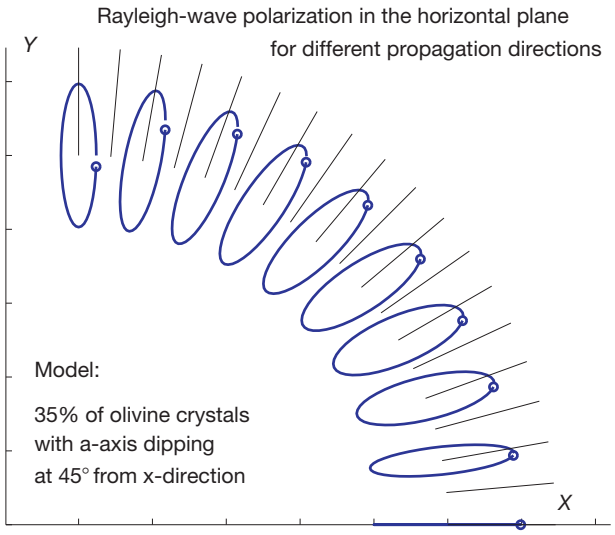

Figure 11 The same as **Figure 10** for an *a*-axis dipping at 45° in the vertical plane containing the *x*-direction. The prograde nature of the elliptic motion is shown with the small symbol at the start of the motion.

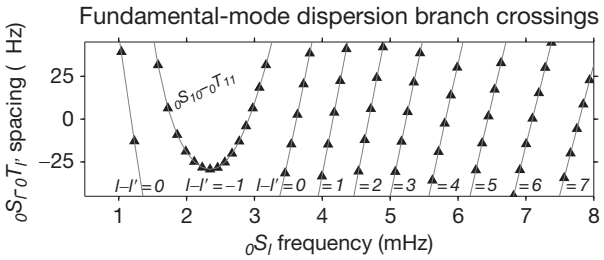

Figure 12 The relative placement of fundamental-mode branches of spheroidal (*S*) and toroidal (*T*) Earth free oscillations determines the coupling pairs $_0S_l$–$_0T_{l'}$ that are asymptotically sensitive to the wavenumber $s = |l - l'|$ of anisotropy along the great-circle path between source and receiver. At $f < 2$ mHz, $|l - l'| = 1$ for many nearest-neighbor mode pairs, so the Earth's Coriolis force has a significant effect. At frequencies $f > 2$ mHz, $|l - l'|$ increases with frequency, increasing the influence of anisotropy.

based on nondegenerate perturbation theory, may need modifications for modes close to each other in phase velocity (Maupin, 2004). Higher-mode Love and Rayleigh dispersion curves are roughly parallel and close to each other over the broad frequency range where they can be identified with multiple SH and SV reverberations in the upper mantle. Fundamental Love and Rayleigh waves arise from dispersion branches that differ greatly, but which cross each other at specific free oscillation multiplet pairs $_0S_l$–$_0T_{l'}$. At these crossing points, the nondegenerate perturbation theory is not valid anymore and one has to use degenerate or quasi-degenerate perturbation methods (Maupin, 1989).

The strength of coupling between two seismic free oscillations is inversely proportional to their frequency spacing. The largest coupling effects are seen for nearest-neighbor coupling pairs on similar dispersion branches, for example, the fundamental branch $n = 0$. At frequencies $f < 2$ mHz (periods $T > 500$ s), most nearest-neighbor fundamental spheroidal–toroidal mode pairs differ by angular degree $s = |l - l'| = 1$ and are influenced strongly by the Earth's Coriolis force (Masters et al., 1983). At higher frequencies, the angular-degree difference $s = |l - l'|$ of these mode pairs increases as the Love and Rayleigh fundamental dispersion branches diverge (**Figure 12**). Coupling between spheroidal and toroidal free oscillations in these branches gives rise to the scattering of Love to Rayleigh and from Rayleigh to Love (**Figure 13**).

Park (1997) showed that, for a particular $_0S_l$–$_0T_{l'}$ coupling pair, the asymptotic effect of anisotropy is maximal for structure with wavenumber $s = |l - l'|$ along the source–receiver great circle. This leads to some unusual effects in hypothetical anisotropy models. For instance, anisotropy with a single angular degree s will influence a narrow frequency interval where dispersion-branch crossings are auspicious for coupling, leading to a longer-duration scattered wave with narrowband frequency content. As the wavenumber s of the anisotropic structure along the great-circle path increases, the wavenumbers and frequencies of the relevant modal coupling pairs increase. Because the fundamental-mode surface-wave perturbation kernels also vary with frequency, the depth of maximum sensitivity shallows as frequency increases. For free oscillation overtone branches, nearest-neighbor toroidal and spheroidal coupling pairs differ little in angular degree (**Figure 14**), suggesting sensitivity to near-constant anisotropy along the great-circle path. Coupling between mode branches will be sensitive to anisotropic gradients, for example, $_1T_{60}$–$_2S_{49}$ near $f = 9$ mHz will be sensitive to wavenumber $s = 11$. The predictability of fundamental-branch surface-wave coupling relations suggests that a linearized inversion of Love–Rayleigh scattering for structure along path is possible (Oda, 2005).

1.09.3 Seismological Observations of Anisotropy

Considerable progress has been made in the last 25 years in mapping the Earth's anisotropy. There is evidence at the

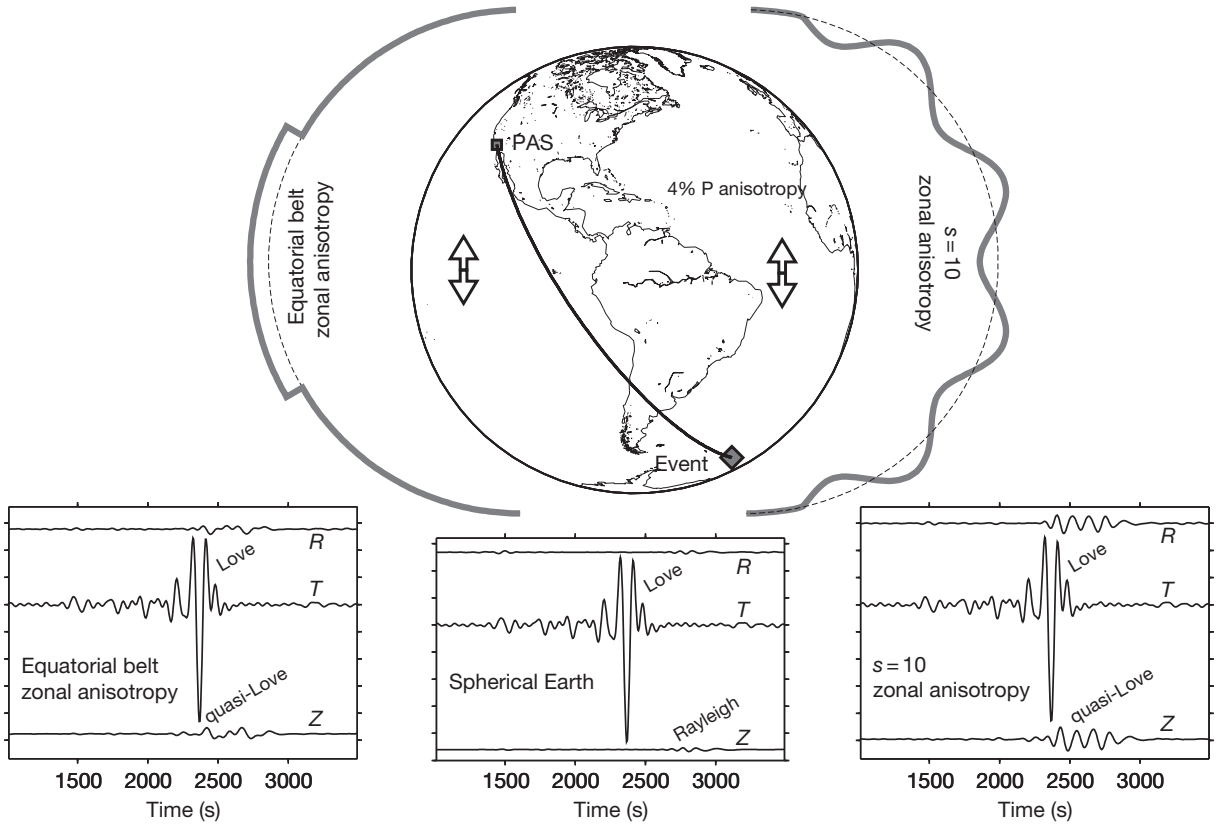

Figure 13 Examples of quasi-Love scattered waves computed for two simple anisotropic Earth models, compared with a synthetic seismogram for an unperturbed spherical Earth model. Coupled free oscillations are summed for all free oscillations with overtone number n≤4 and f≤16 mHz (T≥62 s). Anisotropy with a north–south horizontal axis of symmetry is imposed between the Moho and 220 km depth and the zonal symmetry to facilitate modal coupling computations. The earthquake source and station location are chosen to display a predominant Love wave, so that the quasi-Love scattered wave has larger amplitude than the Rayleigh wave. At the left, the synthetic seismograms for an equatorial belt of anisotropy display two pulses associated with lateral discontinuities at 30S and 30N. At the right, an anisotropic corrugation with wavenumber $s = 10$ generates a broader and more narrowband scattered wave, as a result of asymptotic selection rules in free oscillation coupling.

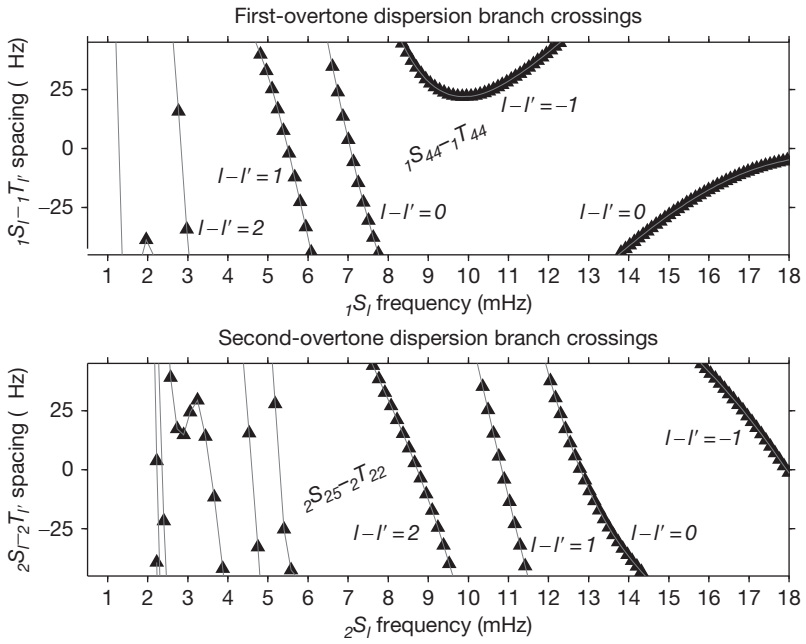

Figure 14 The relative placement of $n = 1$, 2 overtone branches of spheroidal (S) and toroidal (T) Earth free oscillations determines the coupling pairs that are asymptotically sensitive to the wavenumber $s = |l - l'|$ of anisotropy along the great-circle path between source and receiver. At $5 < f < 20$ mHz, $|l - l'| < 2$ for most nearest-neighbor mode pairs, in contrast to the behavior of the fundamental-mode branches. As a consequence, path-averaged anisotropy on the source–receiver great circle has a significant effect on ${}_1T_{l'} - {}_1S_l$ and ${}_2T_{l'} - {}_2S_l$, coupling pairs.

present time for anisotropy in the inner core, in the D″ layer, and from the transition zone up to the surface. But the picture we have of the Earth's anisotropy is indeed blurred and complex, and the mechanisms that create anisotropy are far from completely deciphered.

1.09.3.1 Crustal Anisotropy

Anisotropy in sedimentary layers is commonly observed in seismic exploration. As this subject is beyond the scope of this chapter, we refer to Helbig and Thomsen (2005) and Tsvankin et al. (2010) for reviews of near-surface anisotropy. We focus here on crustal anisotropy pertaining to crystalline basement rocks. The smaller volume and greater complexity of crustal rock relative to upper-mantle peridotites limit the crustal influence in many path-averaged observables, such as SKS birefringence, and the crust is usually considered as isotropic in global- or large-scale models. However, local studies reveal that localized anisotropy is common in the Earth's crust, dominantly in association with oceanic crustal structures, in the deformed regions of the lower continental crust in extensional regions (Endrun et al., 2011; Meissner et al., 2006), and in the vicinity of fault zones (Cochran et al., 2006; Peng and Ben-Zion, 2004). Surface waves at periods with high crustal sensitivity, either generated by earthquakes or measured by ambient-noise interferometry, have contributed to an increase in the number of observations that pertain to crustal anisotropy and show that anisotropy may be present at any depth in the crust. Strong azimuthal anisotropy in the upper crust is observed in South Africa and has been related to extension at the southern tip of the African Rift (Adam and Lebedev, 2012). Midcrustal strong radial anisotropy has been observed in Tibet (Duret et al., 2010; Shapiro et al., 2004), whereas radial anisotropy has been inferred in the lower crust in the Aegean Sea (Endrun et al., 2008, 2011) and azimuthal anisotropy in the lower crust of the western United States (Lin et al., 2011).

Geologic factors that contribute to crustal anisotropy include LPO and shape-preferred orientation (SPO) of mineral crystals, oriented cracks, and fine layering of dissimilar lithologies (Godfrey et al., 2000; Kern, 1993; Kern et al., 2008; Siegesmund et al., 1991a,b). LPO is a microscopic alignment of the atomic lattices within minerals with a macroscopic direction, often developed in response to bulk rock deformation. SPO is a macroscopic alignment of minerals with elongated shapes, often developed as part of metamorphic foliation. Crustal LPO can be substantial, owing to the prevalence of hydrated minerals in sedimentary and metamorphic rocks, susceptible to slip on internal glide planes. The sheet-silicate structure of many hydrated minerals typically induces the axis of symmetry to be slow rather than fast. The anisotropy of aligned planar cracks and of fine-layered dissimilar lithologies is also characterized by a slow axis of symmetry and has much relevance in seismic exploration studies (Helbig, 1994) and in studies of the upper crust in general. Kern et al. (2008) estimated that the SPO of mineral crystals and cracks in foliated gneiss samples can double the intrinsic anisotropy produced by LPO. Ward et al. (2012) found that the anisotropy of natural and synthetic mylonites depends on a combination of mica LPO and quartz SPO.

There is some indication that the seismic lamination, which gives rise to high-reflectivity features in the deep crust, as imaged in active-source seismic surveys, is associated with anisotropy (Godfrey et al., 2000; Meissner et al., 2006). Since high reflectivity and associated anisotropy are characteristic of continental regions submitted to lateral extension, a possible interpretation is that the ductile lower crust reacts to extension by developing LPO in shear zones (Meissner et al., 2006).

Another region where anisotropy is commonly observed is the upper 3–5 km of the crust, likely caused by the opening of cracks in response to tectonic stresses. In the oceanic crust, vertical dikes and cracks associated with hydrothermal cooling of young lithosphere near mid-ocean ridges lead to anisotropy. At large scale, crustal anisotropy affects Pg propagation, for example, with 2% P-wave azimuthal anisotropy in the upper crust of Bohemia (Vavrycuk et al., 2004), and Lg waves, in the form of polarization anomalies (Maupin, 1990). Crack-induced anisotropy has a rich potential for determining stress directions in the shallow crust (Crampin and Chastin, 2003). Even a random distribution of cracks can develop an effective alignment, and elastic anisotropy, if cracks with favorable orientations open in response to the least-compressive regional stress. Keir et al. (2011) argued that the largest anisotropy within the upper crust of the Ethiopian Afar rift (~6%) occurs as a result of dike intrusion within localized areas of magmatism, leading to rift-parallel fast polarization in shear-wave splitting from local earthquakes. Upper-crustal anisotropy weakens to a residual 1–2.8% in areas of the Afar rift where intrusive dikes have solidified, sealing large open cracks.

The orientation of cracks and anisotropy adjacent to fault zones can indicate whether the fault is too weak to sustain shear stresses and may be held open by fluid pressures in the cracks (Balfour et al., 2005). The birefringence of high-frequency S waves from earthquakes at small epicentral distances has been used to monitor how anisotropy increases in the vicinity of major fault systems (Cochran et al., 2006; Peng and Ben-Zion, 2004). Although the depth constraint is usually weak, there seems to be an indication that the fault-associated anisotropy is also confined to the upper few kilometers of the crust. The anisotropy in S-wave velocity increases, for example, from 2% far from the North Anatolian Fault to 7% a few hundred meters close to the fault (Peng and Ben-Zion, 2004). In the near-fault region, the fast directions rotate parallel to the fault plane, showing that the anisotropy is likely to originate from a combination of fabrics and shear-induced cracks. A lively debate continues over whether precursory loading of earthquake fault zones (Chao and Peng, 2009; Durand et al., 2011; Liu et al., 2004; Peng and Ben-Zion, 2005; Saiga et al., 2003) and volcanoes (Savage et al., 2010) can be detected by temporal changes in crack anisotropy. Nakata and Snieder (2012) documented postseismic changes in near-surface anisotropy associated with the great Tohoku-Oki megathrust earthquake of 2011.

1.09.3.2 Origin of Upper-Mantle Anisotropy

Observations of ophiolites and xenoliths and deformation experiments show that upper-mantle rocks develop LPO under strain via dislocation creep within anisotropic olivine crystals. Seismic anisotropy is therefore our most direct

indicator of the upper-mantle deformation associated with thermal convection and plate tectonics. However, the type of fabric developed by olivine LPO depends on the ambient temperature, stress, and presence of melt or volatile compounds, especially water (Holtzman et al., 2003; Jung and Karato, 2001; Kaminski, 2006; Kaminski and Ribe, 2001; Skemer et al., 2006). Moreover, dislocation creep within crystals is not the only mechanism by which olivine-rich rocks can deform (Hansen et al., 2011; Kohlstedt, 2006), and not all deformed anisotropic rocks at upper-mantle depths are olivine-rich (Wang et al., 2012). Relating seismic anisotropy to mantle deformation requires knowledge of chemistry and physics and is reviewed in the chapter by Stixrude and Jeanloz.

Single-crystal olivine exhibits wave speed anisotropy of 24.6% and 22.3% in compressional (P) and shear (S) waves, respectively (Kumazawa and Anderson, 1969) (see also **Figure 2** for anisotropy in an olivine-rich material). Olivine is found with pyroxene and garnet in peridotites. Pyroxene crystals are anisotropic and contribute to bulk anisotropy in mantle peridotite. Garnet crystals are cubic and exhibit a more isotropic elastic behavior. Olivine is roughly twice as abundant as pyroxene in peridotite, and so its alignment is probably a dominant element in its bulk anisotropy (Babuska and Cara, 1991). The *a*-axis of olivine crystals corresponds to the stiffest direction in which P waves have highest velocities. If the *a*-axis is horizontal, it parallels both the 'fast' polarization of vertically propagating quasi-S waves and the propagation azimuth at which Rayleigh waves have maximum phase velocity. The olivine *a*-axis is therefore commonly called 'the fast axis.' There is less difference in stiffness between the *b*- and *c*-axes, so their directions are more difficult to distinguish with seismological data than the direction of the *a*-axis.

The direction of the *a*-axis is often interpreted as parallel to the mantle-flow direction, but such a simple interpretation has caveats. We can say that the competing effects of intracrystalline slip on vulnerable glide planes within the crystal lattice and of dynamic recrystallization associated with grain-boundary migration lead to different LPO in different conditions at different stages of the deformation (Kaminski and Ribe, 2001). A good rule of thumb is that in dry unmolten regions, the *a*-axis aligns within 10–20° of the major axis of the finite-strain ellipsoid (FSE), except where a parcel of mantle peridotite undergoes rapid changes in its strain geometry as it travels along its flow lines. For large simple-shear deformations (**Figure 15**), the fast axis aligns with the shear direction and slower axes in the plane perpendicular to it (Warren et al., 2008; Zhang and Karato, 1995). In uniaxial compression (pure shear), the slower *b*-axis tends to align with the compression direction and the *a*-axis to orient randomly in the plane normal to compression, leading to slow velocities in the compression direction and faster velocities in the plane normal to it (Kaminski and Ribe, 2001).

The presence of water influences the relative strength of mineral slip systems and modifies the relation between strain and LPO. In wet conditions, olivine may develop a B-type LPO (Jung and Karato, 2001), in which the fast *a*-axis orients at 90° from the strain direction. This yields fast directions perpendicular to what they would have been in the same strain field for the classical A-type dry olivine LPO described earlier in the text. Strain partitioning in partially molten regions has a similar

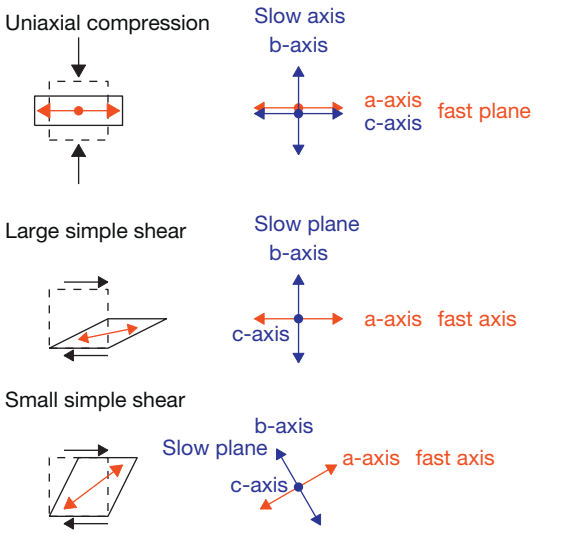

Figure 15 Long-term preferred orientation of dry olivine in simple-shear and in uniaxial compressive deformation. The deformation style is depicted on the left side of the figure, with the direction of the major axis of the finite-strain ellipsoid (FSE) as red arrows. Arrows pointing out of the figure plane are depicted by dots. Generally speaking, the *a*-axis follows the direction of the major axis of the FSE. In uniaxial compression, the *b*-axis orients in the compression direction, defining a slow axis, whereas the *a*- and *c*-axes orient randomly in the plane perpendicular to it, defining a fast plane. In large simple shear, the *a*-axis orients in the shear direction, defining a fast axis. The *b*-axis orients perpendicular to the shear plane and the *c*-axis along the neutral deformation direction. The *b*- and *c*-axis define a slow plane. In small simple shear, the pattern is similar, but tilted away from the shear direction due to the difference in direction between the major axis of the FSE and the shear.

effect (Holtzman and Kendall, 2010; Holtzman et al., 2003), and this may be observed beneath a significant fraction of mid-ocean ridges (Kaminski, 2006). Karato et al. (2008) listed three further olivine fabrics (C, D, and E) observed in laboratory deformations under differing conditions, with anisotropies similar to the A fabric. A diversity of fabrics predict diverse anisotropy styles in subduction zones (Kneller et al., 2005, 2008) and at mid-ocean ridges (Karato et al., 2008).

Anisotropy maps upper-mantle deformation, which relates directly to the flow gradient rather than to the flow itself. The major axis of the finite-strain ellipse, and thereby the fast axis of the anisotropy in usual conditions, may therefore have an orientation away from the flow lines themselves (Kaminski and Ribe, 2002; Nippress et al., 2007), as shown in the ridge model in **Figure 16**. It is only in the case of large simple-shear deformation that the major axis of the FSE coincides with the flow direction and that the anisotropy maps the flow directly. A global map of inferred anisotropic strength and fast-polarization axes would therefore not translate directly into a global map of shallow-mantle convective motions, but would of course provide a valuable starting point for it (Long and Becker, 2010; Wustefeld et al., 2009).

Not all upper-mantle deformation occurs as dislocation creep within minerals. Karato (1992) hypothesized the Lehmann discontinuity at roughly 200 km depth to be a transition of rock-deformation mechanisms and therefore a

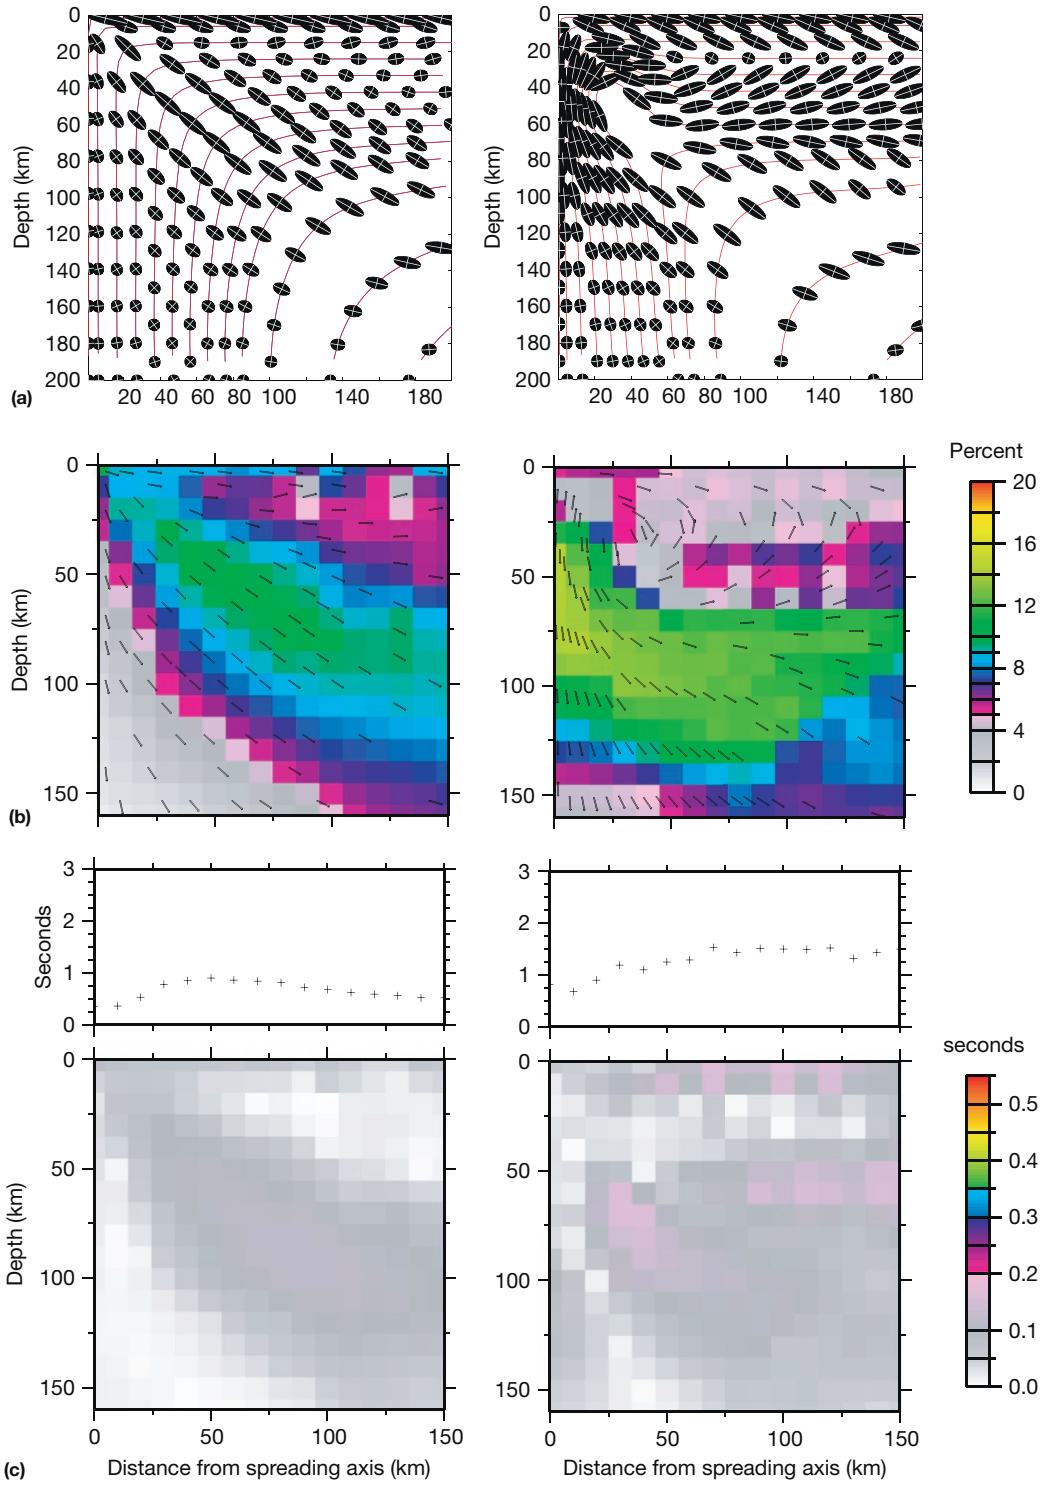

Figure 16 Figure from Blackman and Kendall (2002) showing the relation between flow, deformation, and anisotropy in 2-D models at a spreading margin. The left column corresponds to a passive flow and the right columns to a buoyancy-enhanced flow. (a) Streamlines in red and finite-strain ellipses in black. (c) The degree of shear-wave splitting for vertical incidence, as an integrated value with depth at the top and as a depth section illustrating where the splitting occurs.

transition in anisotropy. Above the Lehmann, anisotropy is generated by dislocation creep within minerals, largely via olivine LPO. Higher temperatures below the Lehmann encourage diffusion creep, in which minerals change shape via atomic diffusion around their grain boundaries, developing either SPO anisotropy or none at all. Kohlstedt (2006) had proposed diffusion creep as dominant wherever the upper mantle has appreciable water, but Karato et al. (2008) argued that this

hypothesis is inconsistent with widespread upper-mantle anisotropy. More recently, Karato (2012) had hypothesized that a different rheological transition activated by temperature and water content, from dislocation creep to grain-boundary sliding, defines the oceanic lithosphere–asthenosphere boundary (LAB) at roughly 70 km depth. Olugboji et al. (2013) showed that physical-dispersion effects associated with grain-boundary sliding can explain the substantial LAB velocity drop. Hansen et al. (2011) argued that shifting deformation from mineral-grain interiors to their boundaries should also effect a change in bulk anisotropy.

It may be wise to test the predictions of Karato's model for the LAB against seismic data, for example, the sharpness and depth of the discontinuity, before investigating grain-boundary sliding as a new mechanism in upper-mantle anisotropy.

1.09.3.3 Traveltime Residuals and Mantle Anisotropy

Azimuthal variation of *Pn* wave speed in early active-source surveys of the oceanic lithosphere was among the first observations of seismic anisotropy on Earth (Hess, 1964). More recent studies have confirmed the early results: azimuthal variations of 5.5% have been observed in the Pacific Ocean (Shearer and Orcutt, 1986) and of 3–4% in the Atlantic Ocean (Gaherty et al., 2004). They also confirm that the direction of maximum Pn-wave velocity aligns with the direction of paleospreading. This rift-normal fast-axis orientation confirms a straightforward relationship between anisotropy and plate divergence (Nippress et al., 2007), in contrast to the crack-dominated anisotropy of the continental Afar rift (Keir et al., 2011).

Pn anisotropy was also evident in active-source surveys in continental regions (Bamford, 1977) but is more difficult to interpret due to the greater geologic complexity. The accumulation of data from local- and regional-distance earthquakes has made possible a better, although still very incomplete, picture of *Pn* anisotropy in continental regions (Buehler and Shearer, 2010; Hearn, 1999; Smith and Ekstrom, 1999). The strength of *Pn* anisotropy, in the limited regions where it has been resolved, is 4% on average, reaching up to 10%. A rather consistent picture is that the fast axis of the *Pn* waves aligns with the strike of suture zones (Nemeth et al., 2005), orogenic regions (Hearn, 1999), and subduction arcs (Smith and Ekstrom, 1999). Seward et al. (2009) found *Pn* anisotropy in New Zealand to have orientation and geographic variation in good agreement with the SKS splitting observations of Greve et al. (2008).

At larger epicentral distances, the P waves dive deeper into the mantle and can be used to analyze the depth dependence of P-wave anisotropy in the lithosphere. P waves recorded on very long-range crossing profiles in Siberia (Oreshin et al., 2002) show that the strongest anisotropy (~3%) is located rather deep in the lithosphere (150–250 km depth) and that shallow anisotropy is more moderate (~2%). Testing of well-calibrated earthquake locations shows that traveltime residuals may be attributed to anisotropy at global scale and that anisotropic corrections would improve earthquake location (Antolik et al., 2001). In general, it is however difficult to discriminate between the effect of lateral heterogeneities and anisotropy on traveltime residuals. Pratt and Chapman (1992) analyzed the inverse problem of *P* waves in crosshole surveys and showed that the problem is ill-conditioned, even with the restriction to TI structures. At global scale, body-wave tomography resolves the lower-mantle well, but the prevalence of perovskite, a high-pressure mineral that develops little anisotropy, has discouraged large-scale anisotropic models. At regional scale, shallow-mantle anisotropy is easier to resolve if observations are plentiful. Modest anisotropy in the lithosphere beneath the Adirondacks terrane of northeast North America (Levin et al., 1996) and the Baltic Shield (Eken et al., 2012) could explain tomographic traveltime residuals that otherwise would imply large isotropic wave speed anomalies. Wang and Zhao (2010) imaged anisotropy beneath northern Honshu, Japan, using 448 000 P-wave arrival times from 18 335 local earthquakes, relating their results to active deformation in the subduction zone there.

1.09.3.4 Single-Station P-Wave Anisotropy Observables

Even though anisotropy is often not introduced directly in tomographic models, the raw data of tomographic studies, the P- and S-wave traveltime residuals, can be used to infer anisotropy locally below individual stations by analyzing their azimuthal and incidence-angle dependence. The azimuthally dependent part of the residuals commonly varies by ~1 s (Babuska et al., 1998). Nearby stations often show a pattern that is better explained by lithospheric anisotropy under the station than by lateral heterogeneities (Plomerova et al., 2012). This analysis does not provide good depth resolution, but can delineate geographic regions with the same pattern of anisotropy.

Anisotropy with a dipping fast P-wave axis is often observed in continental regions, and changes in the characteristics of the anisotropy tend to occur at boundaries between different tectonic units. Continent formation via the accretion of island arcs and oceanic plateaus would be consistent with such anisotropic textures. This would imply that active mantle strain is of secondary importance in continental anisotropy and that seismic observations are mostly influenced by accretion strains and the macrofabrics of relict slabs in accordance with findings done with SKS-splitting analysis. Dipping-axis anisotropy can also be interpreted as horizontal detachment scar, not a relict slab interface (Bostock, 1998; Levin and Park, 2000). More uniform patterns of dipping anisotropy in North America have been put in relation to deeper anisotropy, related to lithosphere–asthenosphere interaction (Bokelmann, 2002), showing, similar to conclusions of SKS-splitting studies, that continental anisotropy originates probably from a combination of frozen and active tectonics.

In anisotropic structures, the P-wave polarization direction does not coincide with the propagation directions. Ray theory predicts the polarization to be affected only by the local structure. At single stations, the deviation of the polarization from the great-circle plane can be measured, but this quantity is not straightforward to interpret since it includes two elements: the deviation of the ray from the great-circle plane and the deviation of the polarization from the ray direction. Schulte-Pelkum et al. (2001) analyzed the deviation of long-period P-wave polarizations worldwide and found in some cases deviations from the great-circle plane larger than 10°. They argue that great-circle deviation predicted by tomographic models can explain only a small part of the deviations and interpret them as polarization deviations due to local anisotropy in the uppermost 250 km of rock below the station. The amplitude and direction of

anisotropy inferred with this method were found to be consistent with other methods, in particular SKS splitting. Using arrays of stations to constrain the propagation direction and polarizations simultaneously shows however that long-period P-wave propagation may be affected significantly by local isotropic structure, so that a simple inference of anisotropy should be made with caution (Schulte-Pelkum et al., 2003).

1.09.3.5 SKS Waves and Upper-Mantle Anisotropy

As opposed to P waves, S waves have a distinctive property in anisotropic media that does not occur in isotropic heterogeneous structures: the two independent shear-wave polarizations suffer birefringence, also known as splitting. This distinctive feature makes split S waves a single-station, single-observation source of information concerning anisotropy. In a split S wave, the anisotropy determines a fast and a slow polarization, and an impinging wave 'splits' into fast and slow waves. A traveltime difference accumulates as the split waves traverse an anisotropic region. If the time difference is larger than the dominant period of the shear wave, for example, for shear waves from small local events, the two pulses can be visually distinguishable. Birefringence time delays of 0.5–2.0 s are shorter than the dominant periods of teleseismic shear waves (5–10 s), so that splitting of these waves manifests itself as an elliptical polarization in the horizontal plane.

Shear-wave birefringence, or splitting, of SKS and SKKS waves is the most popular tool for investigating seismic anisotropy (Long and Silver, 2009; Savage, 1999; Silver and Chan, 1991; Vinnik et al., 1984). This popularity is related to the simplified geometry of birefringence for core-refracted phases, such as SKS, in which S motion converts to P in the liquid outer core before returning to the Earth's surface as an SV-polarized wave. The propagation incidence of core-refracted waves is close to vertical under the station, so that birefringence accumulates in the SH component. A common assumption for interpretation is that the splitting is due to a single homogeneous layer of lithospheric anisotropy with a horizontal axis of symmetry. Under such an assumption, SKS waves split into 'fast' and 'slow' waves with polarization directions at right angles to each other. Travel through the anisotropic mantle introduces a time delay δt between fast- and slow-polarized S waves. A splitting time $\delta t \sim 1$ s is typical, and teleseismic core-refracted SKS waves are typically analyzed at periods > 5 s. Therefore, SKS splitting is not estimated from distinct wave arrivals, but from the interference of the 'fast' and 'slow' waves, which trace an elliptical motion in the horizontal plane. The anomalous transverse-component waveform resembles the time derivative of the 'normal' radial-component waveform in the case where the delay time is much less than the wave period (Vinnik et al., 1989b), a characteristic evident in seismograms (**Figure 17**). This provides a good diagnostic tool for distinguishing anisotropy from other sources of polarization deformation. Measurements of δt and fast-polarization azimuth ϕ are sensitive to the product of layer thickness and layer anisotropy beneath an observation point, offering no unique determination of anisotropy with depth.

Several methods are common for estimating birefringence (Long and Silver, 2009; Menke and Levin, 2003; Vecsey et al., 2008; Wustefeld et al., 2008). Most seek to restore 'split' shear waves to their original polarizations, deconvolving the horizontal motion with a broad set of apparent fast-axis strikes ϕ and delay times δt. The method of Silver and Chan (1991) minimizes the transverse component to restore its SV polarization. A birefringence estimator that maximizes the rectilinearity of horizontal motion (Levin et al., 1999), regardless of polarization, may be more robust in low signal-to-noise records and in cases where multiple layers of anisotropy complicate the birefringence. Sileny and Plomerova (1996) estimated birefringence in a manner that models vertical and horizontal motion. With low signal-to-noise records, one can use data from several back azimuths together and compute a robust composite fast-axis and delay-time estimate, from either stacking (Vinnik et al., 1989b; Wolfe and Silver, 1998) or singular-value decomposition (Chevrot, 2000).

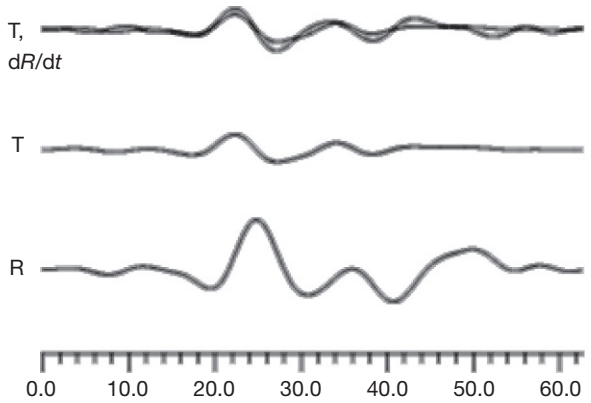

Figure 17 Figure from Long and van der Hilst (2005) showing an example of recorded SKS wave. The bottom trace shows the radial component of the SKS wave. The middle trace shows the transverse component, and the upper trace shows a superposition of the transverse component and the time derivative of the radial one. The traces are band-pass filtered between 0.02 and 0.125 Hz and deconvolved. Please see Long and van der Hilst (2005) for further information.

Numerical experiments have indicated that sparse data and data-averaging techniques can be biased toward the fast-polarization direction of the uppermost anisotropic layer (Rumpker and Silver, 1998; Saltzer et al., 2000), which may explain in part the correlation of many splitting observations with surface tectonic features. The concept of 'splitting intensity' (Chevrot, 2000), which does not rely on resolving a fast axis and a delay time, but keeps these two elements unresolved into one parameter for each data or each set of data having similar polarizations, has proved to be a more robust measurement (Monteiller and Chevrot, 2010) that varies more linearly with the properties of the structure traversed by the waves. It can more easily be incorporated into tomographic studies that allow multiple layers, in particular using finite-frequency kernels (Chevrot, 2006; Sieminski et al., 2008), and combined with surface-wave data in case of lateral and vertical variation of the anisotropy (Romanowicz and Yuan, 2012; Silver and Long, 2011).

Multiple anisotropic layers and other complexities lead as well to frequency dependence in the estimated splitting parameters ϕ and δt (Romanowicz and Yuan, 2012; Silver and Savage, 1994). The parameterization of splitting data in the presence of multiple layers of anisotropy has ambiguities,

however, because a directional dependence of splitting parameters can also be interpreted as 3-D variations in anisotropy. Menke and Levin (2003) proposed a technique for testing a parameterized model space of 1- and 2-layer anisotropic models using a set of raw SKS waveforms, rather than a collection of single-event splitting estimates. Combining data at arrays of broadband stations with appropriate tomographic techniques also seems a promising way to overcome the inherent limitations of SKS-splitting analysis at single stations concerning spatial location and orientation of the anisotropy (Chevrot, 2006; Wookey, 2012).

The majority of the SKS-splitting measurements have been made on land and bring mainly information on continental anisotropy. On land, the apparent mantle textures are often fossil, dating from ancient continental-accretion events. Fast polarization in Central Europe has been associated with a patchwork of accreted lithospheric terranes (Plomerova et al., 2012) and, in southern Africa, exhibits a consistent alignment throughout Archean and Proterozoic continental cratonic zones (Silver et al., 2001). A correspondence of fast polarization with the trends of surface relicts of Precambrian tectonic features in the Canadian Shield also lands support to the notion that mantle textures can be preserved in the continental lithosphere for a billion years or more (Rondenay et al., 2000; Silver and Kaneshima, 1993). In cases where continental tectonics is active, mantle flow from present-day tectonics can be clearly evident (Becker et al., 2003) but superimposed on mantle textures inherited from terrane formation and assembly. On the Adriatic and Ionian side of the Apennines orogen, Margheriti et al. (2003) observed orogen-parallel fast polarization over much of the Italian Peninsula and Sicily, but at the northern end near the Po Valley, the influence of anisotropy in the Paleozoic basement rocks complicates an interpretation in terms of mantle flow (Plomerova et al., 2006). In the Arabian Plate, the fast SKS polarization aligns with a late Proterozoic collisional zone (Levin and Park, 2000; Wolfe et al., 1999), but Hansen et al. (2006) argued that this splitting is caused by present-day asthenospheric flow deflected from the Red Sea Rift.

Anisotropy with a tilted symmetry axis exhibits a variation with azimuth of δt and ϕ that can be distinguished from a multiple-layer effect (Babuska et al., 1993; Chevrot and van der Hilst, 2003). Tilted-axis effects are reported in much of Europe, where they are associated with texture developed during the Variscan orogeny of the late Paleozoic (Plomerova et al., 2012) or, in the Fennoscandian Shield, as evidence of Archean continental accretion from a sandwich of old subducted slabs (Plomerova et al., 2001). Tilted-axis splitting effects are also associated with present-day deformation in Tibet (Hirn et al., 1998) and near the Mendocino triple junction of northern California (Hartog and Schwartz, 2000). In this last region, fast polarization in the upper layer, perhaps most affected by the brittle deformation of the fault zone, is roughly fault-parallel, while fast polarization in the lower layer is roughly east–west, consistent with fast polarization farther inland in the extensional Basin and Range Province.

1.09.3.6 P and S Waves and Subduction Zones

Subduction zones are another plate boundary where mantle anisotropy may help prioritize competing processes (Kneller et al., 2005, 2008). Processes within this small fraction of the Earth's volume control one of the most significant 'products' of the plate-tectonics engine, volcanic arcs, and influence strongly the accretion of continents. The geometric complexity of the region, with mantle wedge, slab, and subslab mantle, together with the possibility of oblique subduction of developing strike-slip motion parallel to the trench, makes this region very challenging for anisotropy studies. Wet conditions may alter the type of olivine fabrics and lead to fast polarizations perpendicular to the deformation, as mentioned in **Section 1.09.3.2**. On the other hand, the presence of many earthquakes distributed with depth and of arrays of stations is a clear advantage for resolving anisotropy.

Most petrologic models of the 'subduction factory' assume that shear coupling to the downgoing slab drives a 2-D corner flow in the upper-mantle wedge above it, leading to predictable thermal effects (Peacock and Wang, 1999). Trench-normal fast polarization in the back-arc has been associated with the entrainment of mantle by shear coupling to the slab (Levin et al., 2004; Schutt and Humphreys, 2001; Wang and Zhao, 2010), but Fischer et al. (1998) found that fast-axis alignment in several Pacific subduction zones parallels back-arc spreading rather than subduction azimuth. Fast polarization in the supraslab mantle wedge, as revealed by the splitting of S waves from earthquakes in downgoing lithosphere, shows a variable pattern. It is either trench-normal (Fischer et al., 1998), consistent with shear-coupled corner flow or back-arc extension; trench-parallel (Cassidy and Bostock, 1996; Long and van der Hilst, 2006), consistent with 3-D flow or B-type fabric; or splitting is absent (Fischer et al., 1998; Wiemer et al., 1999), consistent with poorly developed wedge flows in tank simulations of slab rollback (Buttles and Olson, 1998).

In several regions like the Lau Basin of the SW Pacific (Smith et al., 2001), Japan and Kuriles (Nakajima and Hasegawa, 2004; Nakajima et al., 2006), the Ryukyu arc (Long and van der Hilst, 2006), and to a lesser extent in New Zealand (Greve et al., 2008; Morley et al., 2006), networks of seismometers across the back-arc region reveal trench-parallel fast polarization near the trench that rotates to trench-normal in the back-arc extensional region. The same pattern is obtained with core-refracted S waves in the central Apennines of Italy (Amato et al., 1998; Margheriti et al., 1996) and in Japan (Long and van der Hilst, 2005), as can be seen in **Figure 18**. In Japan, the rotation of fast-axis pattern obtained with S waves compares well with the direction of fast *Pn* waves (Smith and Ekstrom, 1999).

Beneath subducting slabs that suffer retreat away from the trench, asthenosphere beneath the slab hypothetically suffers trench-parallel flow and/or extension. This hypothesis has been confirmed by splitting observations in South America (Polet et al., 2000; Russo and Silver, 1994), Kamchatka (Peyton et al., 2001), and the Apennines (Margheriti et al., 2003; Plomerova et al., 2006). However, Song and Kawakatsu (2012) had argued that subslab anisotropy can be fossil, caused by strong VTI anisotropy with a slow axis of symmetry in asthenosphere that becomes entrained with the downgoing slab. As the entrained asthenosphere tilts with the plunging slab, its fossil anisotropy can generate an apparent trench-parallel fast SKS polarization.

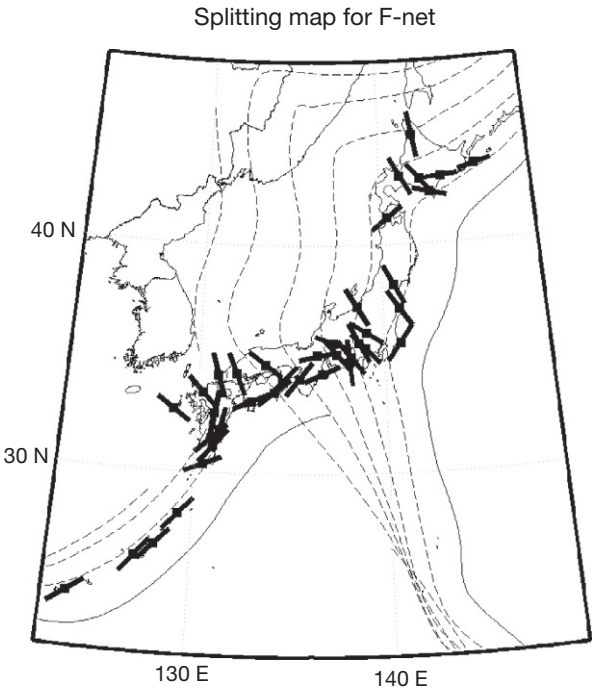

Figure 18 Figure from Long and van der Hilst (2005) showing the fast directions obtained from the analysis of S, SKS, and SKKS splitting at the F-net stations in Japan. The results are shown only for the 36 stations for which a meaningful fast direction could be obtained. For 25 other stations, there is evidence for a complex anisotropy. The contours of the Wadati–Benioff seismicity are also shown at 100 km intervals.

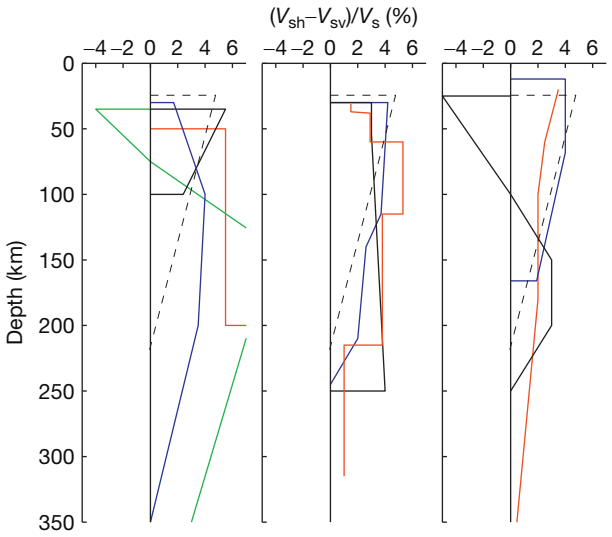

Figure 19 Examples of upper-mantle transverse isotropy obtained from local or regional studies of the Love–Rayleigh discrepancy. The plots show the difference between SH-wave and SV-wave velocity as a function of depth. The values in the PREM model are shown for reference with a dashed black line. The leftmost plot corresponds to studies in continental regions for which Love and Rayleigh-wave velocities have been averaged over azimuth before inversion, in Iberia (Maupin and Cara, 1992) (green), in South Africa (Freybourger et al., 2001) (black), in Germany (Friederich and Huang, 1996) (blue), and in Finland (Pedersen et al., 2006) (red). The central plot corresponds to continental studies made in a single azimuthal direction, in Bohemia (Wielandt et al., 1987) (red), in Australia (Gaherty et al., 1999) (black), and in North America (Gaherty, 2004) (blue). The rightmost plot shows studies made in a single azimuth in oceanic regions, in the northern Pacific (Cara and Leveque, 1988) (blue), in the southern Pacific (Gaherty et al., 1999) (blue), and in the 10–40 My old oceanic lithosphere along the Reykjanes Ridge (Gaherty, 2001) (black).

1.09.3.7 Surface Waves and Upper Mantle

As their dominant propagation direction is horizontal, surface waves offer constraints on anisotropy complementary to those offered by body waves. In addition, they provide global coverage and depth sensitivity that helps to distinguish geodynamic models. As such, surface waves continue to be a major source of information on anisotropy, in particular within oceanic regions.

On average within the Earth's outer layers, Love waves are fast compared to Rayleigh waves, that is, $N > L$ or, equivalently, $\xi > 1.0$. PREM, the first 1-D anisotropic reference model, has mantle $\xi = 1.1$ below the Moho (Dziewonski and Anderson, 1981), decreasing linearly to an isotropic value ($\xi = 1.0$) at 220 km depth (see **Figure 19**). In more recent global models, VTI with $\xi < 1.0$ is found within some depth ranges and geodynamic settings. Beneath mid-ocean ridges, studies have found VTI at 150–300 km depth that induces Rayleigh waves to propagate faster than Love waves (Kustowski et al., 2008; Panning and Romanowicz, 2006; Zhou et al., 2006). Visser et al. (2008) reported 1–2% VTI anisotropy in the mantle transition zone (420–670 km), also with the Love–Rayleigh discrepancy reversed, that is, with $N < L$, and Panning and Romanowicz (2006) argued that the strongest VTI occurs where subducting lithosphere accumulates above the 670 km discontinuity.

Regional analyses of the average Love–Rayleigh discrepancy in different tectonic settings show variations, with a general trend in global long-period data indicating maximum anisotropy in the asthenosphere in the range 200–400 km in old continental regions and 50–150 km in oceanic regions (Gung et al., 2003; Plomerova et al., 2002). Ekstrom and Dziewonski (1998) found similar results but with a stronger anisotropy in the Pacific Ocean, with a value of ξ of up to 1.14 at 100–150 km depth in the central Pacific.

Regional tomographic models provide focused measurements of the Love–Rayleigh discrepancy. It is absent from some regions, for example, northern Europe (Muyzert et al., 1999). The values of $\xi \sim 1.08$, corresponding to 4% difference in SH and SV velocity, are however very common below the Moho and down to at least 200 km depth (Freybourger et al., 2001; Gaherty, 2007; Marone et al., 2004; Panning and Romanowicz, 2006) (see **Figure 19** for some examples). Larger values of $\xi \sim 1.18$ (Debayle and Kennett, 2000; Maupin and Cara, 1992) are challenging to reconcile with olivine LPO and may require additional fine-horizontal layering. Large Rayleigh–Love discrepancies, with fast Love waves, are not limited to waves sensitive to the uppermost mantle, but have also been found at periods sensitive to the crust in tectonic regions, such as Tibet (Duret et al., 2010) and the Aegean Sea (Endrun et al., 2008).

Azimuthal anisotropy can be inferred in the phase velocity of Rayleigh and Love waves at different frequencies (Nishimura

and Forsyth, 1989; Smith and Ekstrom, 1999; Smith et al., 2004; Trampert and Woodhouse, 2003). The azimuthal variation of the Love waves should dominantly follow $\cos 4\phi$ due to the dominance of the partial derivative in N in eqn [36]. Densely sampled global measurements have confirmed the dominance of the 4ϕ terms and found azimuthal variations of up to 2% peak-to-peak amplitude at 40 s period (Trampert and Woodhouse, 2003). The azimuthal variations of the Rayleigh-wave phase velocities are better documented. In tomographic models, the reported values of the azimuthal variations of the Rayleigh-wave phase velocities are often ~1–2% peak-to-peak amplitude (Debayle and Kennett, 2000; Trampert and Woodhouse, 2003), though Ekstrom (2011) reported up to 3.3% azimuthal anisotropy in Rayleigh-wave phase velocity at 60 s period. At greater depth, a global pattern of 1–2% azimuthal anisotropy in the mantle transition zone has been constrained with overtone surface waves (Trampert and van Heijst, 2002; Yuan and Beghein, 2013).

Close to ridges, Rayleigh-wave anisotropy is usually found to possess ridge-perpendicular velocity maxima (Ekstrom, 2011; Laske and Masters, 1998; Montagner and Tanimoto, 1991; Silveira et al., 1998). Although simple continuous-flow models predict anisotropic texture to be frozen into the young oceanic plate as it cools and thickens (McKenzie et al., 1979; Ribe, 1989), modeling of olivine-crystal aggregates suggests that anisotropic texture can be weak in the stiff plate and concentrated in the lithosphere–asthenosphere transition (Blackman et al., 1996; Tommasi, 1998). However, Smith et al. (2004) argued that layered azimuthal anisotropy characterizes the Pacific upper mantle, consistent with both frozen olivine LPOs in the plate underlain by actively deforming asthenosphere. In oceanic regions, the fast direction for Rayleigh-wave phase velocities coincides quite well with the absolute plate motion of the fast-moving plates in the Pacific and Indian Oceans (Ekstrom, 2011; Laske and Masters, 1998; Leveque et al., 1998; Trampert and Woodhouse, 2003). A detailed analysis however shows that the correlation is even better with the direction of finite-strain ellipsoids (FSEs) derived from flow models (Becker et al., 2003). In the slower spreading Atlantic Ocean, basin-wide coherence of fast-axis direction is weak (Ekstrom, 2011), and Silveira et al. (1998) argued that a strong mantle-plume signature complicates the anisotropy away from the ridges.

Correlation between surface tectonics and fast-Rayleigh velocity is more difficult to constrain in continental regions, which are likely to show a more complex pattern of anisotropy, at least in the lithosphere (Priestley et al., 2006). Many studies agree that the cratonic upper mantle beneath North America has distinct layers of azimuthal anisotropy (Chen et al., 2007; Darbyshire and Lebedev, 2009; Deschamps et al., 2008; Yuan and Romanowicz, 2010b; Yuan et al., 2011), confirming behavior reported for surface waves in Australia by Debayle et al. (2005). The nature and inferred origin of anisotropic layering vary across the continent. Some studies agree with early indications from shear-wave birefringence (Darbyshire and Lebedev, 2009; Levin et al., 1999; Marone and Romanowicz, 2007; Snyder and Bruneton, 2007; Yuan et al., 2011) to infer an upper layer with anisotropic textures related to continental formation and a lower layer related to shear associated with absolute plate motion. In the North American Craton, Yuan and Romanowicz (2010a) suggested more complexity, in which fast axes in the upper 150 km of lithosphere, and below the LAB, align with absolute plate motion, but anisotropic fabric in the lower lithosphere deviates from absolute plate motion by more than 50°. Yuan and Romanowicz (2010a) melded receiver functions with surface-wave measurements to bolster the interpretation, also proposed by Deschamps et al. (2008), of the lower lithosphere of the craton as a thermal accretion that acquired its strain fabric independently of the layers above and below. Yuan and Romanowicz (2010b) inferred a different anisotropic layering in western North America, in which shear near the LAB (70–150 km depth) is underlain by a layer with north–south fabric that they associate with a northward extension of the East Pacific Rise under the continent. Deeper in the upper mantle, Yuan and Beghein (2013) offered evidence that rock deformation is disrupted globally by mineral phase changes, for example, at the 410 km discontinuity, suggesting that convective motion of mantle rock decorrelates the anisotropic fabric above and below such interfaces.

The lateral resolution of the global tomographic models is weaker at length scales <1000 km, and one could suspect that the small amplitude of the azimuthal phase-velocity variations reported by tomographic inversions results from the lateral smoothing of small-scale isotropic variations. On a global scale, Debayle and Ricard (2012) showed that large, but feasible, datasets, with >300 000 distinct surface-wave observations, suffer only modest leakage of isotropic upper-mantle structure into anisotropic upper-mantle models, though the potential for bias was greater for the weaker anisotropies of the transition zone and lower mantle. Still, it is interesting to note that local measurements made on arrays of stations often report smaller azimuthal variations than the global models, often less than 1% (Adam and Lebedev, 2012; Freybourger et al., 2001; Friederich and Huang, 1996; Pedersen et al., 2006), with the exception of the Alps where 1–2% are observed mainly range-perpendicular (Fry et al., 2010). In South Africa (Adam and Lebedev, 2012), although the azimuthal variations of Rayleigh-wave phase velocities are less than 1%, they are well constrained and consistent with directions inferred from SKS splitting. The depth distribution of anisotropy inferred from this surface-wave analysis supports models with fossil lithospheric deformation and deeper present-day deformation. An intriguing element in this study is that the Love-wave azimuthal variation aligns maxima and minima with the Rayleigh-wave azimuthal variation, a behavior that no model based on anisotropy alone can explain. Since the olivine fast axis should be dominantly horizontal to explain the positive SH–SV wave velocity difference shown in **Figure 19**, the absence of associated azimuthal variation can only be explained, in the framework of olivine, by a fast axis oriented in the horizontal plane but in azimuths strongly varying either laterally or vertically. This kind of structure has been invoked by Gaherty (2004) in North America to explain the incompatibility of Love–Rayleigh discrepancy measurements with results of SKS splitting. Anisotropy inferred from SKS splitting can predict phase-velocity azimuthal variations.

Results from SKS-splitting studies and global surface-wave tomographic models are rather difficult to compare since they sample the Earth's surface in very different ways. Early studies

did not find good agreement between the models from the two datasets (Montagner et al., 2000). Latest results (Becker et al., 2012a,b; Wustefeld et al., 2009) show that smoothed models of SKS splitting show significant agreement with models from surface waves in terms of directions of the anisotropy but with an amplitude that is twice larger on average. It is clear than in the continental lithosphere, we have a complex picture that is not well understood and that combined studies of different types of data are necessary to get a more coherent view and interpretation. Additional examples of studies of anisotropy and upper mantle can be found in **Chapter 1.19** (Montagner).

1.09.3.8 Polarization of Surface Waves

Observations of polarization anomalies related to anisotropy are not very common in the literature, in part due to the difficulty in distinguishing them from anomalies due to lateral heterogeneities and scattering. A typical polarization anomaly related to anisotropy is the presence of a vertical component associated with the Love fundamental mode at long periods (>70 s) (**Figure 20**). This 'quasi-Love,' which is best observed in back azimuths close to the Love-wave radiation maximum, has amplitudes on the vertical component often equal to 3–20% of the transverse component. It is best explained by lateral gradients in anisotropy at 100–300 km depth (Oda and Onishi, 2001; Yu and Park, 1994). Scattering amplitude is greatest for incidence at 45° from the strike of a horizontal axis of symmetry (Park, 1997; Yu and Park, 1994). Quasi-Love waves are sensitive to both v_P and v_S anisotropy, but with opposing influences, which may aid in distinguishing the two.

Quasi-Love studies have illuminated localized regions of gradients in anisotropy near several plate boundaries and other geodynamic features. The seaward sides of several Pacific subduction zones (Tonga–Kermadec, Japan–Kurile, and central Aleutians) have exhibited quasi-Love observations that are consistent with either strong trench-parallel flow or extension in the asthenosphere beneath a subducting slab (Kobayashi and Nakanishi, 1998; Yu and Park, 1994). Large quasi-Love amplitudes are observed near Tonga–Kermadec (Yu and Park, 1994), where back-arc spreading and rollback is large, and the expected back azimuth-dependent scattering pattern is clearly expressed for several events crossing the Cascadia subduction zone and observed with the EarthScope Transportable Array (Rieger and Park, 2010).

Because quasi-Love waves are generated by localized gradients of anisotropy, one expects a correlation with strong gradients in SKS-splitting measurements. Although such correlation in Tibet was not found by Yu et al. (1995), a dense broadband portable network in central Italy observed one in surface waves from the 2004–2005 megathrust earthquakes in Sumatra (Levin et al., 2007). Quasi-Love waves were observed south of 44N, consistent with trench-parallel SKS fast polarization and anisotropy behind the retreating Apennines slab. North of 44N, the SKS fast polarization swings to north–south, an orientation that does not cause Love–Rayleigh scattering – and none is observed.

Similarly, 'quasi-Rayleigh' waves, with a transverse component of up to 55% of the longitudinal one, have been observed in the vicinity of the Kerguelen hotspot at periods 20–50 s (Pettersen and Maupin, 2002). An example is shown in

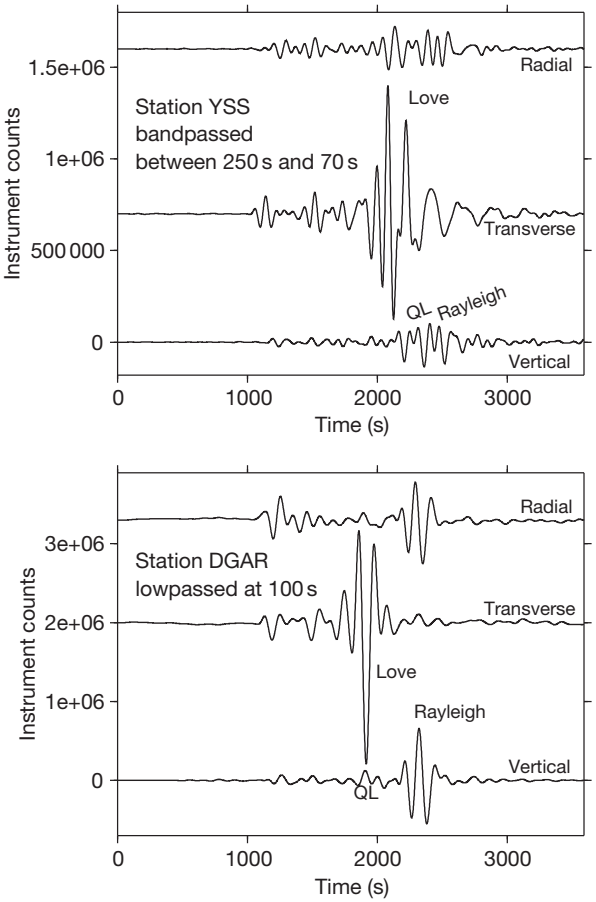

Figure 20 Examples of quasi-Love scattered waves observed in data from the 23 December 2004 $M = 8.1$ earthquake near the Macquarie Islands. This great shallow strike-slip earthquake generated large fundamental Love waves, making quasi-Love modes more visible in low-passed seismic records. Data from GSN station YSS (Yuzhno-Sakhalinsk, Russia) have been band-pass filtered between 4 and 15 mHz to minimize the influence of Coriolis coupling at frequencies f≤4mHz along this propagation path, which is nearly north–south. Data from GSN station DGAR (Diego Garcia, Indian Ocean) are only minimally affected by Coriolis coupling. The quasi-Love wave at DGAR coincides with the main Love wave, suggesting the effect of anisotropy proximal to the mid-ocean island. The quasi-Love wave at YSS, in contrast, is delayed relative to the main Love wave, suggesting the effects of lateral gradients of anisotropy south of the station, for example, along the Japan and Kurile subduction zone.

Figure 21. The polarization anomalies are elliptical, like those shown in **Figure 11**, and are indicative of lithospheric anisotropy with a fast axis dipping away from the hotspot location in a manner very similar to the one in the passive flow shown in **Figure 16**.

Love–Rayleigh scattering can also be seen as the coupling of spheroidal and toroidal free oscillations, a process that can be observed in the Fourier spectrum of long-period seismograms. The spectral peaks of free oscillations are best observed at longer periods than the 100–200 s quasi-Love and quasi-Rayleigh waves discussed in the preceding text. This promises sensitivity to anisotropy beneath the lithosphere–asthenosphere system, particularly in the transition zone (Beghein et al., 2008; Hu et al., 2009, 2012).

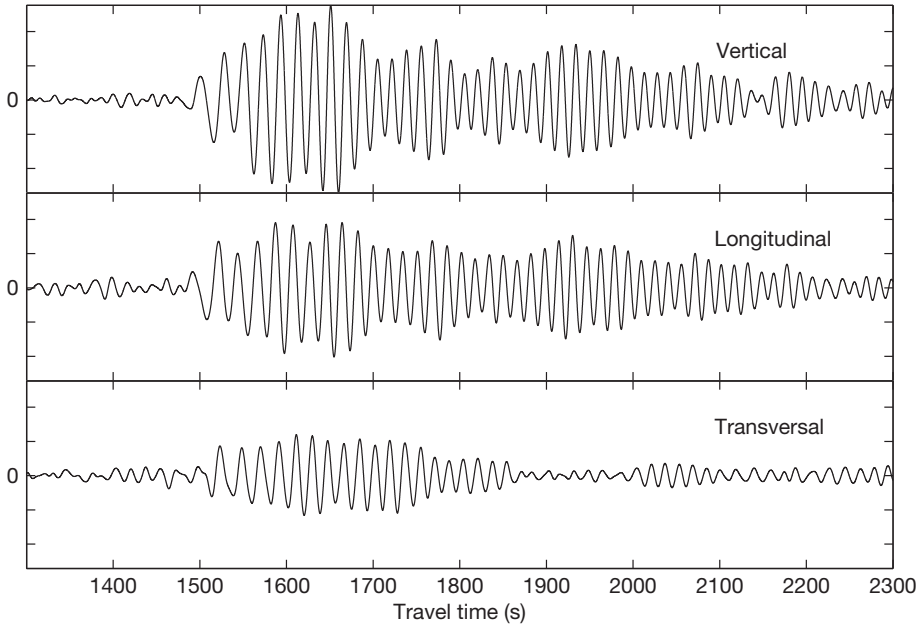

Figure 21 Example of a quasi-Rayleigh wave recorded at the Kerguelen Islands GEOSCOPE station PAF. The three components are plotted at the same scale. Note the prominent transversal component that has the same dispersion characteristics than the vertical and radial ones. The data are from the 4 August 1993 earthquake in the Java subduction zone, which did not generate Love waves in the direction of the PAF station. Reproduced from Pettersen O and Maupin V (2002) Lithospheric anisotropy on the Kerguelen hotspot track inferred from Rayleigh wave polarization anomalies. *Geophysical Journal International* 149: 225–246.

1.09.3.9 Converted Waves and Lithospheric Anisotropy

Anisotropic observables associated with converted body waves, both P-to-S and S-to-P, come in two general types. The first observation type is the birefringence of the converted *Ps* wave. Theoretically, this observable depends on a vertical integral of anisotropy between the converting interface and the surface. Using the Moho *Ps* phase, McNamara et al. (1994) estimated the partition of SKS splitting between crustal and mantle anisotropies in Tibet but found that only 25 out of nearly 700 of their observed *Ps*-converted phases showed evidence of birefringence. The second observation type is the effect of anisotropy at an interface on the amplitude of the converted wave. Theoretically, this observable depends on the anisotropic gradient at or near the converting interface. Although this small-scale sensitivity is complementary to the vertical integration associated with birefringence, there are potential observational overlaps that are not often explored in data analysis. One of the characteristics of birefringence, a pulse on the transverse-horizontal component of motion that resembles the time derivative of the main pulse, can also be generated by *Ps* conversions at the top and bottom of a localized anisotropic shear zone (Levin and Park, 1998). Both birefringence and *Ps* conversion vary with back azimuth with the tilt of the axis of symmetry in anisotropic media with hexagonal symmetry, hampering the use of back-azimuth dependence as a discriminant. A better discriminant would be the detections of P-to-SV conversions on the radial-component receiver function, which should indicate whether one interface or a bounded shear zone is present.

Seismic refraction studies on continents have revealed a wealth of possible 'stretch marks' in the lithosphere at depths < 100 km, and initial *Ps* receiver functions of the transverse component suggest that many 'interfaces' resemble thin shear zones with a discernible rock texture (Bostock, 1998; Byrne et al., 1997; Calvert et al., 1995; Girardin and Farra, 1998; Hajnal et al., 1997; Levin and Park, 1997b; Levin and Park, 2000; Mercier et al., 2008; Sherrington et al., 2004; Warner et al., 1996; Wilson et al., 2004). The S-to-P conversions identified in S receiver functions (Farra and Vinnik, 2000) have been associated with anisotropic shear zones in the uppermost mantle (Wittlinger et al., 2004). The theoretical basis for strain localization in mantle convection is also gaining a theoretical grounding (Bercovici and Ricard, 2003).

Neither arc-slab accretion nor delamination can easily be reconciled with potential relations between anisotropy and globally recognized internal upper-mantle interfaces. The Lehmann discontinuity at 220 km depth has been related to depth-dependent changes in mantle deformation mechanisms (Karato, 1992), and the possible influence of penetrative relict structures on the Lehmann discontinuity requires further study. Based on weak back-azimuthal variation of *Ps* conversions in eastern North America, Vinnik et al. (2005) concluded that the Lehmann discontinuity was not associated with anisotropy, but Levin and Park (2000) reported the Hales discontinuity as anisotropic beneath Arabia. Some converted-wave studies on the LAB have not found evidence for anisotropy in the P-to-SH conversions on the transverse component (Saul et al., 2000; Kind et al., 2012; Kumar et al., 2011), but Rychert et al. (2012) associated anisotropy at the LAB with back-azimuthal variation in underside-reflected SS precursors.

One expects that anisotropy at the upper surface of a subducting slab can arise from either olivine LPO in the downgoing

mantle lithosphere or else mineral alignment or cracks in the downgoing oceanic crust. Although these layers surely make a contribution to *Ps*-converted waves observed above subduction zones, Song and Kim (2012), Park et al. (2004), and Nikulin et al. (2009) argued that an anisotropic layer with high Poisson ratio, likely involving serpentinized rock above the nominal oceanic crust, was the major cause of observed *Ps* waves in receiver functions in Cascadia. Wirth and Long (2012) also interpreted *Ps* conversions from northern Honshu, Japan, as arising partly from an anisotropic layer above the Pacific Plate slab, though in the Kii Peninsula in central Japan, the anisotropy is inconsistent with the seismicity within the downgoing Philippine Sea Plate (Shiomi and Park, 2008).

The Apennines slab is often characterized as continental subduction, but Bianchi et al. (2010) found evidence from P receiver functions for a 10 km anisotropic layer above the downgoing slab beneath central Italy, superficially similar to oceanic subduction zones. The layer above the Apennines slab is evident at 40–80 km depths, whereas *Ps* conversions in Cascadia and Japan are typically strongest at 40 km depth or shallower. Bianchi et al. (2010) interpreted this as evidence of a process peculiar to continental dynamics, in which the lowermost crust peels downward with the subducting mantle lithosphere but eventually rises to form an ultrahigh-pressure (UHP) terrane in a mature eroded orogen, as seen, for example, in the European Alps (Jolivet et al., 2003).

1.09.3.10 ScS, S_{diff}, and the D″ Layer

Except for the D″ layer, just above the core–mantle boundary, there is no evidence for widespread anisotropy in the bulk of the lower mantle (Heintz, 2006; Meade et al., 1995; Restivo and Helffrich, 2006). Due to limitations in station distribution and in the types of waves and events that can be used to study the lowermost mantle, our knowledge of anisotropy in the D″ layer is more patchy in the upper mantle. In addition, the seismic waves that sample the D″ layer may be affected on their descent from the source and ascent to the station by upper-mantle anisotropy. It is possible to ascertain the presence of anisotropy in D″ by comparing waves having traversed the D″ region with those having their turning point just above, but a fully global characterization of D″ anisotropy is best done in the context of inverting for an anisotropic mantle at all depths simultaneously (Kustowski et al., 2008; Panning and Romanowicz, 2006).

The main observations that motivate D″ anisotropy are ScS and core-diffracted S waves whose arrivals are earlier by up to several seconds on the transverse component than on the longitudinal (see also **Chapter 1.22**, Lay). The first such observations were reported by Mitchell and Helmberger (1973) on ScS waves reflected at the Core-Mantle boundary (CMB) below the Caribbean, with delays $\Delta t = 0$–3 s. Similar delays have been observed in subsequent ScS studies and at large epicentral distances on S and diffracted S waves. A review by Moore et al. (2004) shows that $0 < \Delta t < 4$ s in most cases, with some extreme observations of $\Delta t = -2$ s (i.e., SV faster than SH) and $\Delta t = 9$ s. The negative delays correspond mostly to paths in the central Pacific and in the central Atlantic Ocean. Other regions that show mostly positive delays include Alaska, Asia, and India. As with the Caribbean, these areas lie beneath subduction zones. Observed delays can be explained on the average by 1% vertical TI in D″, but Nowacki et al. (2011) pointed out that variations among regions and among studies are quite large. Although at the limit of current resolution, D″ anisotropy is also seen in global tomographic models with in particular a strong negative anomaly (slow SH waves) below Fiji (Panning et al., 2010). Radial anisotropy has also been incorporated in D″ in the mean 1-D model of Montagner and Kennett (1996).

The observation of large diffracted SV waves deep in the core shadow led Vinnik et al. (1989a) to propose that azimuthal anisotropy, acting to couple the SH and SV waves rather than causing simple birefringence, could also be present in D″ in the central Pacific region. Such azimuthal anisotropy has also been found under the Caribbean (Maupin et al., 2005) and under the northwest Pacific Ocean (Wookey et al., 2005) using ScS waves or by joint analysis of SKS and SKKS waves (He and Long, 2011). The difficulty in finding appropriate datasets that provide azimuthal coverage of a given region strongly limits a full characterization of the anisotropy. In most studies, data are available only in one azimuth and the anisotropy has been characterized as a simple tilted version of the more classic VTI model of D″, with tilts of 20–60°. The best coverage has been achieved in Nowacki et al. (2010) with two azimuths in three neighboring regions from the Caribbean to western United States, showing unambiguous non-VTI behavior in two of the six paths and a complex regional pattern that might be correlated with the subduction of the Farallon Plate.

Anisotropy in D″ has been related to its role as a boundary layer in mantle convection and to the expectation that large deformation leads to preferred orientation of melt inclusions (Kendall and Silver, 1998) or minerals. The mineral-orientation hypothesis was revived by the discovery of the phase transition of the dominant lower-mantle component perovskite to postperovskite at D″ *P*–*T* conditions (Murakami et al., 2004). Postperovskite is predicted to be more abundant in the coldest regions, where subducted material accumulates. It has therefore been pointed out that anisotropy, together with other features of D″ observed in the same regions, may be related to the presence of slab remnants, as further discussed in the chapter by Lay in this treatise. Nowacki et al. (2011) explored the likely minerals in D″ and their possible roles in the development of anisotropy. The postperovskite phase exhibits a significantly stronger anisotropy than the ordinary perovskite phase and should develop LPO under shear flow (Murakami et al., 2004). Modeling using a global mantle-flow model shows that dislocations moving on (0 1 0) or (1 0 0) give the best correlation with observed anisotropy (Walker et al., 2011), but the present sampling of D″ anisotropy still leaves room for alternative models.

1.09.3.11 PKIKP, Normal Modes, and the Inner Core

The only truly global observation of the Earth's internal P-wave anisotropy is related to the inner core. This anisotropy is observed in the splitting of the core-sensitive normal modes (Irving and Deuss, 2011; Deuss et al., 2010; Morelli et al., 1986; Woodhouse et al., 1986) and the traveltimes of PKIKP waves for polar paths, close to the Earth's rotation axis,

contrasted with paths in the equatorial plane (Leykam et al., 2010; Morelli et al., 1986; Souriau et al., 2003). P waves following polar paths arrive on the average about 3 s earlier than those following the equatorial paths. The observations can be explained by inner-core TI of about 3% with a north–south fast axis. Early results suggested tilting of the fast axis with respect to the polar direction (Creager, 1992), but more recent models favor some lateral heterogeneity in the distribution of anisotropy (Garcia and Souriau, 2000; Ishii et al., 2002) rather than a tilt of the axis. There is in particular growing evidence for the western core hemisphere (defined as west of Greenwich) having both higher P-wave velocity (Niu and Wen, 2001) and stronger anisotropy (Tanaka, 2012; Tanaka and Hamaguchi, 1997) than the eastern core hemisphere.

This hemispheric dichotomy has also been observed by normal-mode studies (Deuss et al., 2010), suggesting that it is a global feature and that it is likely present in the S wave speed as well, since the relevant normal modes are more sensitive to it. This longitudinal heterogeneity is an intriguing feature that could be related to the presence of an isotropic layer at the top of the outer core that is thicker in the eastern hemisphere than in the western one and has inspired innovative models for the dynamics of the Earth's core (Monnereau et al., 2010).

The PKJKP phase that traverses the core as an S wave is very difficult to observe. Two observations have however been done on stacked data (Wookey and Helffrich, 2008) that are consistent with the anisotropy found with P waves and an interpretation of anisotropy in terms of oriented iron.

As with the Earth's mantle and crust, there are two main possible mechanisms for explaining inner-core anisotropy: preferred orientation of fluid inclusions (Singh et al., 2000) and preferred orientation of minerals, iron crystals in the present case, acquired either during solidification, during subsequent deformation, or in relation to the orientation of the magnetic field (see Deguen, 2012; Steinle-Neumann et al., 2001, for recent summaries). The preferred orientation of iron in its hexagonal close-packed form is favored by several authors and is the mechanism that satisfies most of the observations (Deguen, 2012) at the present time.

Anisotropy in the attenuation of the inner core has also been reported (Souriau and Romanowicz, 1996). The strongest attenuation is found in the fast direction along the polar axis, and the heterogeneity in the attenuation anisotropy seems to follow the east–west pattern in P-wave velocity (Oreshin and Vinnik, 2004). The fact that frequency-dependent analysis of the attenuation of PKIKP waves implies a frequency-dependent Q in the polar direction but not along equatorial paths (Souriau, 2009) may help in revealing the nature of the inner-core anisotropy. Additional references to studies of the inner core anisotropy may be found in Souriau and Calvet (**Chapter 1.23**).

1.09.4 Perspectives

The main challenge concerning seismological observations of anisotropy is to construct a model of the Earth's anisotropy that explains all the data in any one region. Even the best-documented observations, namely, SKS splitting, Love–Rayleigh discrepancy, and Rayleigh-wave phase-velocity azimuthal variations, are sensitive to different aspects of anisotropic rock structure and so do not readily corroborate each other. Where observations are complementary, often they cannot be explained by one simple model of anisotropy, suggesting a combination of fossil anisotropy and ongoing mantle deformation or else a complex 3-D mantle flow, influenced by variations in mineralogy and volatile concentration. Many tectonic regions probably fit these descriptions and will require a patient accumulation of seismic observables to reveal their dynamics.

Acknowledgments

The authors are grateful to Neil Ribe for assistance in describing the orientation of olivine; to Ed Garnero, James Wolfe, Ludek Klimes, Donna Blackman, and Maureen Long for permission to reprint their figures; and to Andreas Köhler for suggestions when writing the second edition of this chapter. We also thank Michael Kendall and Barbara Romanowicz for careful readings of our first-revised draft that identified gaps in our coverage of the literature.

1.10.1 Introduction to Seismic Tomography

Since its beginnings in the mid-1970s, seismic tomography has grown to become one of the fundamental tools of modern seismology. Seismic tomographic models of the three-dimensional (3D) variations of seismic velocity and density play a critical role in the analysis of Earth's structure and dynamics, ranging from planetary-scale convection to the kilometer-scale mapping of subsurface lithology, temperature, fracturing, fluid content, etc. We trace the roots of seismic tomography back to a parallel series of abstracts and papers by Keiiti Aki and coworkers on regional- (teleseismic-) and local-scale body-wave tomography beginning in 1974 and by Dziewonski and coworkers on global-scale body-wave tomography starting in 1975. These workers initially referred to their approaches in terms of 3D inversion and 3D perturbations, not seismic tomography.

The term tomography comes from the Greek 'tomos' that means 'slice.' The mathematical basis for tomography can be attributed to Johann Radon. We found the first use of the term seismic tomography in a remarkable PhD thesis by Reagan (1978) on seismic reflection tomography, although this author also refers to a document from the Jet Propulsion Laboratory (1976) proposing the use of tomographic reconstruction on borehole seismic data. Clayton and Hearn (1982) appeared to have been the first workers in earthquake seismology (as opposed to exploration seismology) to adopt the term tomography, while the Scientific American article by Anderson and Dziewonski (1984) can probably be credited with popularizing the use of the term. As of 2012, a substantial number of books and review papers have been written on the subject. Among these are Thurber and Aki (1987), Nolet (1987, 2008, 2011), Dziewonski and Woodhouse (1987), Woodhouse and Dziewonski (1989), Romanowicz (1991, 2003, 2008), Iyer and Hirahara (1993), Montagner (1994), Ritzwoller and Lavely (1995), Boschi et al. (1996), Trampert (1998), Rawlinson and Sambridge (2003), Thurber (2003), Lees (2007), Zhao (2009), Rawlinson et al. (2010), and Liu and Gu (2012). Our purpose is not to review the vast literature on seismic tomography. Rather, we provide a thorough introduction to the method and highlight

some key issues of particular interest in current research. We pay special attention to the issues of model parameterization, model solution, and especially model assessment, as a tomographic model is only useful if we know (at least approximately) how well it represents the real Earth.

Seismic (or other) modeling of the Earth can be carried out as a 'forward problem' where we presume to know the Earth's structure and properties and use the physics of wave propagation to predict what our observations should be: $\mathbf{d}=F(\mathbf{m})$, where $\mathbf{d}$ are the data, $\mathbf{m}$ is the given model, and F represents the forward problem function. In seismic tomography, we use the observations to infer the Earth's structure, again using the physics of wave propagation but now in combination with a linear or nonlinear inversion technique – an 'inverse problem.' For a linear inverse problem, $\mathbf{d}=F(\mathbf{m})$ can be replaced by an equivalent set of discretized linear equations: $\mathbf{Gm}=\mathbf{d}$, where $\mathbf{d}$ and $\mathbf{m}$ are vectors containing the data and model parameters, respectively, and $\mathbf{G}$ is a matrix embodying the physics of the problem. The model estimate can be written as $\mathbf{m}=\mathbf{G}^{-i}\,\mathbf{d}$, where the superscript $-i$ stands for some type of inverse (pseudoinverse, regularized inverse, etc. – see Section 1.10.4). For a nonlinear problem, one typically determines the misfit between data and predictions $\delta\mathbf{d}$ (computed from the forward problem for a trial Earth model) and computes perturbations to the model, $\delta\mathbf{m}$, that will reduce the misfit in an iterative manner, using $\delta\mathbf{m}=\mathbf{G}^{-i}\,\delta\mathbf{d}$ (see Aster et al., 2012 and references therein).

Seismic imaging has seen a great deal of progress in the past few decades, largely due to the modernization and growth of global and regional networks (e.g., Butler et al., 2004; Committee on the Science of Earthquakes, 2003; Fowler and Pavlis, 1994; Romanowicz et al., 1984; Van der Vink and Working Group, 2002). The earliest global tomographic models were based entirely on the travel time of the first arriving P-waves, documented in catalogs. Contemporary models, however, exploit the wide variety of seismic signals recorded by broadband seismometers, including free oscillations, surface waves, and body waves, which provide complementary sampling of the Earth. In addition, forward modeling theories have been improved (even in 3D; see Chapters 1.01, 1.04, 1.05, and 1.06), and the steady increase of computing power has enabled seismologists to tackle increasingly larger inverse problems. Yet, it remains difficult to construct the 'best' model of seismic velocity variation given a set of seismic recordings. Ongoing debates in the literature on model resolution and interpretation underscore the difficulty of seismic tomography as an ill-conditioned geophysical inverse problem. So, what are some of the major problems?

- Uneven and incomplete sampling by seismic waves is a pervasive problem in virtually all seismic tomography problems. On a global scale, the bulk of seismic stations is onshore (and in the northern hemisphere), and most earthquakes occur in narrow belts along plate boundaries. Vast regions of the mantle are not adequately sampled by seismic waves. On the local and regional scales, sufficiently dense networks are generally concentrated on active fault zones, with major gaps in both sources and receivers elsewhere.
- We need a large number of model parameters to image relatively narrow structures in the mantle (e.g., slabs of subducted lithosphere and mantle plumes) or fine-scale structures in the crust (e.g., fault zones and magma chambers). A whole-mantle model of seismic velocity in 1 by 1 regions with 100 km thick layers would be composed of nearly one million parameters. Similarly, at a regional scale, one might wish to have 1 km^3 cells covering a region 400 km by 250 km by 40 km deep, amounting to four million parameters.
- There is model nonuniqueness due to data errors and incomplete sampling. More than one model, in fact an infinite number of models, can adequately explain a seismic tomography dataset. Given model nonuniqueness, we need to impose (ad hoc) constraints to select a 'reasonable' model. We may prefer a model that deviates little from the chosen reference model or a model with 'smooth' wave speed variations. While removing the nonuniqueness problem, one must realize that a priori constraints bias the attributes of the seismic model. Obviously, velocity heterogeneity in seismic models tends to be smooth when smoothness constraints have been applied.
- Often, we make simple approximations to wave propagation theories (e.g., 'ray theory' for travel time inversions and the 'path-average approximation' for surface-wave inversions). These approximations lessen the computational burden of the inverse problem but compromise model quality especially in high-resolution applications.
- The model is typically focused on one (e.g., isotropic wave speed) or few (e.g., transverse isotropy) parameters, yet seismic-wave propagation is influenced by 21 elastic parameters, attenuation, and density. The resolution of all physical parameters is impossible with available datasets. Furthermore, image artifacts can arise due to trade-offs when only a few seismic parameters are considered.

We present a comprehensive survey of seismic tomography and inversion methods as applied to local-, regional-, and global-scale studies. Section 1.10.2 provides a brief description of the types of seismic waves, including full waveforms, commonly used in tomography (Sections 1.10.2.1–1.10.2.5), and discusses the commonly employed theories that enable us to relate seismic data to Earth's seismic structure, often as deviations from a (1D) reference Earth model (Section 1.10.2.6). We discuss in Section 1.10.3 how the Earth is represented (parameterized) as a model, including cell-based parameterizations and continuous basis functions (Section 1.10.3.1) and irregular meshes and multigrids (Section 1.10.3.2), along with a brief discussion of station and crustal corrections (Section 1.10.3.3). Section 1.10.4 is devoted to the inverse problem. We discuss linear and nonlinear solutions (Section 1.10.4.1) and strategies to regularize the inverse problem (Section 1.10.4.2). The mathematics of the coupling between earthquake locations and velocity structure is the topic of Section 1.10.4.3. In Sections 1.10.4.4–1.10.4.7, we revisit station corrections, discuss Vp/Vs inversion, and introduce double-difference (DD) tomography, waveform tomography, and adjoint methods. Section 1.10.5 illustrates how we can evaluate the quality of the model using formal resolution analysis and by forward modeling (hypothesis) tests. We highlight in Section 1.10.6 areas of current and future research that are at the forefront of seismic tomography.

Our discussions are concentrated on passive-source (i.e., earthquake) tomography at the crustal through global scale; exploration-seismic tomography methods are not covered here. Although there are a number of important tomographic studies focused on seismic anisotropy and wave attenuation, we concentrate our discussions on the imaging of wave speed variations. See **Chapters 1.07** (Maupin and Park) and **1.09** (Romanowicz and Mitchell) for thorough discussions of seismic anisotropy and attenuation, respectively.

1.10.2 Data Types in Seismic Tomography

In this section, we discuss the general types of data (**Figure 1**) and their use in the corresponding tomographic methods: body-wave travel times, the dispersion characteristics of surface waves, free oscillation (normal mode) spectra, full waveforms, and cross correlations of noise. Teleseismic body-wave travel times are most routinely used in both global and regional applications. The first global model of the deep mantle by Dziewonski et al. (1977) was based on travel time picks incorporated in the bulletins of the International Seismological Centre (ISC). Subsequent models have utilized the millions of travel time picks the ISC bulletins now comprise (e.g., Bijwaard et al., 1998; Inoue et al., 1990; Li et al., 2008; Montelli et al., 2004a,b; van der Hilst et al., 1997; Vasco et al., 1995; Zhou, 1996, 2004), or they are based on the modeling of body-wave waveforms (Grand, 1994; Houser et al., 2008; Li and Romanowicz, 1996; Masters et al., 1996; Ritsema et al., 2011; Su et al., 1994). Global-scale travel time tomography has been key in illuminating the variable extent of slab penetration into the lower mantle (e.g., Fukao et al., 2001; Grand, 1994; Grand et al., 1997) and the ascent of mantle plumes from the deep mantle (e.g., Montelli et al., 2004b, 2006; Nolet et al., 2007; Zhao, 2004). Surface waves generally produce the highest-amplitude signals in seismograms and provide constraints on the upper mantle. Measurements of surface-wave dispersion (i.e., the frequency-dependent surface-wave speed) are key in our understanding of lithospheric structure, especially in oceanic regions where few seismic stations are located (e.g., Debayle et al., 2005; Ekström et al., 1997; Laske, 1995; Lévêque and Cara, 1985; Lin and Ritzwoller, 2011; Montagner and Tanimoto, 1991; Nakanishi and Anderson, 1982; Nataf et al., 1986; Ritsema et al., 2004; Trampert and Woodhouse, 1995; van Heijst and Woodhouse, 1999; Visser et al., 2008a; Zhang and Tanimoto, 1993). Normal-mode spectral measurements provide constraints on the longest wavelength part of lateral heterogeneity through the Earth (e.g., Deuss et al., 2011, 2013; Häfner and Widmer-Schnidrig, 2013; He and Tromp, 1996; Masters et al., 1982, 1996; Resovsky and Ritzwoller, 1999). These data lend themselves for joint inversions for shear and compressional velocity (Deschamps and Trampert, 2004; Masters et al., 1996) and even density (Ishii and Tromp, 1999, 2001; Kuo and Romanowicz, 2002). We also briefly discuss the topics of waveform inversion and the use of reference Earth models.

Although several workers have demonstrated that robust body-wave (e.g., Bhattacharya et al., 1996; Komatitsch et al., 2002; Nolet et al., 2005; Reid et al., 2001; Ritsema et al., 2002) and surface-wave (e.g., Billien et al., 2000; Dalton and Ekström, 2006; Romanowicz, 1991; Selby and Woodhouse, 2002) amplitude and polarization patterns can be derived from high-quality data to constrain velocity gradients, attenuation, and anisotropy structure, most tomographic studies of velocity structure are primarily based on wave travel time or phase delay inversions. Compared to amplitudes, travel time datasets possess little scatter, and they can be determined in a relatively straightforward manner.

1.10.2.1 Body Waves

Body waves are relatively low-amplitude, impulsive signals that, at teleseismic distances, propagate along a variety of paths through the mantle and core. Direct waves, surface reflections, and core reflections provide sampling of the mantle along unique paths. In global tomography, teleseismic travel times are key in constraining the structure of the deep mantle. Upper mantle modeling using teleseismic travel times and local and regional tomography modeling generally rely on measurements from a relatively dense regional network of stations.

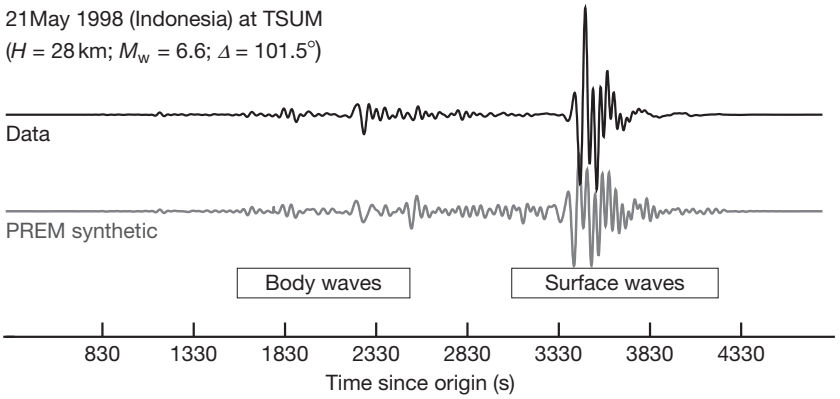

Figure 1 (top) Recorded (vertical component) and (bottom) PREM (Preliminary Reference Earth Model) synthetic seismogram (vertical component) of the 21 May 1998 Indonesia earthquake at station TSUM (Tsumeb, Namibia). The arrival of body waves and surface waves is indicated.

Ray theory and Fermat's principle are at the heart of traditional body-wave travel time tomography. In the infinite frequency limit, travel time T can be written as a path integral:

$$T = \int_{\text{ray path}} u(\mathbf{r})\, ds \qquad [1]$$

where u is the model of slowness (reciprocal of wave speed) at points along the ray path, $\mathbf{r}$ is position, and ds is an infinitesimal element of path length (see **Chapter 1.04**). Our problem of determining the 3D slowness structure $u(\mathbf{r})$ from the arrival-time residuals, obtained by solving a set of equations of the general form

$$\delta T = \int_{\text{ray path}} \delta u(\mathbf{r})\, ds \qquad [2]$$

where δ represents a perturbation, is confounded because we do not know the true ray path (neglecting for the moment the additional issues of the hypocenter location and origin time if an earthquake is the source of the arrival). Looked at another way, the ray path in the reference model will no longer be the correct ray path once the perturbations are applied to the model. Fermat's principle rescues us from this quandary, thanks to the stationary nature of travel time under small perturbations to the ray path. If the path perturbation between the initial and adjusted models is sufficiently small, the travel time (and therefore the travel time residual) will be nearly the same no matter which of the two paths is used. See Snieder (1990), Snieder and Sambridge (1992), and Snieder and Spencer (1993) for a detailed treatment of this issue. For global and teleseismic tomography, this approximation is sufficient if perturbations are not too large, but in local and regional studies, iteration is required (see **Section 1.10.4.1**).

It should be clear from eqns [1] and [2] that body-wave travel time tomography in the infinite frequency limit is relatively simple in theory, but it is more complex if finite-frequency effects are taken into account in broadband travel time data analyses. Two such examples are 'fat ray' tomography (Husen and Kissling, 2001) and 'finite frequency' theory (Dahlen et al., 2000).

Fat ray tomography adopts the view that the entire first Fresnel volume (the volume within which scattered energy arrives within one-half the dominant period of the seismic wave) of the first arriving phase should be considered in relating travel time residuals to model perturbations. Therefore, the region of the model sensitive to a given datum is banana-shaped for a typically curved path, with the source and receiver close to (but not at) the tips of the banana (**Figure 2**). Husen and Kissling (2001) at the local scale and Kárason and van der Hilst (2001) on the global scale developed such an approach, distributing the contributions to a given travel time perturbation (eqn [2]) among the model parameters in proportion to the fraction of the total Fresnel volume present in a given model cell, rather than along a path of infinitesimal width.

The need for finite-frequency theory arises when waveform fitting (e.g., Li and Romanowicz, 1995; Li and Tanimoto, 1993; Mégnin and Romanowicz, 2000) or cross correlation (Dahlen et al., 2000; Hung et al., 2000; Liu and Tromp, 2006; Marquering and Snieder, 1995; Nissen-Meyer et al., 2007) of the observed and synthetic waveforms is used to estimate travel

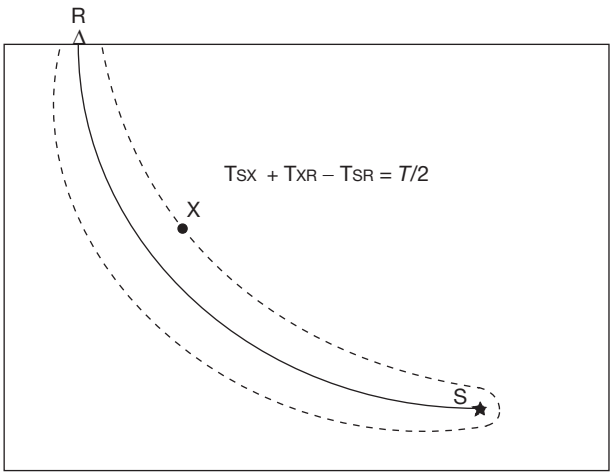

Figure 2 Diagram of the Fresnel zone for a body wave in the Earth. A point is in the first Fresnel zone if the scattered wave from point X reaches the receiver at R within a time equal to 1/2 of the wave period T of the direct arrival from the source S.

times. Equation [2] becomes a volume integral. The kernels that describe the sensitivity of travel times measured by waveform cross correlation (WCC) (i.e., finite-frequency travel times) surround the geometric ray path, and their volumes are determined by the Fresnel zone. Perhaps surprisingly, the cross-correlation measurement is completely insensitive to the model along the (infinite frequency) ray path. In map view, the sensitivity kernel resembles a banana around the ray path and in cross-sectional view looks like a doughnut – hence, the term 'banana–doughnut kernel' is often used. As one might expect, the width of the sensitivity kernel and its interior 'hole' are strongly frequency-dependent. However, whether finite-frequency effects impact the resolution of earth structure is still a matter of debate (Montelli et al., 2004a,b; van der Hilst and De Hoop, 2005).

1.10.2.2 Surface Waves

There are two types of surface waves with different particle motion characteristics, just as there are two types of body waves – but with a 'twist.' Surface waves are evanescent waves (with a purely imaginary vertical wave number $k = i|v|$) that propagate horizontally along the Earth's surface with a 'skin depth' that increases with increasing period (or wavelength). Love waves are composed of horizontally polarized shear waves (P-SV) trapped within a surface layer (or layers). Rayleigh waves form by an interaction between compressional and vertically P-SV at the surface. Earth's sphericity and the increase of wave speed with depth lead to dispersion of surface waves. As a result, surface waves are recorded as a 'train' of waves, with long-period/long-wavelength waves generally arriving first. At teleseismic distances, surface waves have much larger amplitudes than body waves due to their geometric spreading in two dimensions, as opposed to the 3D spreading of body waves.

As a consequence of dispersion, two distinct velocities characterize surface-wave propagation. Let us express displacement $u(x,t)$ as an integral over harmonic plane waves of all frequencies ω:

$$u(x,t) = \int A(\omega) \exp\{\mathrm{i}(\omega t - k(\omega))x + \phi(\omega)\}\, \mathrm{d}\omega \quad [3]$$

If we approximate the wave number $k(\omega)$ by a Taylor series about ω_0

$$k(\omega) = k(\omega_0) + \left(\mathrm{d}k/\mathrm{d}\omega|_{(\omega=\omega_0)}\right)(\omega - \omega_0) \quad [4]$$

it is straightforward to show that the displacement due to harmonic waves near ω_0 is approximately

$$u(x,t) = \int_{\omega_0-\mathrm{d}\omega}^{\omega_0+\mathrm{d}\omega} A(\omega) \exp\{\mathrm{i}(\omega-\omega_0)(t - \mathrm{d}k/\mathrm{d}\omega x)\} \exp\{\mathrm{i}(\omega_0 t - k(\omega_0)x) + \pi)\}\, \mathrm{d}\omega \quad [5]$$

The two sinusoidal functions in [5] correspond to propagating waves with different speeds. The carrier wave at frequency ω propagates at the phase velocity (C) ω_0/k, upon which a more slowly varying envelope with frequency $\mathrm{d}\omega$ and wave number $\mathrm{d}k$ is superposed. This envelope propagates at the group velocity (U) $\partial\omega/\partial k$.

Surface-wave group velocity analysis generally involves multitapered spectral analysis of narrowband filtered signals:

$$s(t) = \int s(\omega)H(\omega)\, \mathrm{d}\omega \quad [6]$$

where $H(\omega)$ is the taper function, usually of the form $\exp\left\{-(\omega-\omega_0)^2/{\omega_0}^2\right\}$. Group velocity can be determined by estimating how the peak of the amplitude spectrum varies as a function of group velocity U (=epicentral distance/travel time) and the central frequency of the taper function. This analysis has been applied globally to determine group velocity dispersion (see **Chapters 1.01** and **1.03**).

Phase velocities are determined with data either from multiple stations or from single seismograms. The phase Φ_i (determined from the Fourier transform) of a recording i at a distance x_i can be written as

$$\Phi_i = \omega t - k(\omega)x_i + \Phi_\mathrm{s} + 2n\pi = \omega[t - x/c(\omega)] + \Phi_\mathrm{s} + 2n\pi \quad [7]$$

where Φ_s is the initial phase (due to the source). Defining Φ_{ij} as $\Phi_i - \Phi_j$ for stations i and j at the same azimuth from the source (so that Φ_s is common to both recordings i and j), we can, in principle, solve for the phase velocity

$$C(\omega) = \omega(x_i - x_j)/\left[\omega(t_i - t_j) + 2(m-n)\pi - \Phi_{ij}\right] \quad [8]$$

using two stations. In practice, however, more stable results are obtained from an array of stations (Cara, 1976; Merrer et al., 2007; Nolet, 1975) or by multiple earthquake analyses (Beucler et al., 2003; Stutzmann and Montagner, 1993). The term $2(m-n)\pi$ is found empirically by ensuring that the phase velocity has a 'reasonable' value at the longest periods. The subsequent analysis at increasingly shorter periods is 'locked in' by requiring that C is a continuous function of ω.

Single-station measurements of phase velocity require knowledge of $\Phi_\mathrm{s}(\omega)$, that is, knowledge of the earthquake focal mechanism:

$$C(\omega) = \omega x/[\omega t + \Phi_\mathrm{s}(\omega) + 2n\pi - \Phi_i] \quad [9]$$

Often, we measure the phase $\Phi(\omega)$ relative to that in a synthetic seismogram for a spherically symmetrical Earth model $\Delta\Phi = \Phi_\mathrm{obs} - \Phi_\mathrm{syn}$. Again, we remove the cycle-skip ambiguity by locking $2n\pi$ at the lowest frequencies and estimating $\Delta\Phi$ at increasingly higher frequencies. For further details, see **Chapters 1.01**, **1.03**, and **1.06**.

1.10.2.3 Ambient Noise

'Noise' tomography and scattered-wave tomography studies (Pollitz and Fletcher, 2005; Sabra et al., 2005; Shapiro et al., 2005) have caught wide attention as an approach that can take advantage of the growing archive of continuous seismic data from dense regional networks. The Earth is constantly vibrating, normally imperceptibly, and these vibrations are known as ambient noise, generated mainly by ocean waves and wind. The key step in the analysis of ambient noise is the cross correlation of continuous records of up to months of seismic noise for each pair of seismic stations in a regional network. The cross correlation brings out the Green's functions of waves traveling from one station to the other, generally dominated by the surface waves. Thus, from long records of continuous noise, one can recover the same kind of information as obtained from two-station surface-wave analysis. This demonstrates clearly that seismic tomography can continue to advance when researchers find clever ways to exploit the full spectrum of signal contained in seismograms. Snieder and Wapenaar (2010) present an excellent overview of this and other correlation-based seismic imaging techniques. Campillo (**Chapter 1.12**) provides a comprehensive discussion of this relatively new domain of research.

1.10.2.4 Normal Modes

Normal modes (also known as 'free oscillations') are standing waves excited by the largest earthquakes on Earth. Like standing waves on a string, normal modes have distinct frequencies determined by Earth's finite size and its internal elastic structure. The gravest normal mode, the so-called football mode, has a period of about 54 min. In analogy to surface waves (intimately related to normal modes), there are two types of normal modes, distinguished by their mode of oscillations. Torsional modes are analogous to Love waves. They do not have radial displacements and they do not cause volume changes. Spheroidal modes are analogous to Rayleigh waves and involve a combination of radial and transverse motions. We can express the displacement field in the Earth as a sum of normal modes (e.g., Dahlen and Tromp, 1998; Gilbert, 1970):

$$u(x,t) = \sum_n \sum_l \sum_{m=-1}^{l} {}_nA_l^m(\omega)\, {}_nY_l(r) X_l^m(\theta,\phi) \exp\left\{\mathrm{i}\omega_l^m t\right\} \quad [10]$$

Each mode is described by its radial order n and surface order l and m. These integers describe the frequency ${}_n\omega_l^m$ of the normal mode and the spatial shape of the radial eigenfunction ${}_nY_l(r)$ and surface eigenfunction $X_l^m(\theta,\phi)$. A sum of normal modes describes the complete wave field up to frequency ω_l^m. However, due to the computational burden, normal modes are used to study primarily long-period ($T > 20$–50 s) wave propagation, in practice.

A multiplet ${}_n\omega_l$ consists of $2l+1$ singlets ${}_n\omega_l^m$ (m takes values between $-l$ and $+l$). For a spherically symmetrical Earth, the singlet eigenfrequencies are the same. For a laterally heterogeneous Earth, the multiplet 'splits,' rendering singlets ${}_n\omega_l^m$ with slightly different eigenfrequencies. Earth's rotation has an observable effect on the gravest multiplets (e.g., ${}_0S_2$ and ${}_0S_3$). Lateral heterogeneity (both elastic heterogeneity and anisotropy) also has a significant effect. Tomographers use observations of splitting to constrain the large-scale variations (e.g., Deuss et al., 2011, 2013; Giardini et al., 1987; He and Tromp, 1996; Ishii and Tromp, 1999; Masters et al., 1996; Resovsky and Ritzwoller, 1999; Ritzwoller et al., 1998), although in general only the 'even-degree' structure of the Earth can be constrained in a direct manner.

Splitting measurements are not easy to make. Spectral peaks have a finite width, because seismograms are not infinitely long and due to the effect of anelasticity. Moreover, multiplets can overlap, which makes it impossible to treat them in isolation. However, analysis of the splitting of coupled multiplets enables us to constrain both even-degree and odd-degree structures (Dahlen and Tromp, 1998). See **Chapters 1.01**, **1.03**, and **1.06** for further details.

1.10.2.5 Waveforms

While travel times and phase delays represent parametric measurements made from seismograms, it is also possible to model the seismograms directly 'wiggle-for-wiggle.' Waveform inversion is particularly advantageous in that it allows for the analysis of strongly interfering signals. A waveform inversion is typically posed as a search for the model $\mathbf{m}$ that best minimizes the (least-squares) fit between the observed seismogram (or a segment of it) $u(t)$ and a computed seismogram $s(\mathbf{m},t)$:

$$F(M) = \int \mathrm{d}t\{u(t) - s(m,t)\}^2 \qquad [11]$$

In global tomography, waveform fitting was introduced by Woodhouse and Dziewonski (1984) using digital seismic data from upgraded global seismic stations. An important novelty of their approach is that it allows for the recovery of both even and odd spherical harmonic coefficients. In their approach, still widely used today, synthetic seismograms were computed using normal-mode summation. The 'path-average approximation' accounts for the effects of lateral heterogeneity by perturbing the eigenfrequency of each multiplet. Using [10] as a description of a long-period seismogram, we can find perturbations to $\delta\alpha(t)$, $\delta\beta(t)$, and $\delta\rho(t)$ due to perturbations in frequency $\delta\omega$. We can write the dependence of $\delta\omega(\theta,\varphi)$ as

$$\delta\omega = \int_{\text{gc path}} \left(K_\alpha\delta\alpha + K_\beta\delta\beta + K_\rho\delta\rho\right)\mathrm{d}r \qquad [12]$$

where the 1D kernels K_α, K_β, and K_ρ describe the dependence of perturbations in eigenfrequency ω on perturbations to P velocity, S velocity, and density, respectively (see Dahlen and Tromp, 1998 for an extensive theoretical treatment).

The 'partitioned waveform inversion technique' (Nolet and Snieder, 1990) also utilizes the path-average approximation approach, but given its focus on smaller (continental-scale) regions (e.g., Das and Nolet, 1998; Lebedev et al., 1997, 2005; van der Lee and Nolet, 1997; Zielhuis and Nolet, 1994), it is limited to minor-arc waveforms only, albeit at somewhat higher frequencies. The method enables the separate analysis (and data weighing) of fundamental-mode surface waves and overtone signals (such as triplicated SS and SSS waves) and background seismic models unique to different propagation paths.

More realistic kernels have also been developed. 2D kernels computed using across-branch coupling (e.g., Li and Romanowicz, 1995; Li and Tanimoto, 1993; Marquering and Snieder, 1995; Zhao and Jordan, 1998) include (frequency-dependent) sensitivity within the plane of propagation. These higher-order approaches (compared to the path-averaged approximation by Woodhouse and Dziewonski, 1984) better describe the sensitivity of overtone surface waves and complex body waves like SS (the surface-reflected S wave) and S_{diff} (the core-diffracted S wave) to Earth structure. Models SAW12-D (Li and Romanowicz, 1996) and SAW24B16 (Mégnin and Romanowicz, 2000) are based on these 2D kernels. Zhou et al. (2004) computed 3D kernels for phase, amplitude, and arrival angle using surface-wave normal-mode summation. The first application of this theory in global upper mantle tomography has been carried out by Zhou et al. (2006).

Zhao et al. (2005), at the regional scale, and Tromp et al. (2005), on the global scale, demonstrated the ability to compute the Fréchet kernels for the full-waveform inverse problem using a 3D starting model, opening up the avenue of iterative waveform tomography. The data are frequency-dependent travel times (Maggi et al., 2009), phase delays, and amplitude anomalies (Gee and Jordan, 1992), which are evaluated using cross correlation between the observed data and synthetics. Chen et al. (2007) and Tape et al. (2009) applied this approach to the Los Angeles region. Regional-scale studies by Fichtner et al (2009) and Zhu et al. (2012) have improved existing models of 3D structure that were based on travel time tomography and active-source models. See **Section 1.10.4.7** for further discussion of waveform tomography and the use of adjoint methods.

1.10.2.6 Reference Model

Radially symmetrical (1D) models of wave speed, such as the Jeffreys–Bullen tables (Jeffreys and Bullen, 1958), 1066A (Gilbert and Dziewonski, 1975), Preliminary Reference Earth Model (PREM) (Dziewonski and Anderson, 1981), IASP91 (Kennett and Engdahl, 1991), and ak135 (Kennett et al., 1995), still take a central role in the analysis of global seismic data and global tomography. They provide wave speed or a combination of wave speed, density, and attenuation as a function of depth in the Earth and explain to first order the characteristics of global wave propagation, such as the propagation time of teleseismic body waves, and the dispersion of surface waves (including in some cases the effect of upper mantle anisotropy). Using digital broadband recordings, tomographers have built catalogs of surface-wave dispersion measurements (e.g., Ekström et al., 1997; Trampert and Woodhouse, 1996) and catalogs of body-wave travel times (e.g., Ritsema et al., 2002; Su et al., 1994; Woodward and Masters, 1991) by systematically comparing recorded and synthetic waveforms for 1D models (**Figure 1**).

The 1D reference model is also used in the forward modeling theory. For example, a body-wave travel time anomaly, δT, can be defined in terms of velocity as (see Section 1.10.2.1)

$$\delta T \approx \int_{S^0} \frac{1}{V_0^2(\mathbf{r})} \delta V(\mathbf{r}) \mathrm{d}s \qquad [13]$$

where the path S^0 and the velocity V_0 are computed for a 1D reference model. Similarly, a surface-wave phase-velocity perturbation $\delta C(\omega)$ due to shear-velocity heterogeneity in the mantle can be written as

$$\delta C(\omega) = \int_{gc} \mathrm{d}s \int \mathrm{d}\mathbf{r} \left(\frac{\partial C(\omega)}{\partial V_S^0(\mathbf{r})} \right) \delta V_S(\mathbf{r}) \qquad [14]$$

where we have assumed that surface waves propagate along the great circle path gc and that the relationship between phase velocity C and shear velocity V_S can be calculated for the 1D reference model. It is straightforward to compute 1D synthetics, body-wave paths, and kernel functions that relate surface-wave dispersion to seismic velocity for 1D seismic models. Moreover, eqns [13] and [14] render linear relationships between the seismic observables and wave speed heterogeneity. These can be solved using standard linear inverse techniques (see Section 1.10.4). Current research addresses how better, but more complex, theories affect the model solution by using 3D seismic models as initial solutions and by computing the kernels for 3D structures.

In local-scale studies, the importance of the starting 1D model has been clearly demonstrated. For example, Kissling (1988) proposed the use of the 'minimum 1D model' determined by inversion for a layered structure as the starting model for 3D tomography. Refraction models provide another potential source for a starting 1D model. Because the local earthquake tomography (LET) problem is strongly nonlinear, a suitable starting model is critical for reaching an optimal solution.

1.10.3 Model Parameterization

The Earth's seismic velocity structure has been represented in a wide variety of ways in seismic tomography studies. All are only approximations to the true 3D structure of the Earth, or some portion of it. The Earth has heterogeneous structure on a vast range of spatial scales, including complications such as discontinuities, faults, layering, intrusions, inclusions, zones of elevated temperature or partial melt, and random geologic heterogeneities. The spatial scale of heterogeneity that can be imaged with seismic tomography depends primarily on the density of wave sampling, with a lower bound proportional to the minimum wavelength of recorded seismic-wave energy.

1.10.3.1 Cells, Nodes, and Basis Functions

No single scheme can fully represent all aspects of the Earth's heterogeneity. At the local scale, the constant-velocity, uniform volume block approach of Aki and Lee (1976), and the variable volume block approach of Roecker (1982) treat a volume of the Earth as a set of cells within each of which the seismic velocity is constant (**Figure 3(a)**). This approach has the advantage of simplicity, but it clearly lacks the ability to represent gradients in velocity or oblique discontinuities. From the inverse theory point of view, a block/cell inversion is often set up as an overdetermined problem (more independent data than unknowns), but this strategy can be criticized for being underparameterized (insufficient parameters to adequately represent the real Earth). At the same time, some model parameters may actually be unconstrained even though there are more data than unknowns, resulting in a mixed-determined problem (simultaneously over- and underdetermined). Alternatively, one can employ a large number of small cells, allowing gradual or rapid velocity changes from block to block to mimic gradients or discontinuities, respectively (Lees and Crosson, 1989; Nakanishi, 1985; Walck and Clayton, 1987). Unfortunately, the use of a large number of cells, if not compensated for, results in a severely underdetermined problem (many more unknowns than independent data) and increased computational burden. These two problems are typically dealt with by applying a smoothing operator and a sparse-matrix solver, respectively (see Section 1.10.4).

Variations on the discrete block parameterization include laterally varying layers (Hawley et al., 1981) and a 3D grid of nodes (Thurber, 1983). In the approach of Hawley et al. (1981), the model is divided into horizontal layers in which velocity is constant in the vertical direction, but velocity is obtained by interpolation in the horizontal directions among vertical nodal lines (**Figure 3(b)**). The spacing between nodal lines may vary from layer to layer. Thurber (1983) used a 3D grid approach (**Figure 3(c)**), in which velocity varies continuously in all directions, with linear B-spline interpolation among nodes. Alternatively, one can use cubic B-splines with continuous second-order derivatives (Michelini and McEvilly, 1991).

Another variant of the 3D grid theme is to consider each set of four neighboring nodes as defining the vertices of a tetrahedron (**Figure 3(d)**; Lin and Roecker, 1997). The four node velocities can be used to define a unique linearly varying velocity field within the tetrahedron; the velocity gradient can thus point in any direction. Snell's law is used to cross tetrahedral boundaries. This allows the use of an analytic formula for ray tracing using an initial-value ('shooting') approach, as ray paths are circular arc segments in a medium with constant-velocity gradient. Other alternative interpolation schemes are possible but would require different ray tracing procedures. See also Section 1.10.3.2 for an example of the use of tetrahedrons in adaptive-mesh tomography.

Similar approaches have been adopted for regional- and global-scale tomography. Aki et al. (1977) employed constant-slowness, uniform volume cells in their original teleseismic (regional) inversion work, and that method ('ACH' after the authors Aki, Christoffersson, and Husebye) has proven to be a 'workhorse' for the seismology community (see Evans and Achauer, 1993). Some improvements have been made to the algorithm over the years, including allowing for variable block thickness with depth (Evans and Achauer, 1993) and using nodes with spline interpolation (VanDecar et al., 1995), and problems and code errors have been pointed out (Julian et al., 2000; Masson and Trampert, 1997), but the basic method continues to be used widely. Humphreys, Clayton, and coworkers developed a similar algorithm (Humphreys et al., 1984), and Spakman, Nolet, and coworkers developed a third comparable algorithm (Spakman and Nolet, 1988), both of which have also been put to wide use. A key distinction between the latter two is

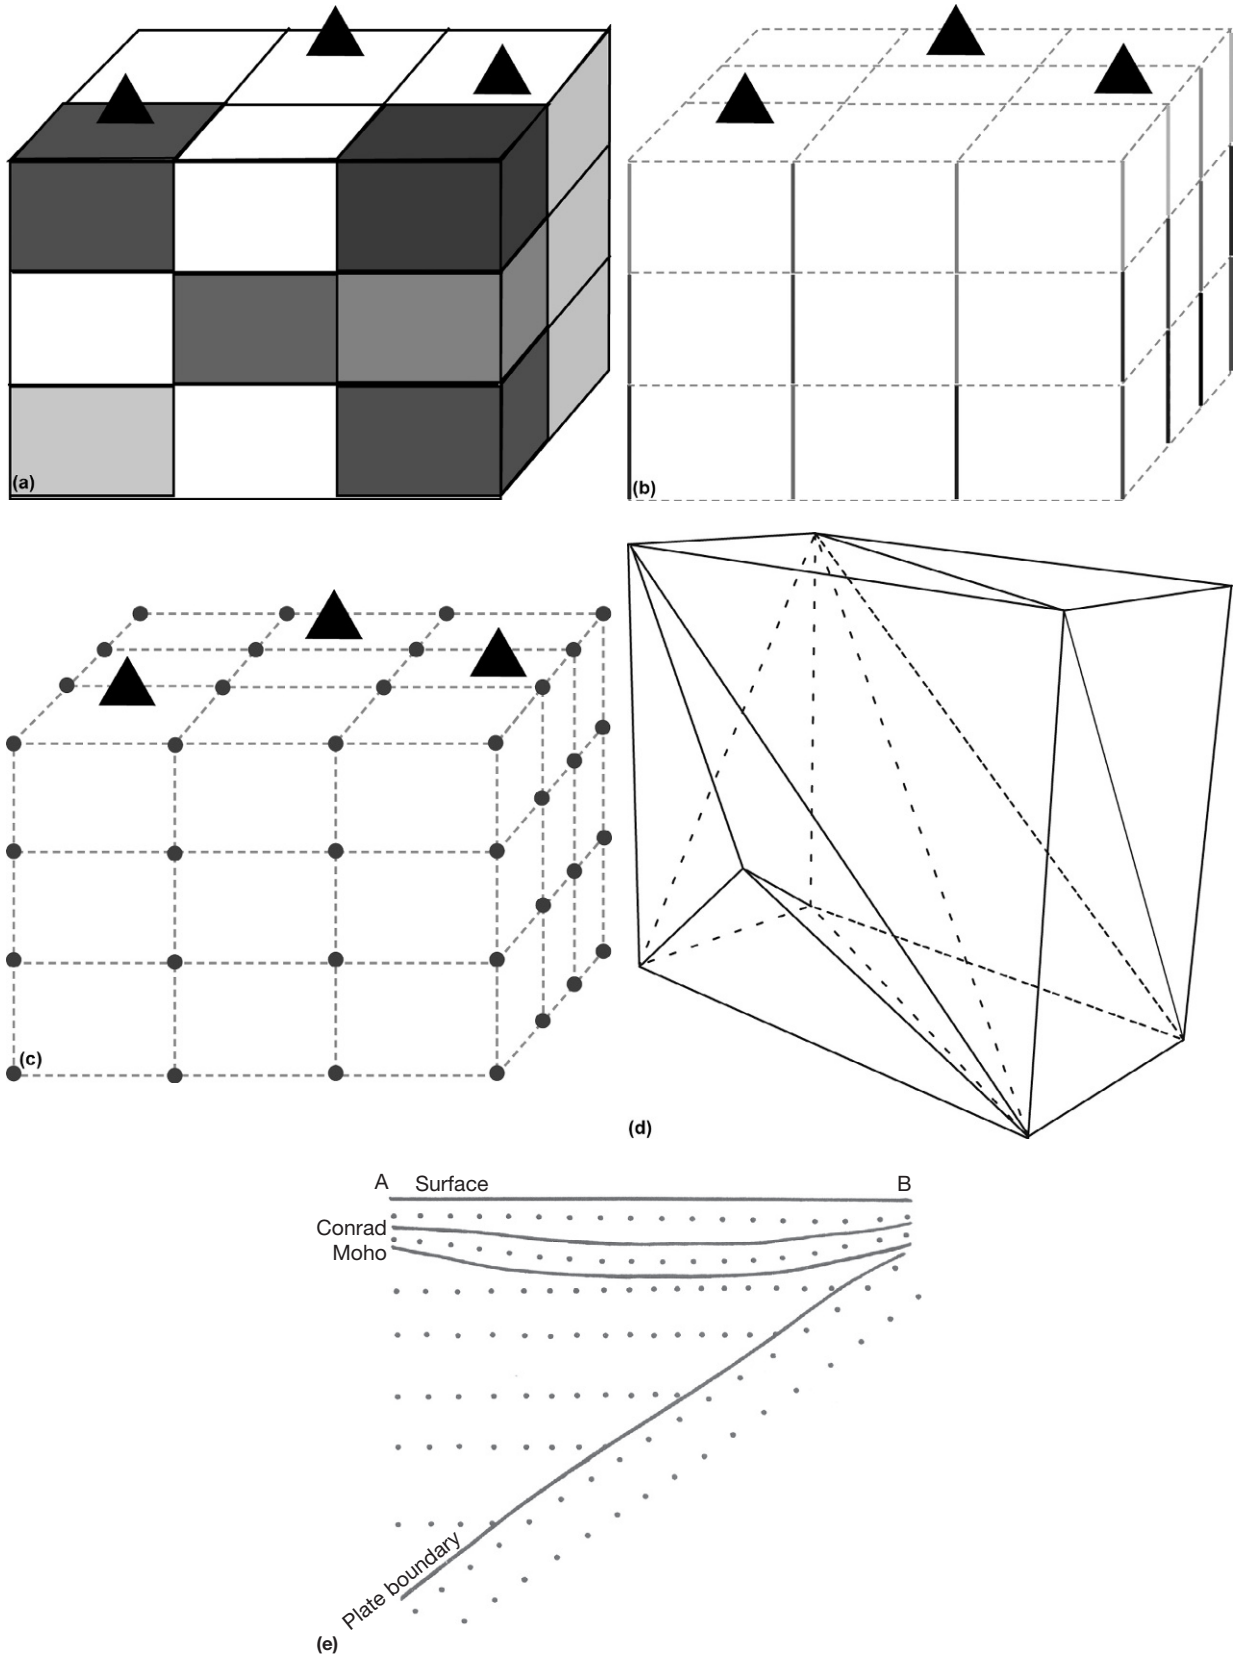

Figure 3 Examples of types of model parameterization schemes. (a) Constant-velocity, uniform volume blocks. (b) Layers of laterally varying but vertically constant velocity within a given layer. (c) Regular grid of nodes. (d) Variable-size tetrahedral cells. (e) Interfaces separating regions with velocity defined on a grid. Reproduced from Zhao D, Hasegawa A, and Horiuchi S (1992) Tomographic imaging of P- and S-wave velocity structure beneath northeastern Japan. *Journal of Geophysical Research* 97: 19909–19928.

the inverse problem solution method, simultaneous iterative reconstruction technique (SIRT) for the former and LSQR for the latter (see **Section 1.10.4**).

Zhao and coworkers have taken a slightly different approach that emphasizes the importance of major seismic velocity discontinuities along with velocity heterogeneity. Using the study of northeastern Japan by Zhao et al. (1992) as an example, the authors define the discontinuities and imbed a velocity grid within each layer (**Figure 3(e)**). The method allows the inclusion of secondary phase data (e.g., converted phases) to model the positions of the discontinuities, although this particular study did not utilize this capability.

Similarly, Zhao (2004) incorporated discontinuities and a 3D grid in a global tomographic model, with a grid spacing of 3–5°. Specifically, he included the Moho and the 410 and 660 km discontinuities, keeping them fixed during the inversion. More commonly, global tomographic models utilize spherical 'blocks' of uniform latitude and longitude extent or roughly uniform size (Inoue et al., 1990; Sengupta and Toksöz, 1976; Simmons et al., 2010; van der Hilst et al., 1997; Vasco et al., 1995; Zhou, 1996).

Alternatively, one can adopt a functional approach to representing 3D structure, with either a set of basis functions or an a priori functional form. An example of the former is an expansion in a set of continuous, orthogonal basis functions (e.g., sinusoidal or spherical harmonic functions) where the spatial resolution is limited by the number of terms included in the expansion (Novotny, 1981). Examples of the latter are the subducting slab parameterization of Spencer and Gubbins (1980), in which the slab is represented by its strike, dip, width, slowness contrast, and decay rate with depth; the fault zone parameterization of Wesson (1971), in which the fault zone is represented by its velocity decrease, decay with depth and distance, and the velocity contrast across it; and the quasilayered parameterization of Ashiya et al. (1987) employing a sum of hyperbolic tangent functions for the depth variation of velocity and Chebyshev functions for the lateral variation of velocity.

Early global P-wave travel time studies used spherical harmonic expansions in latitude and longitude and polynomials in depth (Dziewonski, 1984). As of this writing, global tomography has reached degree 40, corresponding to a lateral dimension of as little as 500 km (Kustowski et al., 2008; Ritsema et al., 2011). One source of concern for this approach is the tendency for the truncated basis functions to leak into the solution, leading to a biased model estimate (Trampert and Snieder, 1996). If the power in the model spectrum above the truncation point is weak, this may not be a serious issue, but of course it is difficult to prove that this is the case, in general. We also point out that truncation is a risk to virtually any tomographic method that adopts an overdetermined ('underparameterized') inverse approach. Trampert and Snieder (1996) in fact present a technique for correcting (to first order) the biasing effect of truncating spherical harmonic basis functions.

Recently, wavelets (e.g., Chevrot et al., 2012; Simons et al., 2011) and cubic splines have been used for global tomography (Antolik et al., 2000; Mégnin and Romanowicz, 2000). Typically, spherical splines (Wang and Dahlen, 1995) are used for the horizontal variations and radial splines for the vertical. This approach has the advantage of being a local parameterization, leading to a sparse solution matrix and potentially avoiding the bias problems of spherical harmonics, combined with the desirable smoothing properties inherent in splines. For the same number of parameters, the spherical harmonic solution should yield a comparable solution to that of a uniform spline model, but the spline approach does have the advantage of allowing for a nonuniform grid. Sparsity is discussed further in **Section 1.10.4.2.2**.

A distinct alternative to the philosophy of discrete model parameterization is to treat the velocity structure explicitly as a continuous function of the spatial coordinates. Two examples are the Backus–Gilbert approach of Chou and Booker (1979) and the 'no-block' approach of Tarantola and Nercessian (1984). In principle, these approaches allow for essentially arbitrary model solutions with no parameterization bias. In practice, however, models must be constrained in one way or another, as they are again underdetermined. The models must also ultimately be discretized for calculation and representation by computer. Chou and Booker (1979) remove the nonuniqueness by evaluating 'ideal averaging volumes,' which reflect the spatial variations in ray sampling of the structure. The idea is to view the Earth structure through the window with the maximum spatial resolution allowed by the data. Pavlis and Booker (1980) employed this method (generalized to include hypocenter parameters) for 1D modeling. The Bayesian strategy of Tarantola and Valette (1982) and Tarantola and Nercessian (1984) makes use of a priori information on the Earth's velocity structure and its 3D spatial covariance function to construct a unique solution. Their nonlinear approach 'anchors' the solution to the starting model and imposes a smoothness constraint that acts on the scale of the correlation distance. Of course, this requires independent knowledge of the 3D spatial covariance function, which is typically (but not always) assumed to be homogeneous throughout the medium. See **Section 1.10.4.2** for additional discussion.

1.10.3.2 Irregular-Cell, Multigrid, and Adaptive-Mesh Methods

In almost all seismic tomography applications, data coverage is highly uneven due to nonuniform station geometry, uneven distribution of seismic sources, missing data, and ray bending. Some nodes or cells may not be sampled at all, while others may be sampled repeatedly. The standard regular cell–grid spacing approach makes it difficult to adapt the model to the uneven sampling. The mismatch between the data distribution and the cells or grid chosen for the tomographic inversion destabilizes the inversion. Preferably, the inversion cells or grid should be distributed adaptively to match with the resolving power of the data and to better condition the inverse problem. At the same time, one can hope to image structural details (e.g., subducting slabs or narrow fault zones) that are smaller in scale than could be represented practically with a uniform-cell global or local model. For a review of irregular-cell and adaptive-mesh methods for seismic tomography, the interested reader is referred to the review paper by Sambridge and Rawlinson (2005).

The goal of matching the ray distribution to the mesh or cells naturally leads to the use of an irregular mesh or cells. One strategy is to explicitly treat the inversion mesh node positions as part of the set of inversion parameters. Michelini (1995)

proposed an adaptive-mesh scheme for relatively small-size inverse problems by simultaneous determination of seismic velocities and node positions, with position adjustments damped more heavily. This concept works because node position adjustments by themselves do alter the velocity structure, steepening or reducing gradients for nodes that move closer together or farther apart, respectively, and of course by shifting the points in space where the specific node velocity values are attained. Thus, there is a natural tendency for nodes to cluster where velocity is changing more rapidly, but the method does not lead to a denser node distribution where the sampling is denser.

Alternatively, one could adapt the irregular inversion mesh or cells using a priori information and/or some measure of solution stability or resolution, without formally including it in the inversion. Abers and Roecker (1991) proposed an irregular-cell representation of the model in which the inversion cells (larger cells) are constructed from basic cells (smaller cells) by using a 'cross-reference table' (an index for defining which cells are combined together). The table is mainly constructed by hand, which limits the practical size of the parameterization one can handle. Vesnaver (1996) proposed a different irregular-cell parameterization approach, in which the cells are interactively modified by merging adjacent cells, shifting cell boundaries, and splitting a cell into two or more according to the null space energy. The null space energy measures the local reliability or the physical resolution of the model. Cells are removed where null space energy is too high, and cells are added where it is adequately low. The null space energy is determined using the singular value decomposition (SVD) $\mathbf{U}\,\mathbf{S}\,\mathbf{V}^{\mathrm{T}}$ (Aster et al., 2012) of the partial derivative matrix for the inversion and is calculated for each model parameter by summing the squares of the elements of the row of the orthogonal matrix $\mathbf{V}$ corresponding to the given model parameter for singular values below a chosen threshold. This process is extremely time-consuming for large-scale problems, as it is not fully automatic.

In contrast, for LET, Zhang and Thurber (2005) developed an automatic adaptive-mesh tomography method based on tetrahedral cells that matches the inversion mesh to the data distribution. As a result, the number of inversion mesh nodes is greatly reduced compared to a regular inversion grid with comparable spatial resolution, and the tomographic system is more stable and better conditioned. They start the inversion from a slightly perturbed regular inversion grid, constructing the tetrahedral cells (or alternatively the Voronoi diagram) around the nodes using the Quickhull algorithm (Barber et al., 1996). Rays are traced between events and stations based on the current regular velocity grid. The rays are used to find the partial derivatives of the travel times with respect to the model slowness parameters on the current inversion mesh. In the process, the values of the 'derivative weight sum' (DWS – the sum of the interpolation weights for the partial derivatives corresponding to each model parameter; Thurber and Eberhart-Phillips, 1999) for the inversion mesh nodes are calculated. Threshold DWS values are set for adding or removing nodes. Once the inversion mesh is determined to be optimal, a new set of tetrahedral cells (or new Voronoi diagram) is constructed, and the partial derivatives of the travel times with respect to the new set of inversion mesh nodes are calculated. Following each simultaneous inversion, the velocity values on the irregular inversion mesh nodes are updated, rays are traced through the new model, and the inversion mesh is again updated following the same procedure to assure a good match with the ray distribution, which will change as the velocity model changes and hypocenters move. Compared to the earlier-mentioned methods, key advantages of this approach are that it is fully automatic and it uses the sampling density to control the mesh density.

Another alternative is the use of multiple-scale grids (multigrids), either overlapping ('superposed') or nonoverlapping ('nested'). In an early study, Thurber (1987) applied a nested-grid inversion to Kilauea volcano to image the finer-scale structure of Kilauea caldera within a larger model of the volcano. Lin et al. (2010) combined results from a number of nested-grid inversions to develop a statewide tomography model for California. Zhou (2004) applied the superposed grids approach to southern California.

A variety of irregular-cell, multigrid, and adaptive-mesh techniques have also been developed for teleseismic and whole-Earth tomography. One common approach is again nested grids, the use of larger cells for a 'background' global 3D model plus smaller cells in a region of interest (Widiyantoro and van der Hilst, 1997). This was extended to a triple-nest grid by Weidle et al. (2005). In a similar but more versatile vein, Spakman and Bijwaard (2001) followed the basic idea of Abers and Roecker (1991) discussed earlier but adopted a different strategy for irregular-cell design by developing a completely automated and fast algorithm for the construction of the cross-reference table. The design of irregular cells can be constrained by some scalar function, for instance, a measure of model sampling such as cell hit count. Wavelet-based representations, discussed in **Section 1.10.3.1**, implicitly provide a multiscale approach (Chiao and Kuo, 2001; Chiao and Liang, 2003; Gung et al., 2009). 'Progressive' inversions that solve for increasingly finer structures as perturbations to coarser models are similar in effect to the wavelet approach (Simons et al., 2011).

Sambridge and Gudmundsson (1998) proposed an irregular-cell approach for global tomography based on tetrahedral diagrams. Their initial application was to a regionalized model using a priori information on tectonic provinces and subducting slab geometry to construct a fixed-grid model (Gudmundsson and Sambridge, 1998), but they did not explicitly explain how to optimize the cells. Some possibilities are to adjust them based on the model null space energy (Vesnaver, 1996) and/or the velocity gradient. Sambridge and Faletic (2003) and Debayle and Sambridge (2004) introduced a data-driven tetrahedral cell adaptive scheme based on the maximum spatial gradients in seismic velocity perturbation across each tetrahedron face. This is useful for trying to characterize regions of rapid velocity change, but it does not account for the ability of the data to resolve such changes. Nolet and Montelli (2005) took a similar tetrahedral parameterization approach but included an estimate of local resolving length in deriving the optimal spacing of mesh nodes.

It is clear that there are many options available for model parameterization. How does one make a choice? One approach that has some advantages is to adopt a two-stage modeling strategy. An initial phase of modeling can be carried out using a more 'traditional' regular parameterization. The

results of the first phase can then serve as both starting model and point of comparison for a second phase using some type of irregular model parameterization. Any significant increase in anomaly amplitudes should be accompanied by a significant decrease in data misfit (e.g., as measured by an *F*-test) if the results of the second phase are to be preferred over the first. The irregular parameterization also is a hindrance to carrying out some of the traditional resolution tests, such as spike or checkerboard tests (see **Section 1.10.5**). Such resolution tests from the regular parameterization model can provide valuable information that might not easily be obtained otherwise. At the same time, there is potential concern about the model resolution for models with locally fine parameterization – unless a complete resolution analysis is carried out, the reality of fine-scale features resulting from irregular mesh tomography may be questioned. See **Sections 1.10.4** and **1.10.5** for detailed discussion of model resolution issues.

1.10.3.3 Static (Station) and Crustal Corrections

In almost all cases, the adopted model parameterization is incapable of representing all aspects or scales of Earth heterogeneity. The most common situation is treating the shallow structure (e.g., the top few hundred meters at a local scale or the crust at the global scale) using static (station) corrections. These corrections can be defined a priori or determined as part of the inversion. The mathematics of the latter option are treated in **Section 1.10.4** in the succeeding text; examples include Bijwaard et al. (1998) for global and DeShon et al. (2006) for local body-wave tomography. Examples of the a priori approach include using time and phase delays computed from a global crustal model (Mooney et al., 1998; Nataf and Ricard, 1996) in global or regional surface-wave tomography (Boschi and Ekström, 2002; Boschi et al., 2004; Montager and Tanimoto, 1991; Panning et al., 2010; Ritsema et al., 2009) and using a fixed crustal refraction model in teleseismic tomography (Waldhauser et al., 2002). In all of these cases, the goal is to prevent shallow heterogeneity from 'leaking' into the deeper structure. The effectiveness of this strategy obviously hinges on the quality of the a priori or derived correction values (e.g., Bozdag and Trampert, 2008) and on how well the highly nonlinear effects of strong lateral variation in crustal structure are dealt with. Recognizing this, Li et al. (2006) adopted a strategy for teleseismic tomography that allows for perturbations to the a priori crustal model by including a regularization term in the inversion that penalizes deviations from the a priori model. Thus, the crustal model will be perturbed where the data require it, although the penalization will generally moderate such changes.

1.10.4 Model Solution

In the early days, the limited computer capabilities (typical mainframes with a 1 MB of memory, 100 MB of disk space, and megahertz CPU speeds) put severe limits on the mathematical and computational sophistication that could be implemented for solving tomography problems. Now, we have inexpensive desktop systems with three to four orders of magnitude larger memory and storage and faster speed than the mainframes of the mid-1970s, yet tomographers will still complain that their computers are too slow and their memory and storage capabilities are not adequate! As computer power has increased, the amount of data and the complexity of both the model parameterization and the associated forward problem solver have risen as well.

The preceding sections set the stage for the critical process of determining a model that adequately fits the available data and known constraints. To get to this point, the tomographer needs to make numerous decisions regarding the scale of the problem to be tackled, the types of data to include, the manner in which the 3D Earth structure will be represented, how the forward modeling will be carried out, etc. Deriving an 'optimal' model and evaluating its quality fall under the domain of inverse theory, about which numerous books have been written (Aster et al., 2012; Menke, 2012; Parker, 1994; Tarantola, 2005). A series of papers by Backus and Gilbert (Backus and Gilbert, 1967, 1968, 1970) brought linear inverse theory to the attention of geophysicists, and Wiggins (1972) wrote a noteworthy paper on resolution of seismic models in particular. While we do not have space to review all the fundamental aspects of inverse theory as they can be applied to seismic tomography, we can provide a 'road map' to guide the appropriate application of inverse methods to tomography problems.

1.10.4.1 Linear Versus Nonlinear Solutions

One key aspect that separates some tomography problems from others is whether the problem is linear or nonlinear. For example, fitting a straight line or a parabola to a set of x–y points is a linear problem. In the former case, the equations are of the form

$$y = (l)m_1 + (x)m_2 \qquad [15]$$

whereas in the latter case, they are of the form

$$y = (l)m_1 + (x)m_2 + (x^2)m_3 \qquad [16]$$

Both can be expressed directly in the form

$$\mathbf{d} = \mathbf{Gm} \qquad [17]$$

where $\mathbf{d}$ is the data vector of length N, $\mathbf{m}$ is a vector with M model parameters, and $\mathbf{G}$ is the matrix of partial derivatives of the data with respect to the model parameters. In contrast, fitting a Gaussian curve to a set of x–y points is a nonlinear problem, because the formula

$$y = m_1 / \left[(2\pi)^{1/2} m_2\right] \exp\left[-(x - m_3)^2 / \left(2m_2^2\right)\right] \qquad [18]$$

cannot be reduced to a linear equation in terms of the variables m_i. We point out that solving nonlinear problems in seismic tomography is generally accomplished via linearizing the problem about a trial solution and improving the model iteratively (e.g., Aster et al., 2012; Tarantola and Valette, 1982). Some exceptions apply global optimization methods such as Monte Carlo (Shapiro and Ritzwoller, 2002), but that is beyond the scope of this chapter.

To some degree, this distinction is fuzzy for tomography problems because the same problem has been tackled with

linear and nonlinear approaches. Take, for example, the original LET study of Aki and Lee (1976). In a single step, they inverted simultaneously for local earthquake locations and 3D structure (in terms of constant-slowness 'blocks') using an initial homogeneous background velocity model. They explored the linearity of the problem and model uniqueness by repeating the inversion with two different background models. Given the convergence to the same 3D structure, they concluded that a linear solution was adequate. Subsequent work on an expanded dataset from the same region demonstrated that a nonlinear solution actually was required to converge to a valid solution. In this case, the lateral heterogeneity was so strong that the linear inversion had not converged. Starting with the study of Thurber (1983), nonlinear solutions have become the norm for LET.

Similarly, the original 'ACH' (Aki et al., 1977) teleseismic tomography study used a linear inversion. The work by Ellsworth (1977) determined that a nonlinear solution agreed well with the linear solution for a dataset from Hawaii. In this case, however, the amplitude of the anomalies was relatively modest (mainly within ±5%), so a linear approximation was in fact adequate. For regions with higher-amplitude anomalies, a nonlinear solution could be significantly different. Early efforts at nonlinear teleseismic inversion were made by Thomson and Gubbins (1982), Koch (1985), and Nakanishi and Yamaguchi (1986). More recently, Weiland et al. (1995) and VanDecar et al. (1995) developed nonlinear algorithms for teleseismic tomography and applied them to Long Valley Caldera, California, and eastern Brazil, respectively. In the case of Long Valley, anomalies on the order of ±20% were recovered, about three times larger than a linear inversion by Dawson et al. (1990) using the same dataset. A similar study for Valles Caldera, New Mexico (Steck et al., 1998), obtained even greater anomalies (±25%) using nonlinear inversion. Pesicek et al. (2010) used an iterative method (see **Section 1.10.4.2.2**) to obtain a nonlinear teleseismic solution for the structure in the region of the great 2004 Sumatra earthquake. They showed that the iterative solution sharpened the image of the subducting slab significantly. Despite such impressive results with a nonlinear approach, linear inversions are predominant in teleseismic tomography studies.

On a global scale, linear solutions are also the norm for travel time inversions, whether they are block or spline inversions or spherical harmonic expansion inversions. Beginning with Sengupta and Toksöz (1976) and Dziewonski et al. (1977) and continuing through Su et al. (1994) and van der Hilst et al. (1997) (and many others), the inverse problems were mainly set up and solved in a linear manner. Some notable exceptions are the P-wave study of Bijwaard and Spakman (2000) and the S-wave study of Widiyantoro et al. (2000), which are both fully nonlinear solutions. We also note that Dziewonski (1984) carried out an iterative inversion but with an approximate inverse that neglected hypocenter–structure coupling (see **Section 1.10.4.3**).

Using a 3D ray tracer (Bijwaard and Spakman, 1999) and a 3D starting model (Bijwaard et al., 1998), Bijwaard and Spakman (2000) carried out inversions for cell slowness perturbations, cluster relocation vectors (average hypocenter adjustment for all events in a given latitude–longitude–depth bin), and station corrections. They found no dramatic changes in the pattern of anomalies compared to Bijwaard et al. (1998), but did observe some sharpening of features. Surprisingly, the improvement in data fit compared to Bijwaard et al. (1998) was marginal – the variance reduction after two nonlinear iterations was 57.2% compared to 57.1%. This may be because the authors used the original event locations from Engdahl et al. (1998) as their starting locations rather than using locations updated via individual event relocations or using the cluster relocation vectors determined by Bijwaard et al. (1998). Since these same locations were used to derive the starting 3D velocity model, one would expect that the first-iteration location perturbations would be biased toward low values. A total of only two iterations were carried out, so the small additional model perturbations would in turn lead to minor earthquake relocations and hence small model perturbations in the subsequent iteration. It is also possible that the model damping required to limit the negative effects of noise in the dataset used (from the Engdahl et al., 1998 'groomed' catalog derived from ISC data) may simply be too great to allow a higher-amplitude model to be extracted. This is supported by the analysis of Dorren and Snieder (1997), who showed that noisy data might result in a linear model estimate that is superior to a nonlinear one in travel time tomography. Finally, it may be the case that the LSQR solution fails to account for the small singular values for the location parameters compared to the much larger singular values expected for most velocity model parameters.

Widiyantoro et al. (2000) carried out a similar nonlinear study for S waves, with a somewhat different outcome. They included event locations as free parameters but heavily penalized relocations because the S-wave data alone are not actually sufficient to produce well-constrained locations. Thus, the hypocenters varied very little from their initial locations, again obtained from Engdahl et al. (1998). They included both damping and smoothing constraints and a constraint penalizing deviation from the 1D ak135 model (Kennett et al., 1995) (see **Section 1.10.4.2** for a discussion of constraints). Their solution yielded a significant improvement in data fit, increasing the variance reduction from the 33% reduction obtained by Widiyantoro et al. (1998) to 40%. Some of this improvement can be attributed to the use of a higher-quality dataset (Engdahl et al., 1998). On the other hand, the model results do show significant spatial sharpening and amplitude increase compared to Widiyantoro et al. (1998). In particular, the deep signature of some slabs appears substantially sharpened.

1.10.4.1.1 Iterative solvers

A common inversion approach is the use of iterative matrix solution methods (Aster et al., 2012), such as Kaczmarz's algorithm and the related algebraic reconstruction technique (ART), SIRT, and conjugate gradient least squares (CGLS). ART has convergence and stability problems, but SIRT and especially CGLS have found wide application. The LSQR algorithm of Paige and Saunders (1982) is probably the most widely used of these iterative methods. The interested reader is referred to van der Sluis and van der Vorst (1987) for an exhaustive discussion of these techniques and to Trampert and Lévêque (1990) for an analysis of the SIRT method, which we note is subject to convergence problems. Although this class of solvers is known as iterative methods, we emphasize that they address linear matrix problems. Due to their popularity, we

include a brief introduction to the CGLS and the LSQR algorithms here.

CGLS is a general method for solving linear equations of the form $\mathbf{Gm}=\mathbf{d}$ by forming the normal equations

$$\mathbf{G}^{\mathrm{T}}\mathbf{Gm}=\mathbf{G}^{\mathrm{T}}\mathbf{d} \quad [19]$$

and constructing a convenient set of basis vectors $\mathbf{p}_k$ that are mutually conjugate with respect to $\mathbf{G}^{\mathrm{T}}\mathbf{G}$ (Aster et al., 2012; Scales, 1987). Using these basis vectors, the least-squares solution for $\mathbf{m}$ can be calculated with an efficient iterative algorithm requiring only matrix–vector and vector–vector products in a recursive scheme; no actual matrix decomposition or inversion is involved. Efficiency can be further enhanced by the use of sparse-matrix methods (Davis, 2006), because the procedure does not involve matrix factorizations that can destroy sparseness. Sparse-matrix methods are particularly effective in tackling massive-scale tomography problems.

LSQR (Paige and Saunders, 1982) is probably the most widely used algorithm for the solution of large least-squares problems in seismology. LSQR is a recursive procedure for solving the normal equations that is in theory mathematically equivalent to CGLS (in the absence of machine accuracy problems) but is more stable in practice. The LSQR algorithm involves a technique known as Lanczos bidiagonalization, which transforms an initial symmetrical matrix into one with nonzero values only on the diagonal and the elements immediately above it. For a detailed examination of LSQR and a comparison to other methods in a seismological context, the reader is referred to Nolet (1985, 1987) and Spakman and Nolet (1988).

1.10.4.2 Regularized and Constrained Inversion

Even if there are far more observations than model parameters in a given seismic tomography problem, the inverse problem is almost always rank-deficient, meaning that $\mathbf{G}$ has one or more zero singular values and that it is has an unstable solution in the presence of noise. This is expected because some model parameters may not be directly sampled by the data (i.e., cells without 'hits') (see **Section 1.10.3.2**). The condition number of $\mathbf{G}$ (ratio of largest to smallest singular value) provides one direct measure of noise sensitivity (Aster et al., 2012), but it can only be estimated with some of the popular solution techniques (e.g., LSQR). To solve such stability problems, some form of regularization or constraint is required (Aster et al., 2012; Sambridge, 1990).

1.10.4.2.1 Generalized inverse and damped least-squares solutions

Equations [13] and [14] are linear relationships between the seismic data (i.e., body-wave travel time anomaly δT or surface-wave phase shift δC) and perturbations from the wave speed in the reference model. They can be discretized and written in matrix form as before:

$$\mathbf{Gm}=\mathbf{d} \quad [20]$$

$\mathbf{G}$ relates the model to the data, or more typically the data misfit to the model perturbations, and is often based on wave theory for a 1D reference model (e.g., PREM and ak135). In seismic tomography, we typically have many more data than unknowns ($N \gg M$). Given data errors, the equations in [20] are inconsistent and do not have an exact solution. Therefore, we usually minimize a measure of discrepancy (misfit):

$$(\mathbf{Gm}-\mathbf{d})^{\mathrm{T}}(\mathbf{Gm}-\mathbf{d}) \quad [21]$$

Here, we have chosen the Euclidian norm that defines [21] to be a least-squares problem. The least-squares formulation is often used because of its mathematical simplicity. However, it is not necessarily the best for tomographic problems, given the large influence of data outliers. Other norms have been adopted in some cases (e.g., Bube and Langan, 1997), but the least-squares approach is predominant.

In damped least squares (DLS), we minimize

$$(\mathbf{Gm}-\mathbf{d})^{\mathrm{T}}(\mathbf{Gm}-\mathbf{d})+\varepsilon^2\mathbf{m}^{\mathrm{T}}\mathbf{m} \quad [22]$$

The damping term $\varepsilon^2\mathbf{m}^{\mathrm{T}}\mathbf{m}$ serves to penalize models $\mathbf{m}$ with a large norm. In global and teleseismic tomography, this is equivalent to preferring models that are close to the (1D) reference model. Particularly in regions poorly sampled by seismic waves, the wave speed will retain values close to the reference model.

We obtain the DLS solution by differentiating [22] with respect to the model parameters $\mathbf{m}$ and solving for $\mathbf{m}$:

$$\mathbf{m}_{\mathrm{DLS}}=\left[\left(\mathbf{G}^{\mathrm{T}}\mathbf{G}+\varepsilon^2\mathbf{I}\right)^{-1}\mathbf{G}^{\mathrm{T}}\right]\mathbf{d} \quad [23]$$

This solution is of the general form

$$\mathbf{m}_{-\mathrm{i}}=\mathbf{G}^{-\mathrm{i}}\,\mathbf{d} \quad [24]$$

where $\mathbf{G}^{-\mathrm{i}}$ is a 'generalized' inverse. If $\mathbf{USV}^{\mathrm{T}}$ is the SVD of $\mathbf{G}$, then we can write the DLS inverse and the corresponding solution as

$$\mathbf{G}^{-\mathrm{i}}_{\mathrm{DLS}}=\mathbf{VF}\,\mathbf{S}^{\dagger}\mathbf{U}^{\mathrm{T}} \text{ and } \mathbf{m}_{\mathrm{DLS}}=\mathbf{G}^{-\mathrm{i}}_{\mathrm{DLS}}\mathbf{d} \quad [25]$$

where $\mathbf{S}^{\dagger}$ is the pseudoinverse of $\mathbf{S}$ (with diagonal elements $1/s_{\mathrm{i}}$ unless $s_{\mathrm{i}}=0$, in which case the diagonal element of $\mathbf{S}^{\dagger}$ is 0) and the diagonal elements of $\mathbf{F}$ (the 'filter factors') satisfy

$$f_i^2=s_i^2/\left(s_i^2+\varepsilon^2\right) \quad [26]$$

(Aster et al., 2012). In addition to determining the solution itself, we desire to know the quality of the solution as well. Two measures of quality are the model resolution matrix, which indicates the model 'blurriness,' and the model covariance matrix, which indicates the uncertainty of and covariation among model parameters (Aster et al., 2012). The definition of the model resolution matrix $\mathbf{R}_{\mathbf{m}}$ is obtained by substituting $\mathbf{Gm}=\mathbf{d}$ into [24], obtaining

$$\mathbf{m}_{-\mathrm{i}}=\mathbf{G}^{-\mathrm{i}}\mathbf{Gm}=\mathbf{R}_{\mathbf{m}}\mathbf{m} \quad [27]$$

The model covariance matrix $\mathbf{C}_{\mathrm{m}}$ has the form

$$\mathbf{G}^{-\mathrm{i}}\mathbf{C}_{\mathrm{d}}\left(\mathbf{G}^{-\mathrm{i}}\right)^{\mathrm{T}} \quad [28]$$

where $\mathbf{C}_{\mathbf{d}}$ is the data covariance matrix, often assumed to be diagonal (uncorrelated errors). In the case of the DLS solution in [23], $\mathbf{R}_{\mathrm{m}}$ and $\mathbf{C}_{\mathrm{m}}$ are given by

$$\begin{aligned}\mathbf{R}_{\mathrm{m}}&=\mathbf{VFV}^{\mathrm{T}}\\ \mathbf{C}_{\mathrm{m}}&=\mathbf{VFS}^{\dagger}\mathbf{U}^{\mathrm{T}}\mathbf{C}_{\mathrm{d}}\mathbf{U}\left(\mathbf{S}^{\dagger}\right)^{\mathrm{T}}\mathbf{F}^{\mathrm{T}}\mathbf{V}^{\mathrm{T}}\end{aligned} \quad [29]$$

We face the inevitable trade-off that decreasing ε improves the estimated model resolution (i.e., brings $\mathbf{R}_{\mathrm{m}}$ closer to an

identity matrix), but at the same time, it increases the model uncertainty (i.e., increases the size of the diagonal elements of $\mathbf{C}_m$). A trade-off analysis can be carried out to try to identify the optimum damping value (e.g., Eberhart-Phillips, 1986). This is basically equivalent to an L-curve analysis (Aster et al., 2012), whereby the corner of a log(misfit) versus log(model norm) plot can be used to determine a good damping value.

One can also apply weights to the data (W_d) and model (W_m), forming the weighted DLS equations to be minimized:

$$(\mathbf{Gm}-\mathbf{d})^{\mathrm{T}}W_d(\mathbf{Gm}-\mathbf{d})+\varepsilon^2\mathbf{m}^{\mathrm{T}}W_m\mathbf{m} \quad [30]$$

If we then define

$$\mathbf{M}^{\mathrm{T}}\mathbf{M}=W_m;\ \mathbf{D}^{\mathrm{T}}\mathbf{D}=W_d \quad [31]$$

and the transformations

$$\mathbf{m}'=\mathbf{Mm};\ \mathbf{d}'=\mathbf{Dd};\ \mathbf{G}'=\mathbf{DGM}^{-1} \quad [32]$$

it is straightforward to demonstrate that minimizing [30] is identical to minimizing

$$(\mathbf{G}'\mathbf{m}'-\mathbf{d}')^{\mathrm{T}}(\mathbf{G}'\mathbf{m}'-\mathbf{d})+\varepsilon^2\mathbf{m}'^{\mathrm{T}}\mathbf{m}' \quad [33]$$

An alternative approach to damping that yields similar results is singular value truncation (Aster et al., 2012). The truncated SVD (TSVD) solution forms an approximate inverse matrix using the p largest singular values s_i of $\mathbf{G}$:

$$\mathbf{G}^{\mathrm{TSVD}}=\sum_{i=1}^{p}\mathrm{U}_i\mathrm{S}_i\mathrm{V}_i^{\mathrm{T}} \quad [34]$$

If p is the rank of $\mathbf{G}$, then we have the pseudoinverse solution. See Aster et al. (2012) for a detailed discussion and comparison of the least-squares, pseudoinverse, and TSVD solutions.

Another 'trick' for improving stability of the inversion is preconditioning (Gill et al., 1981). In general, the ratio of the largest to smallest singular value (the condition number) provides a measure of the stability of the inverse model, particularly its sensitivity to noise in the data (Aster et al., 2012). Furthermore, the convergence rate for the CGLS and LSQR methods can be improved if the system can be transformed (scaled) to one with many unit-value singular values. Thus, scaling the system of equations to reduce the condition number and/or increase the number of unit-value singular values is a desirable step to implement in many cases.

Convergence of CGLS and similar methods leads to a quandary when regularization is desired. As Aster et al. (2012) showed, the convergence rate is typically rapid in the initial iterations for unregularized CGLS, after which noise in the solution tends to build up rapidly. This is a combination of accumulated effects of roundoff errors and the fact that the iterative solution is converging toward an unregularized solution. If regularization is introduced, the algorithm will converge more slowly and will generally fit the data better than the unregularized case for a given model norm, but the cost is an order of magnitude increase in the number of required iterations. Since seismic tomography problems virtually always require some form of regularization, the extra computational burden is generally unavoidable.

As noted earlier, the original Aki et al. (1977) (ACH) teleseismic and Aki and Lee (1976) LET methods both involved single-step linearized inversions for the model parameters. This approach allowed the use of linear inverse theory techniques for model estimation and also for model resolution and uncertainty analysis. Aki et al. (1977) compared models obtained using both a generalized inverse (TSVD) and a DLS ('stochastic') inverse. For the teleseismic case, the system of equations is always linearly dependent due to the trade-off between average layer velocity and event origin times, so a simple least-squares solution was impossible. The generalized inverse approach uses the nonzero singular values of the $\mathbf{G}$ matrix to compute a least-squares solution, whereas the stochastic inverse approach computes a DLS solution using a damping value (ε^2) equal to the a priori ratio of the data variance to the solution variance (Aki et al., 1977). Aki and Lee (1976) used just the stochastic inverse approach, because their matrix was not strictly singular but contained very small singular values that would amplify the effect of data errors on the model.

1.10.4.2.2 Sparsity and the L1 norm solution

An exciting line of research involves approaches for determining sparse solutions to tomographic problems. The idea of preferring a sparse model essentially stems from 'Occam's razor,' which is a 'simpler is better' philosophy. This idea should not be confused with sparse-matrix inversion, for which the equations relating the model to the data have far more zero than nonzero coefficients. As demonstrated by Loris et al. (2007) and others, L1 minimization naturally leads to a relatively sparse solution. This can be motivated by considering a simple 2D inverse problem for which one desires to find the 'smallest' solution that satisfies a constraint equation $Ax=b$, a straight line. The minimum L2 norm solution that satisfies the constraint equations will lie on a circle of constant L2 norm of c_2 (**Figure 4**), and thus, both model parameters will be

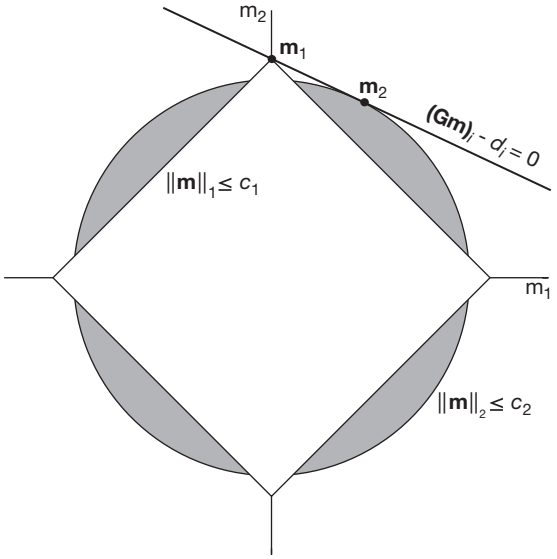

Figure 4 Illustration of the tendency for L1 solutions to promote sparsity, in 2D. An L2 solution can be thought of as finding the point on the circle with smallest radius that fits a constraint equation (such as fitting the data). In contrast, the L1 solution looks at points on a square with its vertices on the axes, leading to a solution that is nonzero only for one parameter, and therefore tends to be sparse.

nonzero. In contrast, the constant L1 norm defines a square of side c_1 with vertices on the coordinate axes. The minimum L1 norm solution will lie on one vertex (Figure 4) and thus will be sparse, with only one nonzero parameter.

Loris et al. (2007, 2010) and Simons et al. (2011) combine the sparse solution approach with a wavelet basis (Cartesian in the case of Loris et al., 2007, 2010, spherical in the case of Simons et al., 2011) for parameterizing the model. Where sampling is sparse or the data do not demand significant heterogeneity, only a few low-order wavelet coefficients will be nonzero. Conversely, where the data require it, more higher-order wavelet coefficients will be nonzero. This allows for model solutions that can have both smoothly varying regions and sharp discontinuities.

Another way in which the L1 norm has been used is to obtain more robust iterative solutions. L2 solutions are susceptible to producing large model errors when data outliers are present (Aster et al., 2012), since a solution is sought that minimizes the sum of the squares of the residuals. Since L1 instead minimizes the sum of the absolute value of the residuals, it is less sensitive to outliers. But given the discontinuity of $|x|$ at $x=0$, how can one practically obtain the minimum-misfit L1 solution? One standard approach is iterative reweighted least squares, or IRLS (Aster et al., 2012). An initial solution is obtained with least squares, and the misfit values (residuals) for that model are determined. Then, an updated solution is computed by solving a weighted system of equations $\mathbf{WGm}=\mathbf{Wd}$, again using least squares, with $\mathbf{W}$ a diagonal matrix whose diagonal elements are the reciprocal of the square root of the absolute value of the corresponding residual. Thus, you are trying to determine a least-squares solution to a problem where the residuals are the square root of the original least-squares residual (with the appropriate sign). The IRLS solution converges to the L1 solution under reasonable conditions. Pesicek et al. (2010) used the IRLS approach to sharpen their tomographic image of the subducting slab in the Sumatra region.

1.10.4.2.3 Occam's inversion and Bayesian methods

In addition to the techniques discussed earlier, there are two other philosophically different approaches for treating underdetermined tomographic problems. One can be labeled an Occam's razor approach and the other Bayesian (see Scales and Snieder, 1997 for an interesting discussion of the latter).

The Occam's approach (**Section 1.10.4.2.2**), commonly attributed to the work of Constable et al. (1987) on electromagnetic inversion, involves the inclusion of constraint equations in the inversion enforcing minimized first- or second-order spatial differences of the model perturbations, weighted relative to achieving a data misfit no better than the data uncertainty. We note that this is an example of what is often called Tikhonov regularization (see Aster et al., 2012), in this case using the discrepancy principle to select the weighting. The first-order constraint attempts to minimize model perturbation gradients, leading to a 'flat' model perturbation. The second-order constraint attempts to minimize model perturbation curvature, leading to a 'smooth' model perturbation. In general, this regularization can be achieved by augmenting $\mathbf{Gm}=\mathbf{d}$ with a set of equations of the form $w\mathbf{Lm}=\mathbf{0}$ and minimizing the system

$$\begin{bmatrix}\mathbf{G}\\ w\mathbf{L}\end{bmatrix}\mathbf{m}=\begin{bmatrix}\mathbf{d}\\ 0\end{bmatrix} \quad [35]$$

For a 1D tomography problem, $\mathbf{L}$ for first-order regularization would be a banded matrix with rows of the form $[0\ \ 0\ \ 0\ \cdots\ -1\ \ +1\ \cdots\ 0\ \ 0\ \ 0]$, whereas for second-order regularization, the rows would be of the form $[0\ \ 0\ \ 0\ \cdots\ -1\ \ +2\ \ -1\ \cdots\ 0\ \ 0\ \ 0]$.

Examples of the use of first- or second-order smoothing include Lees and Crosson (1990), Benz et al. (1996), Hole et al. (2000), and Zhang and Thurber (2003). A variant by Symons and Crosson (1997) penalizes the roughness of the sum of the current model plus the perturbation, so that the final model remains smooth. Once again, an L-curve analysis (Aster et al., 2012) can be valuable for determining the appropriate weighting of the regularization equations (the value of w). The use of smoothing constraints tends to result in fewer artifacts in poorly sampled regions compared to simple damping. At the same time, however, one desires to be able to 'tease out' heterogeneity and sharp spatial changes in structure as effectively as possible with seismic tomography, so the use of smoothing comes at a cost.

An example of a Bayesian approach, mentioned in **Section 1.10.3.1**, involves the specification of a spatial covariance function that reflects the tendency for nearby points in the Earth to have similar wave speeds. Following Tarantola and Valette (1982) and Tarantola and Nercessian (1984), an a priori model covariance function $\mathbf{C}_{\mathbf{m}_0}$ (e.g., of Gaussian form) and a data covariance function $\mathbf{C}_{\mathbf{d}_0}$ are defined, and the solution is obtained by minimizing

$$(\mathbf{Gm}-\mathbf{d})^{\mathrm{T}}(\mathbf{C}_{\mathbf{d}_0})^{-1}(\mathbf{Gm}-\mathbf{d})+\mathbf{m}^{\mathrm{T}}(\mathbf{C}_{\mathbf{m}_0})^{-1}\mathbf{m} \quad [36]$$

(note the close correspondence in form to [30]). Tarantola and Valette (1982) showed that a nonlinear algorithm for minimizing [36] is

$$\mathbf{m}=\mathbf{m}_0+\mathbf{C}_{\mathbf{m}_0}\mathbf{G}^{\mathrm{T}}\left(\mathbf{C}_{\mathbf{d}_0}+\mathbf{G}(\mathbf{C}_{\mathbf{m}_0})^{-1}\mathbf{G}^{\mathrm{T}}\right)^{-1}\{\mathbf{d}_0-\mathbf{g}(\mathbf{m})+\mathbf{G}(\mathbf{m}-\mathbf{m_0})\} \quad [37]$$

where $\mathbf{g}$ is the (nonlinear) forward equation and $\mathbf{m}_0$ is the a priori model. Based on the way Tarantola and Nercessian (1984) formulated their problem, [37] is constructed using numerical integration along the current ray paths, rather than by apportioning ray paths into cells for the computation of derivatives. In practice, we view this distinction as somewhat minor, because at some level, discretization of the model will be required once the current model is no longer homogeneous and wave propagation in 3D must be considered. Recent examples of the Bayesian approach include Trampert et al (2004), Bodin and Sambridge (2009), Visser et al (2008b), and Mosca et al. (2012). For the interested reader, a broad presentation of Bayesian methods for geophysics can be found in Sambridge and Mosegaard (2002).

1.10.4.3 Hypocenter–Structure Coupling

A solution strategy adopted by some researchers involves first solving for 3D structure with earthquake locations fixed and then solving for earthquake locations with the structure fixed. Theoretical and numerical studies (e.g., Roecker et al., 2006;

Thurber, 1992) have shown that this approach leads to bias in both locations and structure. We summarize the analysis from Roecker et al. (2006) to clarify the nature of this important problem. The coupled hypocenter–velocity structure problem can be stated as

$$\mathbf{H}\mathbf{dh} + \mathbf{S}\mathbf{ds} = \mathbf{r} \quad [38]$$

where $\mathbf{H}$ and $\mathbf{S}$ are the derivative matrices and $\mathbf{dh}$ and $\mathbf{ds}$ are perturbation vectors for hypocenters and slowness structure, respectively. The SVD of $\mathbf{H}$ is

$$\mathbf{H} = \mathbf{U}\Lambda\mathbf{V}^{\mathrm{T}} = \left[\mathbf{U}_{\mathrm{p}}|\mathbf{U}_0\right]\Lambda\mathbf{V}^{\mathrm{T}} \quad [39]$$

where $\mathbf{U}_{\mathrm{p}}$ is the range of $\mathbf{H}$ and $\mathbf{U}_0$ is the null space of $\mathbf{H}$ (Aster et al., 2012). Multiplying the original equation by $\mathbf{U}^{\mathrm{T}}$ and separating the p and 0 components give

$$\begin{bmatrix}\mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\,\mathbf{H}\\ \mathbf{U}_0^{\mathrm{T}}\,\mathbf{H}\end{bmatrix}\mathbf{dh} + \begin{bmatrix}\mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\,\mathbf{S}\\ \mathbf{U}_0^{\mathrm{T}}\,\mathbf{S}\end{bmatrix}\mathbf{ds} = \begin{bmatrix}\mathbf{r}_{\mathrm{p}}\\ \mathbf{r}_0\end{bmatrix} \quad [40]$$

Noting that $\mathbf{U}_0^{\mathrm{T}}\mathbf{H} = 0$ by definition and if we initially relocate the earthquakes, then $\mathbf{r}_{\mathrm{p}} = 0$ also, we have

$$\begin{bmatrix}\mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\mathbf{H}\\ 0\end{bmatrix}\mathbf{dh} + \begin{bmatrix}\mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\,\mathbf{S}\\ \mathbf{U}_0^{\mathrm{T}}\,\mathbf{S}\end{bmatrix}\mathbf{ds} = \begin{bmatrix}0\\ \mathbf{r}_0\end{bmatrix} \quad [41]$$

This separates into two sets of equations:

$$\mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\mathbf{H}\,\mathbf{dh} + \mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\mathbf{S}\,\mathbf{ds} = 0 \quad [42]$$

and

$$\mathbf{U}_0^{\mathrm{T}}\mathbf{S}\,\mathbf{ds} = \mathbf{r}_0 \quad [43]$$

We can determine $\mathbf{ds}$ simply by solving the second set of equations, which is the decoupled problem (the separation of parameters method of Pavlis and Booker, 1980). If instead we decide to solve the entire system of equations involving $\mathbf{ds}$ but incorrectly ignore the contribution of $\mathbf{dh}$ in eqn [41], we actually solve

$$\begin{bmatrix}\mathbf{U}_{\mathrm{p}}^{\mathrm{T}}\,\mathbf{S}\\ \mathbf{U}_0^{\mathrm{T}}\,\mathbf{S}\end{bmatrix}\mathbf{ds} = \begin{bmatrix}\mathbf{0}\\ \mathbf{r}_0\end{bmatrix} \quad [44]$$

This is equivalent to solving eqn [43] but with the added constraint that a weighted sum of $\mathbf{ds}$ will be zero. This is the bias that is caused by not carrying out the full simultaneous inversion.

The aforementioned analysis explains some observations regarding the behavior of a joint hypocenter–velocity structure inversion versus a velocity-only inversion. In doing a velocity-only inversion, the added constraints [44] force $\mathbf{ds}$ to be small, which in turn means that subsequent estimations of $\mathbf{dh}$ will be small as well (small velocity perturbations will result in small hypocenter perturbations). The $\mathbf{ds}$ term is kept small at a cost of misfit to the data, because in trying to keep $\mathbf{ds}$ small, the fit to $\mathbf{r}_0$ will be degraded. This is the tendency that is documented in Thurber (1992) and that can be observed in velocity-only inversion tests with real data – both $\mathbf{dh}$ and $\mathbf{ds}$ are much too small in a velocity-only inversion, even when alternated with hypocenter relocation, and the data fit is poor. To illustrate, consider a simplified 1D Earth model (**Figure 5**), following Thurber (1992), with four seismic stations straddling a fault across which velocity changes discontinuously from 5.0 to 6.0 km s^{-1}. If a hypothetical earthquake occurs on the fault and a homogeneous velocity model of 5.5 km s^{-1} is used to locate the event, its calculated location would be 0.75 km to the right of the fault. If we then invert for a laterally heterogeneous velocity model using least squares, placing a discontinuity at the fault (using a priori information) but ignoring the hypocenter–velocity structure coupling (i.e., we keep the event location fixed), we obtain a model with a velocity of 5.44 km s^{-1} to the left of the fault and 5.56 km s^{-1} to the right. In contrast, if we perform a simultaneous inversion for structure and location, the earthquake is relocated to within 0.06 km of the fault, and we obtain a model with a velocity of 5.04 km s^{-1} to the left of the fault and 6.06 km s^{-1} to the right. Thus, the velocity-only inversion underestimates the velocity contrast by nearly an order of magnitude, while the simultaneous inversion recovers the true structure to within 1% and determines the event location within 100 m. The conclusion is that for LET, solving the full system of equations is critical in order to obtain an unbiased solution.

Although many tomography algorithms utilize the fast sparse-matrix solvers such as LSQR, it is worth noting the historical use of subspace methods (e.g., Kennett et al., 1988) for efficient inversion procedure, and in particular for dealing with matrix size issues when many earthquakes are included in an inversion. For LET, three groups independently and nearly simultaneously published comparable methods for separating hypocenter parameters from velocity model parameters, allowing the efficient solution of smaller matrix problems in place of one giant problem (Pavlis and Booker, 1980; Rodi et al., 1981; Spencer and Gubbins, 1980). As a motivation for this approach, consider an LET problem with 10 000 earthquakes observed on average at 50 stations and with 20 000 model parameters. The

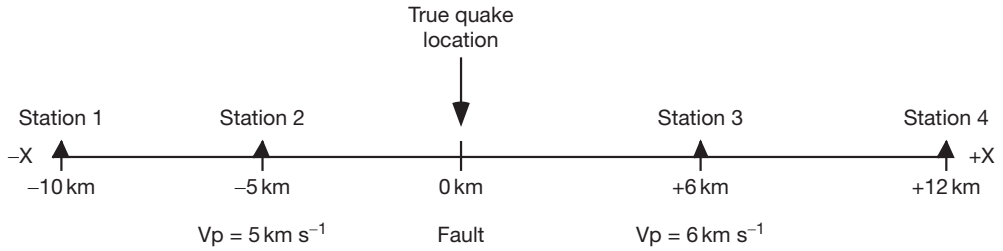

Figure 5 Hypothetical 1D Earth with a velocity discontinuity across a fault with a velocity discontinuity at X = 0.0 km, four seismic stations, and an earthquake occurring on the fault. Reproduced from Thurber CH (1992) Hypocenter–velocity structure coupling in local earthquake tomography. In: "Lateral Heterogeneity and Earthquake Location," *Physics of the Earth and Planetary Interiors* 75: 55–62.

full system matrix would be of the size $(50 \times 10\,000)$ by $(4 \times 10\,000 + 20\,000)$, or 500 000 by 60 000. If we take advantage of the annulling procedure of Pavlis and Booker (1980), for example, we can decompose the coupled hypocenter–structure equations for each earthquake i:

$$\mathbf{H}_i\,\mathbf{dh}_i + \mathbf{S}_i\,\mathbf{ds}_i = \mathbf{r}_i \qquad [45]$$

where, as before, $\mathbf{H}_i$ and $\mathbf{S}_i$ are the matrices of derivatives of arrival times with respect to hypocenter and model parameters, respectively (now for a single earthquake), and $\mathbf{dh}_i$ and $\mathbf{ds}_i$ are the corresponding parameter perturbations. Then, using the orthogonal matrix $\mathbf{U}_{0i}$ that satisfies $\mathbf{U}_{0i}$, $\mathbf{H}_i = 0$ allows us to assemble the decoupled equations:

$$\mathbf{U}_{0i}\,\mathbf{H}_i\,\mathbf{dh}_i + \mathbf{U}_{0i}\,\mathbf{S}_i\,\mathbf{ds}_i = \mathbf{U}_{0i}\,\mathbf{r}_i \text{ or } \mathbf{S}'_i\,\mathbf{ds}_i = \mathbf{r}'_i \qquad [46]$$

The matrix in the original partial system in [45] would be of size 40 by 20 004, whereas the matrix in the decoupled system in [46] would be of size 36 by 20 000. If we treat all the events this way, the result is a system of equations of size 460 000 by 20 000, a substantial size reduction achieved at relatively low computational cost. Even greater reduction of the problem size can be achieved by incrementally constructing the normal equations, $\mathbf{S}'^{\mathrm{T}}\mathbf{S}' = \mathbf{S}'^{\mathrm{T}}\mathbf{r}'$ (Spencer and Gubbins, 1980), resulting in a system of equations that is only 20 000 by 20 000. Unfortunately, the cost of this last step is a squaring of the condition number of the system matrix and a loss of matrix sparseness, but the price may be worth paying in some cases.

1.10.4.4 Static (Station) Corrections Revisited

Static (station) corrections, a constant time delay or advance applied for a given station, are commonly included in some types of seismic tomography problems, as discussed earlier. It is worth noting that static corrections can be analyzed in a manner equivalent to that used for the hypocenter–structure coupling issue (**Section 1.10.4.3**). Just as in the hypocenter–structure coupling situation, including static corrections can result in a suppression of model heterogeneity, particularly at shallow depths near the stations. The corrections can absorb some of the heterogeneity that otherwise would have been projected into the 3D model. One compromise approach (Michael, 1988) is to solve the tomography problem without static corrections and then solve the system with static corrections included but the 3D model held fixed. Michael (1988) had shown that this can be an effective technique for improving earthquake locations without biasing the 3D tomographic model.

1.10.4.5 Inversion for Vp/Vs (Poisson's Ratio)

Often, knowledge of Vp/Vs or Poisson's ratio (which are directly related to each other) is desired for interpretation purposes. Poisson's ratio by itself provides significant diagnostic power regarding lithology and, in combination with Vp, can be even more useful for constraining lithology (Christensen, 1996) and estimating crack density, temperature, vapor, fluid, or melt content (Julian et al., 1996; O'Connell and Budiansky, 1974). Deriving Vp/Vs (and hence Poisson's ratio) by simply dividing the Vp model by the Vs model, however, will introduce noise and artifacts due to the different samplings and therefore resolution of the Vp and Vs models (Eberhart-Phillips, 1990; Wagner et al., 2005). A strategy for direct inversion for Vp/Vs (Thurber and Atre, 1993; Walck, 1988) or for joint inversion for Vp, Vs, and Vp/Vs (Zhang and Thurber, 2006) is preferable. A limitation of the earlier techniques for direct inversion of S–P times for 3D Vp/Vs structure is the underlying assumption that the P and S ray paths are very similar. In the case of complex 3D structure, however, some P and S ray paths may differ significantly, and thus, the results may be biased. In order to avoid this bias and to allow for the construction of Vp and Vs models as well as Vp/Vs, a new algorithm was developed by Zhang et al. (2009) to solve simultaneously for Vp, Vs, Vp/Vs, and event locations using P, S, and S–P times. Their strategy is to check P and S ray paths and remove the corresponding S–P time from the Vp/Vs inversion if the paths differ by more than a specified threshold. Their tests with synthetic data showed that this approach is successful in producing models with minimal artifacts.

1.10.4.6 DD Tomography

The use of differential times for determining relative locations of earthquakes (or explosions) has been a fruitful field of work for many decades (e.g., Douglas, 1967). A number of studies over the last decade have shown spectacular improvement in earthquake or explosion location precision when precise differential times from WCC are used in combination with joint location techniques. Some examples of applications to earthquakes include Hawaii (Got et al., 1994; Rubin et al., 1998), California (Waldhauser et al., 1999), New Zealand (Du et al., 2004), the Soultz geothermal field, France (Rowe et al., 2002), and Mount Pinatubo volcano (Battaglia et al., 2004) and to explosions at the Balapan test site (Phillips et al., 2001; Thurber et al., 2001). These and other studies have demonstrated the substantial improvement in the delineation of seismogenic features or in the accuracy of relative locations of ground-truth events that is possible using multiple-event location methods with high-precision arrival-time data. These successes inspired efforts to incorporate differential times in seismic tomography. The first and so far most widely used algorithms for DD tomography are due to Zhang and coworkers (Zhang and Thurber, 2003, 2005; Zhang et al., 2004).

To set the stage for understanding DD tomography, we first briefly review the DD location problem (see Wolfe, 2002 for a thorough analysis). Following the notation of **Section 1.10.4.3**, for single event location, we iteratively solve an equation of the form

$$\mathbf{r} = \mathbf{H}\,\mathbf{dh} \qquad [47]$$

where **dh** includes perturbations to location and origin time, **H** is the partial derivative matrix, and **r** contains the arrival-time residuals. If we now consider eqn [47] for a pair of events and subtract the equations for the two events observed at one station, we have a set of equations of the form

$$r_k^i - r_k^j = \sum_{l=1}^{3} \frac{\partial T_k^i}{\partial x_l^i}\Delta x_l^i + \Delta\tau^i - \sum_{l=1}^{3} \frac{\partial T_k^j}{\partial x_l^j}\Delta x_l^j + \Delta\tau^j \qquad [48]$$

where r_k^i and r_k^j are the residuals from events i and j at station k, T's are travel times, and x and Δx are hypocenter coordinates

and their perturbations. Note that the residual difference can be rewritten as $(t^i_{obs} - t^j_{obs}) - (t^i_{cal} - t^j_{cal})$, the 'double-difference,' where t_{obs} and t_{cal} indicate the observed and calculated arrival times, respectively. For DD location, one solves for perturbations to the relative locations (and an origin time shift) to minimize the residual differences. A key aspect is that observed differential arrival times $(t^i_{obs} - t^j_{obs})$ can be determined to high accuracy using waveform correlation methods (Waldhauser and Ellsworth, 2000).

Menke and Schaff (2004) demonstrated that differential time data are capable of resolving absolute locations. Ideally, one would like to take that one step farther and utilize all the information from differential times and absolute arrival times to determine both locations and structure. To that end, Zhang and Thurber (2003) generalized the DD location method to determine jointly the 3D velocity structure and the absolute event locations. The equations for DD tomography are a combination of the standard tomography equations and a generalization of eqn [48]:

$$r^i_k - r^j_k = \sum_{l=1}^{3} \frac{\partial T^i_k}{\partial x^i_l} \Delta x^i_l + \Delta\tau^i + \int_i^k \delta u \, ds - \sum_{l=1}^{3} \frac{\partial T^j_k}{\partial x^j_l} \Delta x^j_l + \Delta\tau^j + \int_j^k \delta u \, ds$$

$$r^i_k = \sum_{l=1}^{3} \frac{\partial T^i_k}{\partial x^i_l} \Delta x^i_l + \Delta\tau^i + \int_i^k \delta u \, ds \qquad [49]$$

where δu is perturbation to slowness and ds is an element of path length, as in [2]. Three types of data, absolute arrival times, catalog differential arrival times, and WCC data, are used in the inversion. To combine these three types of data into one system, a hierarchical weighting scheme is applied during the inversion, similar to hypoDD (Waldhauser, 2001; Waldhauser et al., 1999).

Zhang and Thurber (2003) solved the complete system of linear equations [49], along with smoothing constraint equations, by means of the LSQR algorithm (Paige and Saunders, 1982) (see **Section 1.10.4.1**). Each equation is weighted according to the a priori data uncertainty, data type, distance between the event pair, and misfit at each iteration. The relative weighting for the different data types and the distance weighting are determined a priori, whereas the residual weighting is determined a posteriori, with large residuals rejected or downweighted by a biweight function (Waldhauser and Ellsworth, 2000). For LSQR, the number of iterations required to reach a desired accuracy depends strongly on the scaling of the problem (Paige and Saunders, 1982). For this reason, before the system is fed into the LSQR solver, scaling is applied (**Section 1.10.4.3**) so that each column has an L_2 norm equal to 1.

There are distinct advantages of DD tomography compared to conventional tomography. In conventional tomography, there is no mechanism for incorporating the higher-accuracy differential times, meaning that the event locations remain scattered as in, for example, a normal seismicity catalog. The ability of DD tomography to include the differential times leads to a sharpening of the seismicity distribution and, in turn, an improved velocity model as well. In **Figure 6(a)** and **6(b)**, we show an example of the sharpening of both the seismicity and the velocity structure achieved by DD tomography compared to conventional tomography for the San Andreas fault near Parkfield, CA (Thurber et al., 2004; Zhang and Thurber, 2005).

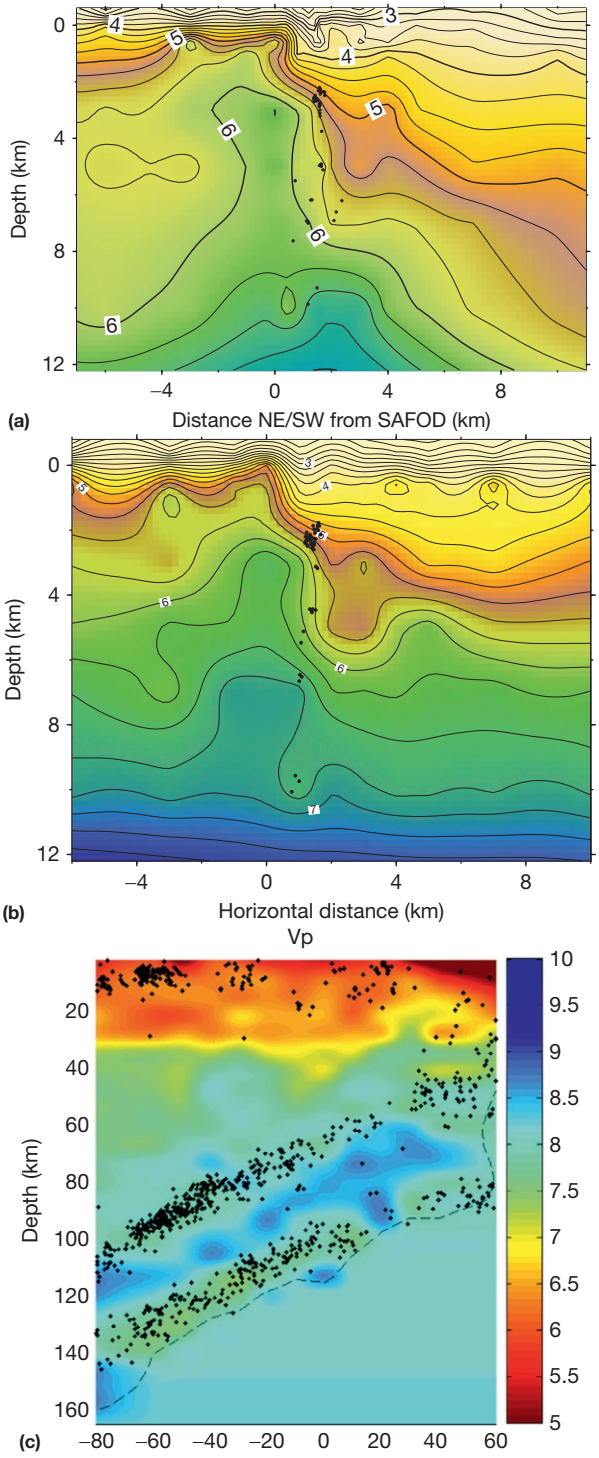

Figure 6 Comparison of (a) conventional tomography (from Thurber et al., 2004) and (b) DD tomography (from Zhang and Thurber, 2005) models for a section across the San Andreas fault at the San Andreas Fault Observatory at Depth (SAFOD) drill site. Note the sharpening of features in both the seismicity and the velocity structures. (c) Image of the internal structure of the subducting slab beneath northern Honshu, Japan, imaged by DD tomography.

At a larger scale, Zhang et al. (2004) showed the dramatic variations in structure deep within a subducting slab that can be imaged with the DD tomography technique (**Figure 6(c)**). Zhang and Thurber (2006) showed that model resolution in earthquake source regions is improved by including differential times.

1.10.4.7 Waveform Tomography and Adjoint Methods

Most data types used in tomographic inversions, such as the travel time of a body wave or the frequency of normal modes, capture only a limited amount of the information contained in full seismograms. Of course, utilizing all seismic signals is the ultimate goal in tomography. In recent years, full-waveform inversions have become feasible given newly developed numerical techniques and the advent of powerful, yet relatively cheap, computers. Full-waveform tomography relies on accurate computations of waveforms for 3D Earth structure (e.g., Capdeville et al., 2003; Komatitsch and Tromp, 1999; Komatitsch and Vilotte, 1998; Komatitsch et al., 2002) (see **Chapter 1.07** by Jeroen Tromp) and 3D sensitivity kernels that relate any portion of the observed waveform to seismic structure. Since it is based on accurate waveform simulations and 3D Fréchet kernels, waveform tomography does not depend on regularization. Hence, it enables the resolution of fine-scale structure (anomalies smaller than the Fresnel zone) and high-amplitude velocity variations (**Figure 7**).

Calculations of exact 3D sensitivity kernels have been based upon spherical-Earth normal-mode summation (Zhao et al., 2000; Capdeville et al., 2003), finite differences (Zhao et al., 2005), and spectral-element simulations (Tromp et al., 2005). The approach by Tromp et al. (2005), in particular, demonstrates how the combination of numerical wave simulations and adjoint techniques (e.g., Tarantola, 1984, 1988) can be used to compute the Fréchet derivatives efficiently for any portion of the waveform and for 3D Earth models (see Liu and Gu, 2012 for an extensive review). Liu and Tromp (2006, 2008) showed examples of adjoint sensitivity kernels based on cross-correlation travel time measurements for a number of body-wave phases. However, the Fréchet derivatives of any seismic observable, such as SKS splitting (Sieminski et al., 2008) or 'seismic noise' (Tromp et al., 2010), can be computed with the adjoint approach.

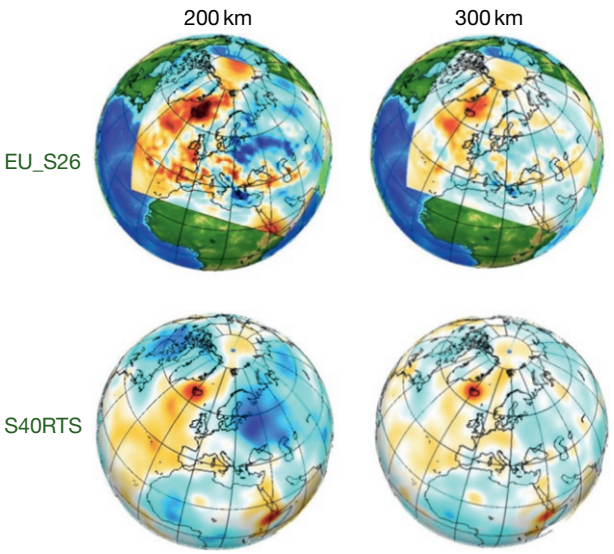

Figure 7 Comparison of (a) regional shear-velocity model EU-S26 (27 iterations) by Fichtner and Trampert (2011) and (b) global shear-velocity model S40RTS (Ritsema et al., 2011) at depths of 200 and 300 km. Note that the shear-velocity variations in EU-27 are stronger and that smaller-scale structures have been resolved.

Perhaps, the simplest example of an adjoint solution to a tomography problem is back projection of travel time residuals. Given the forward problem $\mathbf{G}\Delta\mathbf{m}=\mathbf{r}$ (where we have explicitly written the equation in terms of a perturbation to the model related to the travel time residuals), the back-projection (adjoint) solution is $\Delta\mathbf{m}=\mathbf{G}^{\mathrm{T}}\mathbf{r}$, although in practice, some 'conditioning' (filtering) of this system of equations is employed (Humphreys and Clayton, 1988). This can be thought of as back-propagating the residuals into the model along the ray paths, spreading the residual equally among the model parameters sampled by the ray, and using the associated length of path to scale the residual, with units of time, to a velocity (or slowness) perturbation.

For waveform tomography, the mathematical derivation of the adjoint inversion equations is rather complex (Akcelik et al., 2003; Fichtner et al., 2006a,b; Tarantola, 1984; Tromp et al., 2005) and will not be summarized here. The standard approach is to compute simultaneously a forward simulation and a reverse-time simulation, with the latter using the differences between the data and the current synthetics as the 'source.' The interaction between the two resulting wave fields at each time step, generally involving a zero-lag correlation of the two fields, integrated over time, provides the desired sensitivities (Rawlinson et al., 2010; Tromp et al., 2005).

Although the adjoint approach is extremely powerful, its application is still hindered by the extraordinary computational requirements. For truly 3D inversions, the sensitivity kernels must be recomputed after each iteration. Moreover, global simulations of waveforms with periods shorter than 10–20 s, where body-wave signals display interesting variability, are still out of our reach except for seismologists with access to the largest and fastest supercomputers. Therefore, most inversions are applied to relatively long-period signals of surface waves and regional scales. There are also other steps to minimize the computational demands. This includes source stacking (Capdeville et al., 2005) and the use of adjoint kernels for spherical symmetrical Earth models (Nissen-Meyer et al., 2007) or 2D kernels (Lekic et al., 2010). To overcome the highly nonlinear nature of full-waveform inversions, the misfit functions are often designed to emphasize the phase (or travel time) information contained in seismograms. This can be accomplished by using frequency-dependent travel time analysis through WCC (e.g., Maggi et al., 2009; Sigloch and Nolet, 2006; Zaroli et al., 2010), time–frequency analysis (Fichtner et al., 2008), instantaneous phase measurements (Bozdağ et al., 2011), and the analysis of separate waveform segments (e.g., Li and Romanowicz, 1996; Nolet, 1990).

There have been a number of applications of the adjoint method for seismic tomography, using several variations on

the same general approach. Early work on the application to southern California (Chen et al., 2007; Tape et al., 2007) has been followed by more extensive inversions using increasing numbers of earthquakes and iterations (Tape et al., 2009, 2010). Other applications have focused on Australia (Fichtner et al., 2009), the Middle East (Savage et al., 2011), and Europe (Fichtner and Trampert, 2011; Zhu et al., 2012) (see **Figure 7**). Bozdag et al. (2012) had presented the results of two iterations of adjoint tomography on the global scale using 255 earthquakes and periods longer than 27 s.

1.10.5 Solution Quality

While the previous sections have laid out the procedures involved in tomographic modeling, the ultimate question – how well does the tomographic model reflect the true Earth? – is the most important and perhaps the most difficult one to answer. Without exception, tomography provides distorted images of the real Earth. The image resolution is imperfect due to, for example, choices in parameterization (e.g., block size) and regularization (e.g., smoothing), and it is spatially variable due to the heterogeneous data coverage. Yet, an understanding of seismic data, formal resolution analyses, and hypothesis tests is helpful to guide tomographic model interpretation.

While it is not so straightforward to generalize model resolution issues, we focus on global model S20RTS to demonstrate how hypothesis tests can be helpful in model interpretation.

1.10.5.1 Model Resolution and Uncertainty Analysis

Quantitatively, model resolution is assessed by calculation of the full model resolution and model covariance matrices. In essence, the task is to understand the properties of the generalized inverse matrix $\mathbf{G}^{-\mathbf{i}}$ (eqn [24]). As discussed in **Section 1.10.4.2.1**, we can decompose $\mathbf{G}$ into a product of three matrices, $\mathbf{USV}^{\mathrm{T}}$, with $\mathbf{U}$ and $\mathbf{V}$ being orthogonal matrices (i.e., $\mathbf{U}^{\mathrm{T}}\mathbf{U}=\mathbf{UU}^{\mathrm{T}}=\mathbf{I}$ and $\mathbf{V}^{\mathrm{T}}\mathbf{V}=\mathbf{VV}^{\mathrm{T}}=\mathbf{I}$). If $\mathbf{G}$ has p nonzero singular values and no regularization is applied, then the model resolution matrix $\mathbf{R}_{\mathrm{m}}$ is simply given by $\mathbf{R}_{\mathrm{m}}=\mathbf{V}_{\mathrm{p}}\mathbf{V}_{\mathrm{p}}^{\mathrm{T}}$. $\mathbf{R}_{\mathrm{m}}$ generally will not be an identity matrix and thus can be thought of as a 'filter' that blurs the true model. Application of regularization or singular value truncation will only make the blurring worse. Similarly, for this case, if we further assume that the data covariance matrix is of the form $\sigma^2\mathbf{I}$, then the model covariance matrix $\mathbf{C}_{\mathrm{m}}$ is given by

$$\mathbf{C}_{\mathrm{m}} = \sigma^2\mathbf{V}\mathbf{S}^{\dagger}\left(\mathbf{S}^{\dagger}\right)^{\mathrm{T}}\mathbf{V}^{\mathrm{T}} \qquad [50]$$

where, as before, $\mathbf{S}^{\dagger}$ is the pseudoinverse of $\mathbf{S}$. The square root of the diagonals of $\mathbf{C}_{\mathrm{m}}$ provides an estimate of the (1-standard deviation) model uncertainties. The small singular values, which enter the calculation for $\mathbf{C}_{\mathrm{m}}$ as the square of their reciprocals, thereby amplify data-caused uncertainties (and model errors) in the model associated with the corresponding singular vectors in $\mathbf{V}$. Application of regularization or singular value truncation reduces this problem by suppressing or eliminating the small singular values. See Aster et al. (2012) for additional details.

An effective way of displaying model resolution is via Backus–Gilbert resolution kernels $\mathbf{R}(\mathbf{r},\mathbf{r}_0)$ (Backus and Gilbert, 1968), which are defined (in the original continuous form) as

$$\mathbf{m}(\mathbf{r}_0) = \int_{\mathrm{V}} \mathbf{R}(\mathbf{r},\mathbf{r}_0)\,\mathbf{m}(\mathbf{r})\,\mathrm{dV} \qquad [51]$$

In this example, [51] is utilized in the discrete form. The kernel $\mathbf{R}(\mathbf{r},\mathbf{r}_0)$ illustrates how the model $\mathbf{m}(\mathbf{r}_0)$ at $\mathbf{r}_0$ represents a (weighted) average over the entire model. Hence, it illustrates whether isolated regions of the model of the mantle are independently resolved. **Figure 8** shows four Backus–Gilbert kernels computed for model S20RTS. The relatively broad lateral extents of these kernels reflect the coarse degree-20 parameterization of S20RTS, while the variable vertical extent is, again, an indication of the heterogeneous model resolution (velocity variations with wavelengths shorter than 2000 km at the Earth's surface are unresolved). Resolution is best in the uppermost mantle (0–200 km) (**Figure 8(a)**). Here, S20RTS employs a relatively fine spline parameterization (Ritsema et al., 2004), and this region is well sampled by fundamental-mode Rayleigh waves. Vertical resolution is poor in the transition zone. The Backus–Gilbert kernel computed for a depth of 350 km and the location south of New Zealand (**Figure 8(b)**) is broad, reflecting the poor vertical resolution in the transition zone, especially in the southern hemisphere. Therefore, the low-velocity structure in this region, which is prominent in S20RTS (as well as SB4L18), has an uncertain vertical extent. The Backus–Gilbert kernel in **Figure 8(c)** has a narrower depth extent, given the relatively high data coverage of the western Pacific by both body waves and overtone Rayleigh waves. Finally, the Backus–Gilbert kernel at 1075 km depth (**Figure 8(d)**) beneath Southeast Asia is less than 200 km wide. Given this relatively narrow extent, we may conclude that the high-velocity anomaly in this region of the mantle is resolved independently from anomalies shallower in the mantle. Hence, it appears not to be an artifact from vertical averaging of high-velocity (slab) structure in the transition zone of Indonesia.

While formal resolution tests are feasible for moderately large inversions (e.g., Ishii and Tromp, 1999; Kuo and Romanowicz, 2002; Ritsema et al., 1999) when the model comprises fewer than 10 000 parameters, calculation of the full model resolution matrix can become impractical for extremely large problems. Boschi (2003) and Soldati and Boschi (2005) provided some enlightening discussions of whole-Earth model resolution matrix calculations. Beginning with Nakanishi and Suetsugu (1986), a number of authors have proposed methods for deriving approximate model resolution and/or covariance matrices (Nolet et al., 1999; Yao et al., 1999; Zhang and McMechan, 1995). The effectiveness and efficiency of these methods has been subject to some debate.

Two other approaches for obtaining model resolution information are presented by Zhang and Thurber (2007) and MacCarthy et al. (2011). Zhang and Thurber (2007) made use of the efficient partial reorthogonalization package (PROPACK) of Larsen (1998) to calculate the full model resolution matrix. PROPACK has similar computational speed to LSQR, but it is able to estimate the singular values and vectors more accurately. This approach will also reach its limit, however, for extremely large tomography problems.

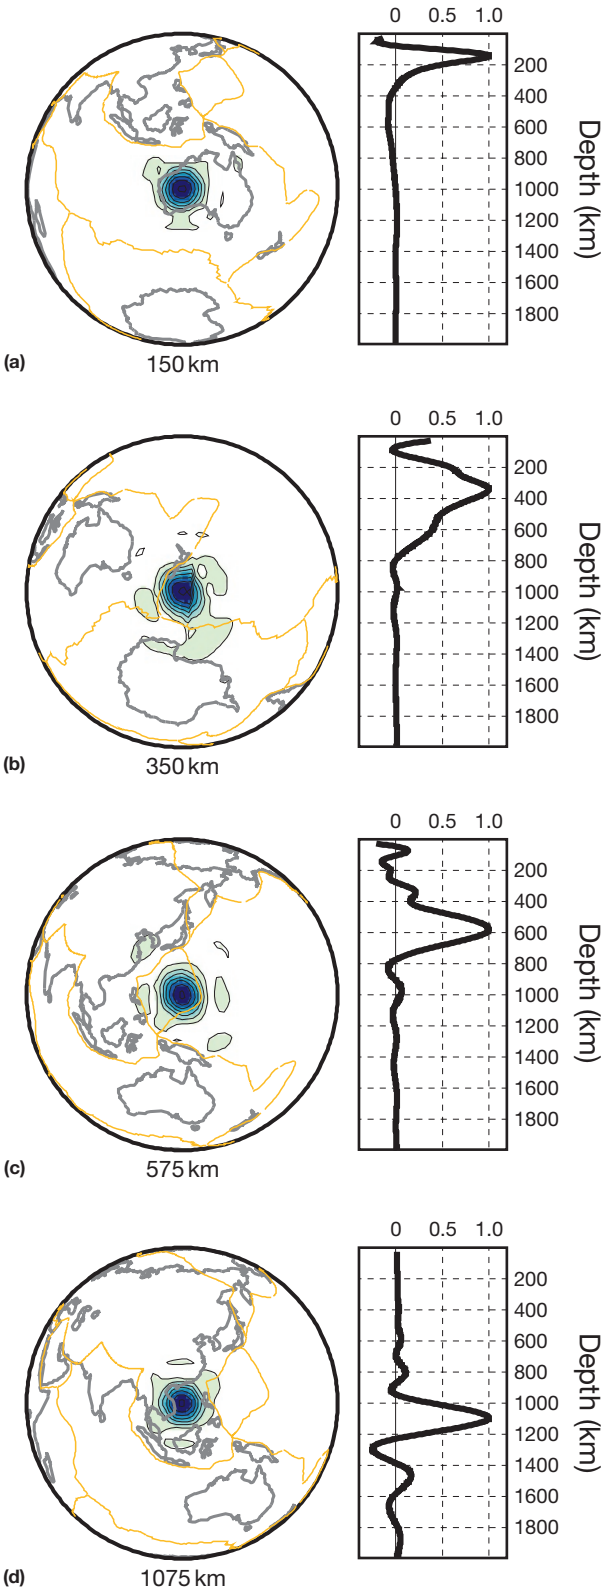

Figure 8 Backus–Gilbert resolution kernels for locations beneath (a) Western Australia (150 km depth), (b) Southwest Pacific (350 km depth), (c) Mariana Islands (575 km depth), and (d) Southeast Asia (1075 km) for model S20RTS. Map views are shown on the left. Vertical cross sections through the kernels are shown on the right. The geographic variability of these kernels reflects the heterogeneous mantle resolution, typical for any tomographic model.

If one is satisfied to determine just the diagonal values of the resolution matrix, then the approach described by MacCarthy et al. (2011) is an excellent alternative. It is based on the method of Bekas et al. (2007) for estimating the diagonal elements of a square symmetrical matrix using a stochastic approach. Following MacCarthy et al. (2011), a set of s random vectors, $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_s$, of length n (in this case, the dimension of the model resolution matrix) are defined, with independent elements drawn from a standard normal distribution. Bekas et al. (2007) showed that for an arbitrary n by n square matrix $\mathbf{A}$, the sth estimate of the diagonal of $\mathbf{A}$ is

$$\mathrm{diag}(\mathbf{A})_s = \left[\sum_{k=1}^{s} \mathbf{v}_k \bullet \mathbf{A}\mathbf{v}_k\right] \oslash \left[\sum_{k=1}^{s} \mathbf{v}_k \bullet \mathbf{v}_k\right] \qquad [52]$$

where $\bullet$ and $\oslash$ denote element-wise multiplication and division, respectively, and the median of these s realizations gives the final estimate of diag($\mathbf{A}$). In this case, we let $\mathbf{A}$ be the model resolution matrix $\mathbf{R}_\mathrm{m}$, $\mathbf{G}\mathbf{G}^{-\mathrm{i}}$. The first term on the right-hand side thus contains $\mathbf{R}_\mathrm{m}$, but in fact, we just need the product $\mathbf{A}\mathbf{v}_k$, which MacCarthy et al. (2011) showed can be determined by defining $\mathbf{y} = \mathbf{A}\mathbf{v}_k$ and solving the least-squares problem $\mathbf{y} = \mathbf{G}\mathbf{G}^{-\mathrm{i}}\mathbf{v}_k s$ times for each random vector $\mathbf{v}_k$. The value of s can be relatively small (order of 100–1000) even for problems with values of n in the tens to hundreds of thousands. For example, Aster et al. (2012) showed that a value of s of 256 is sufficient to yield an excellent estimate of the diagonal of $\mathbf{R}_\mathrm{m}$ for a tomographic problem of dimension 27 000. In particular, for a random set of 100 model elements, the stochastic estimate of the diagonal element matches the exact value within a few percent (**Figure 9**). A similar approach can be applied to estimate diagonal values of $\mathbf{C}_\mathrm{m}$.

Displaying model resolution and covariance results is also problematic, since both matrices have dimensions equal to the number of model parameters. One strategy for compressing the full-resolution matrix into a compact form that can be displayed in a manner similar to that of the model itself is resolution spread (Michelini and McEvilly, 1991), which produces a scalar field quantifying the spatial extent of blurring at each point in the model.

Another thorough approach to the quantification of model uncertainty is the use of global optimization methods, such as Monte Carlo (Mosegaard and Tarantola, 1995), to explore the range of possible solutions. Press (1968) took the Monte Carlo approach for modeling global 1D Earth structure. Shapiro and Ritzwoller (2002) applied a Markov-chain Monte Carlo analysis to a global surface-wave model of the crust and upper mantle structures. As one might expect, the uncertainties that they quantify substantially exceed standard estimates based on the model covariance matrix.

1.10.5.2 Hypothesis Testing

An entirely different strategy for evaluating the quality of a tomographic model involves hypothesis tests. In such tests, it is determined how a hypothetical structure of the Earth would be recovered tomographically. There are two common ways to approach such tests. One could evaluate the resolution operator $\mathbf{R}_\mathrm{m}$, which is defined as [27]:

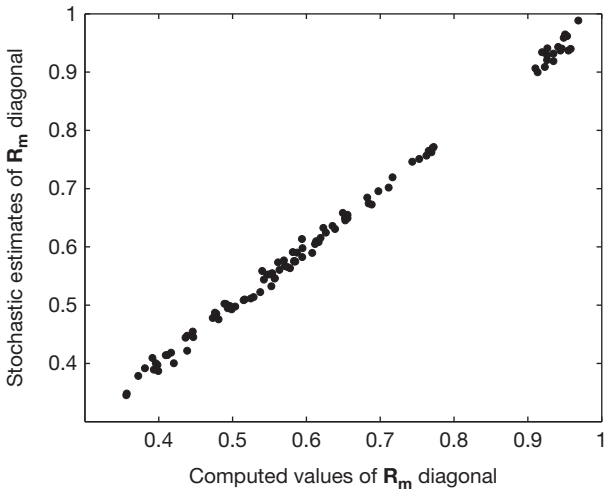

Figure 9 Comparison of exact model resolution diagonal values to those computed with the stochastic method for estimation of the diagonal values of a matrix. Modified from Aster RC, Borchers B, and Thurber CH (2012) Parameter Estimation and Inverse Problems, 2nd edn, 376 pp. Elsevier/Academic Press.

$$\mathbf{m}_{out} = \mathbf{R}_m \mathbf{m}_{in} \quad [53]$$

Simply convolving $\mathbf{R}_m$ with a conceptual input model $\mathbf{m}_{in}$ renders $\mathbf{m}_{out}$ that is the tomographically resolved structure if $\mathbf{m}_{in}$ were the true earth. The degree of recovery of $\mathbf{m}_{in}$ in various parts of $\mathbf{m}_{out}$ is used to define the well-resolved parts of the model. Alternatively, one can mimic the effects of [27] by inverting synthetic data generated for $\mathbf{m}_{in}$ following the same procedure applied to the real data. Tomographers choose a variety of synthetic structures for $\mathbf{m}_{in}$ including spikes (isolated anomalies), checkerboards (models with alternating high- and low-velocity anomalies), and conceptual geologic structures.

Figure 10 shows an application to the Icelandic upper mantle, where model S20RTS features a low-velocity anomaly that extends much deeper into the upper mantle than what is typical for the Mid-Atlantic Ridge (Figure 10(a)). To assess this depth extent, we can test how relatively narrow structures (cylinders) with variable depth extents are recovered tomographically. The 200 km wide cylinders of $\mathbf{m}_{in}$ are at least five times wider in $\mathbf{m}_{out}$ (Figure 10(b)). This is entirely due to the parameterization of model S20RTS (spherical harmonics up to order and degree 20) that cannot accommodate velocity variations with a half wavelength smaller than 1000 km. Furthermore, we can observe vertical stretching of the cylinders due to the finite depth resolution. For example, the input cylinder that extends from the surface to a depth of 400 km is projected into $\mathbf{m}_{out}$ as an anomaly that reaches the 670 km discontinuity. The relatively broad averaging lengths deeper in the transition zone are also evident in Figure 10. The peak anomaly of the 100 km thick cylinder that, in $\mathbf{m}_{in}$, was placed immediately below the 660 km discontinuity is reduced by about a factor of 6 in $\mathbf{m}_{out}$. While it is impossible to conclude which true Earth structure is responsible for the tomographic image of Figure 10(a) (we can only determine $\mathbf{m}_{out}$ given $\mathbf{m}_{in}$, but not vice versa), it appears that heterogeneity in the mantle below the 660 km discontinuity is independently resolved from the mantle above it. It is plausible, however, that a low-velocity anomaly in the upper 400–500 km of the mantle is artificially extended to 700 km depth. The hypothesis tests of Figure 10 suggest also that the lower bound of the Icelandic anomaly is a real feature.

Another approach is to use geophysically more meaningful input models. An example is provided in Figure 11. Here, an input model ($\mathbf{m}_{in}$) is derived from a numerical calculation of mantle convection (McNamara and Zhong, 2005; Ritsema et al., 2007), and $\mathbf{m}_{out}$ is obtained by convolving $\mathbf{m}_{in}$ with $\mathbf{R}_m$. Figure 11 demonstrates how small-scale structures such as thermal instabilities from thermochemical basal structures cannot be resolved at the resolution of S20RTS (and presumably other global models). In addition, even large-scale structures in $\mathbf{m}_{in}$ are artificially stretched and tilted in $\mathbf{m}_{out}$ in regions (e.g., the central Pacific lower mantle) with unidirectional mantle sampling.

Hypothesis tests like those in Figures 10 and 11 have serious pitfalls when only a number of cases of $\mathbf{m}_{in}$ are tested. One can only infer how $\mathbf{m}_{in}$ is mapped tomographically into $\mathbf{m}_{out}$, but not vice versa, because the components of a model in the null space of $\mathbf{G}$ (the components of $\mathbf{V}$ corresponding to the zero singular values) cannot possibly be resolved. It is therefore dangerous to generalize the resolution of a tomographic model from the outcome of only a few tests. In fact, Lévêque et al. (1993) showed, perhaps counterintuitively, that the success of a checkerboard test to resolve the small-scale checkerboard structure cannot guarantee that larger-scale structures will be resolved with the same dataset. In other words, it is possible for some small features to be resolvable when some larger-scale features are not. For instance, they illustrate how horizontal variations can be well recovered while the large-scale radial variation is poorly resolved if most of the rays are subparallel and steeply incident. This is of course an inherent problem of the teleseismic travel time inversion, such as the ACH tomography method (Aki et al., 1977).

We also point out that cell-based tomographic systems have a natural tendency for negative model covariance between adjacent cells. This is caused by the fact that, when resolution is imperfect, a positive perturbation in one cell can be counterbalanced by negative perturbations in adjacent cells (the exact pattern of a checkerboard) with little effect on the data fit. Hence, noisy (underdamped or undersmoothed) tomographic models typically show oscillatory behavior. Thus, checkerboard tests may yield overly optimistic estimates of model quality due to the presence of error in the synthetic data coupled with the character of the model covariance.

'Model restoration' tests are another popular approach. Here, a model with all of the main features of the model obtained from the real data (sometimes with the sign of the anomalies reversed; Husen and Kissling, 2001) is used to generate synthetic observations, which are then inverted using the same method and parameters as those used for the real data. When extended to include comparable assessment of models lacking some of the key features (Zhang et al., 2004), this approach can be very effective.

Given the difficulties of fully evaluating model resolution and covariance matrices, tomographers often resort to the kind of simplified hypothesis tests described earlier to estimate the significance of interesting model attributes. There is one important additional caveat. When testing how $\mathbf{m}_{in}$ is projected into $\mathbf{m}_{out}$ according to the model resolution operator

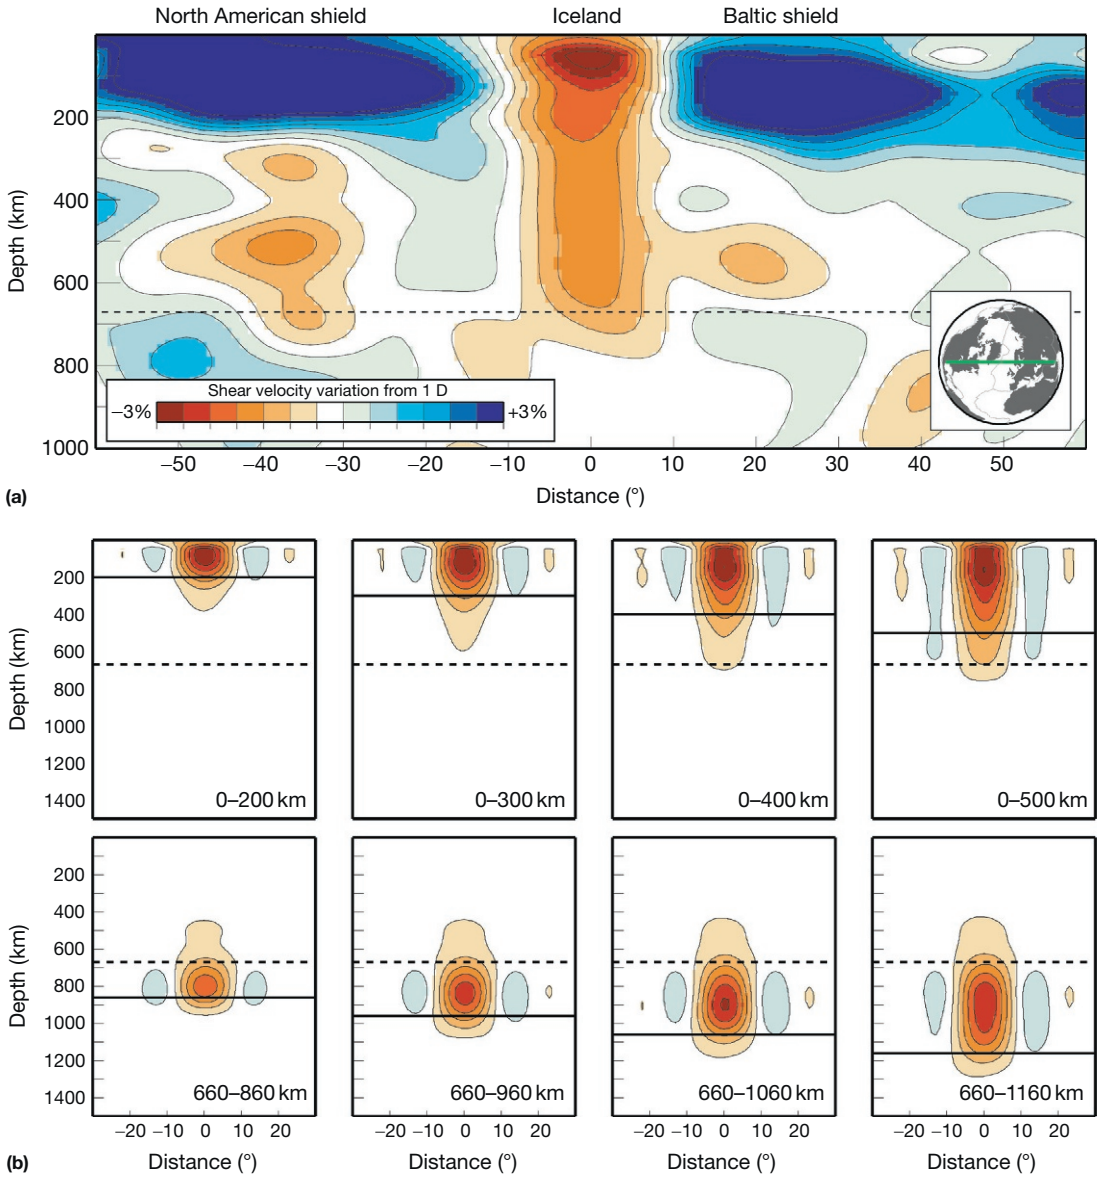

Figure 10 (a) Upper mantle cross section through model S20RTS, showing a low-velocity anomaly beneath Iceland that extends to about 800 km depth. (b) 'Spike tests' designed to evaluate whether the Icelandic low-velocity anomaly points to a deeper-than-normal mantle upwelling beneath the Icelandic region of the Mid-Atlantic Ridge or whether it is a tomography artifact. The cross sections show $\mathbf{m}_{out}$ obtained by convolving hypothetical models $\mathbf{m}_{in}$ with the resolution operator $\mathbf{R}_{\mathbf{m}}$. The input models $\mathbf{m}_{in}$ are 200 km wide cylinders of the mantle beneath Iceland with a uniform velocity perturbation from the reference model. Their tops are top row at the Earth's surface or bottom row at the 660 km discontinuity, and their vertical extent varies from left to right between 100 and 500 km. The numbers indicate to which depth the cylinders in $\mathbf{m}_{in}$ extend.

$\mathbf{R}_{\mathbf{m}}$, we are not addressing the effects of simplifications in the forward modeling theory. We assume that anomalies in the mantle, no matter how small, perturb a wave that propagates through it and that this perturbation (e.g., travel time delay) is recorded at the Earth's surface. In the real Earth, delay times dissipate due to 'wave front healing' (e.g., Nolet and Dahlen, 2000; Wielandt, 1987). Wave front healing is related to the finite-frequency nature of a seismic wave and is ignored in ray theory. Wave front healing can be significant for small (compared to the wavelength) and deep anomalies (Hwang et al., 2011; Malcolm and Trampert, 2011). Going back to our example from Iceland, it is possible that a narrow (e.g., plume-stem) seismic anomaly is present below a depth of 700 km, which has imparted a travel time delay to a throughgoing wave that is still not observable at the surface. The effect of wave front healing, omitted in the forward modeling theory applied to S20RTS, can only be tested with more realistic forward modeling theories (Montelli et al., 2004a) or by comparing seismic waveforms with 3D wave simulations (e.g., Allen and Tromp, 2005; Komatitsch et al., 2002).

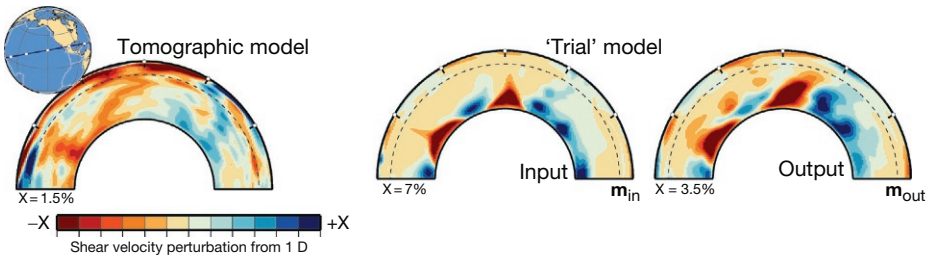

Figure 11 (left) Whole-mantle cross section through model S20RTS (from the Southwest Pacific to the Atlantic) depicting broad lower mantle anomalies beneath the Pacific and a high-velocity anomaly beneath North America. (right) Recovery tests designed to estimate how a thermochemical model of shear-velocity heterogeneity in the lower mantle (see McNamara and Zhong, 2005; Ritsema et al. 2007) would be seen tomographically. A comparison of $\mathbf{m}_{in}$ and $\mathbf{m}_{out}$ illustrates the image distortions, especially in regions (e.g., the lower mantle beneath the central Pacific) with relatively poor data coverage. Relevant to this comparison is the questionable resolution of thermal plumes from the edges of thermochemical deep mantle structures and the artificial tilt of the seismically derived central Pacific low-velocity structure.

1.10.6 Future Directions

We close by commenting on some areas of research in which we anticipate exciting progress in seismic tomography in the future. The tomographic study of temporal changes in structure ('4D tomography') is one relatively new frontier. Some examples are the study of geothermal reservoir changes at The Geysers, California (Gunasekera et al., 2003), the investigation of temporal changes at Mammoth Mountain, California, related to CO_2 outgassing (Foulger et al., 2003), temporal changes at Mt. Etna, Sicily, associated with magma intrusions (Patanè et al., 2006), and similarly temporal changes at the Kluchevskoy group of volcanoes in Kamchatka, Russia, associated with subsequent eruptions (Koulakov et al., 2013). A major concern is the potential for differences in data sampling for datasets from different time periods to cause apparent temporal changes. An inversion strategy that solves for 4D models with a constraint to restrict model changes to those truly required by the data may be the key to deriving robust results in such studies (Ajo-Franklin and Minsley, 2005; Day-Lewis et al., 2003).

Multimethod seismic inversions (e.g., surface waves and receiver functions; Julia et al., 2000) and multiproperty geophysical inversions, for example, seismic and gravity data (Roecker et al., 2004) and seismic and magnetotelluric data (Bennington et al., in press; Gallardo and Meju, 2004, 2007) also present opportunities for significant advances. In the joint seismic–gravity case, it is common to use an empirical velocity–density relationship as a constraint in the inversion. In the seismic–magnetotelluric case, an empirical relationship is not available, so 'structural constraints' (Haber and Oldenberg, 1997) are most commonly applied. The approach of Haber and Oldenberg (1997) proposes the evaluation of the gradients or Laplacians of the two scalar fields of the physical properties to define feature boundaries, incorporating a threshold value above which the features are constrained to be aligned via a penalty function. An alternative approach involves the use of the absolute value of the cross product of the gradients (the 'cross gradient'), with the constraint being to minimize the total cross gradient (Gallardo and Meju, 2004, 2007). This approach can be readily extended to multiple geophysical parameters (Gallardo et al., 2012).

A very different approach to joint inversion is global joint seismic–geodynamic tomography. Rather than obtaining a global seismic model or joint global seismic-density model, using that to compute mantle flow, and comparing the result to geodynamic observables, it is possible to invert seismic and convection-related datasets jointly (Forte and Woodward, 1997; Forte et al., 1994; Simmons et al., 2006, 2007, 2009, 2010). This powerful approach is described in more detail in Forte (**Chapter 1.27**, this volume).

Although joint inversions are receiving increasing attention in academia and industry, in our own experience, great care must be taken in establishing effective values for the scaling and regularization parameters so that convergence is achieved across all models and constraints. Despite this word of caution, we anticipate a great increase in the use of joint inversion methods in the future.

Acknowledgments

Our thanks to Haijiang Zhang for contributing material and for providing comments on a draft version of the manuscript. We are grateful to the volume editors Adam Dziewonski and Barbara Romanowicz for their comments and assistance and to Malcolm Sambridge, Nathan Simmons, and an anonymous reviewer for their constructive comments on various versions of this chapter. 1.11.1 Introduction, Purpose, and Scope

The Earth's crust preserves the record of the evolution of our planet, provides our natural resources, and presents social challenges in the form of natural hazards, such as earthquakes and volcanoes. Despite its importance, the clear recognition of a universal crust encircling the Earth dates back to slightly more than 100 years (Mohorovičić, 1910). In fact, as recently as the 1960s, it was hypothesized that the ocean floor was entirely composed of serpentinized peridotite (hydrated ultramafic mantle rocks; Hess, 1962), a view that would have restricted true crustal material (i.e., silica-rich rocks) to the continents and its margins. Today, it is well established that melt extracted from the mantle forms an outer crust in most regions of the Earth, oceanic and continental.

The Earth's crust has profound implications for all aspects of the planet's physical state and evolution. The process of crustal formation led to the complementary formation of an underlying mantle lithosphere, classically referred to by seismologists as 'the mantle lid' due to its finite (c. 50–250 km) thickness (Gutenberg, 1959; Oliver et al., 1959). The physical properties of the crust plus mantle lithosphere modulate the rate at which heat is released to the Earth's surface, regulates mantle convection, determines the location of earthquakes and

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00010-5

volcanoes, and more generally defines the rules for plate tectonic processes.

The foundations of seismic studies of the crust and upper mantle were laid in the period 1909–69 when the results of many pioneering studies provided a global view of the structure of the Earth's crust (Table 1). However, most of these early studies were hindered by technical limitations that yielded field observations that presented an aliased image of the crust. It is not surprising that, with some notable exceptions (Meissner, 1967; Mueller, 1977), these data were commonly interpreted in terms of two or more homogeneous layers, the upper layer (compressional wave, $V_P = 6.0–6.2\ km\ s^{-1}$) assigned a granitic composition and the lower layer ($V_P = 6.5–7.0\ km\ s^{-1}$), a basaltic composition (Birch, 1952; Pakiser and Steinhart, 1964). The advent of higher-resolution data has revealed a much richer and complex picture of the crust, as well as many unresolved questions. Among the outstanding questions are the age and physical properties of the Moho and midcrustal seismic discontinuities, the possible presence of deep crustal fluids, the geometry of crustal faults at depth, crustal modification by lateral crustal flow, and the magnitude of crustal seismic anisotropy.

Our understanding of the seismic structure of the crust began to change radically with the advent of deep seismic reflection profiling (Meissner, 1973; Oliver et al., 1976) and the development of numerous stand-alone, portable seismographs used for seismic refraction/wide-angle reflection profiling (Healy et al., 1982). These data provided an unaliased view of the crust to frequencies of 20 Hz and higher (corresponding to 300 m and higher resolution within the crust). Compilations of crustal seismic data into global models can be traced to the global Moho map of Soller et al. (1982). This map, while highly informative, did not easily lend itself to use in numerical calculations that make quantitative corrections for the crust. A major step forward was the publication of the global $2° \times 2°$ 3SMAC model (Nataf and Ricard, 1996) that for the first time permitted the calculation of crustal corrections to seismological and other geophysical observations. In the past decade, a tremendous amount of new seismic field observations have been made, thereby making it possible to improve the accuracy of previous global crustal models (Mooney et al., 1998; Pasyanos et al., 2004). In this chapter, we document these advances and summarize the current status of global crustal models.

1.11.2 Geology, Tectonics, and Earth History

The Earth's lithosphere is qualitatively defined as the cold, upper layer of the Earth and is divided into large blocks called tectonic plates (Figure 1). The lithosphere is on the order of 100 km thick, being the thinnest (20–100 km) in oceanic regions and the thickest (50–250+ km) in continental regions. The base of the crust is the depth within the lithosphere where V_P increases from about $6.5–7.3\ km\ s^{-1}$ to greater than $7.6\ km\ s^{-1}$ (James and Steinhart, 1966). This boundary between the lower crust and the upper mantle is called the Mohorovičić discontinuity (Jarchow and Thompson, 1989; Mohorovičić, 1910) and is usually at a depth (below sea level) of 10–14 km for oceanic crust and 30–50 km for

continental crust. The Earth's crust, which was originally extracted from the mantle, constitutes only about 0.7% of the total mass of the crust–mantle system (Taylor and McLennan, 1985). The Mohorovičić discontinuity, commonly referred to as the Moho, may not always be the base of the crust in a petrologic sense because the seismic definition of crustal material (V_p less than 7.6 km s^{-1}) may not include high-grade metamorphic rocks (e.g., eclogite) or a crust–mantle mix of mafic and ultramafic rocks (Griffin and O'Reilly, 1987; Rudnick and Gao, 2005). Further seismic discontinuities below the crust divide the interior of the Earth into the upper mantle, transition region, lower mantle, outer core, and inner core. These other discontinuities are discussed in companion papers in this volume.

As a consequence of plate tectonics (**Figure 2**), oceanic crust and continental crust vary systematically in their principal physical properties, including density, thickness, age, and composition. Continental crust has an average thickness of 39 km, density of 2.84 g cm^{-3}, and an average age of 1500 Ma, whereas the oceanic crust (excluding 4–5 km of seawater) has an average thickness of about 6 km and density of 3 g cm^{-3} and is everywhere younger than 200 Ma. Oceanic crust is largely made up of theoleiitic basalt, which has a dark, fine-grained texture that formed from rapidly cooling magma. In contrast, continental crust ranges in thickness from 20 km in the Afar Triangle, northeast Africa, to about 80 km in the southern Tibetan Plateau. Ninety percent (by area) of the continental crust, however, is between 22 and 56 km thick (Mooney et al., 1998).

This chapter presents a holistic view of the Earth's crustal structure and summarizes the types of velocity and density models that characterize the crust on a global scale. In recent years, several seismological techniques have been used to explore the crust. These include seismic refraction/wide-angle reflection profiles, near-vertical incidence reflection profiles, receiver functions, local earthquake tomographic inversions, and inversions of ambient noise data. Some of these survey techniques have been in use for more than a half century, and the results are reported literally in thousands of publications (Prodehl and Mooney, 2012). In contrast, the inversion of seismic ambient noise to determine crustal structure is a relatively new and powerful technique (Campillo and Paul, 2003; Shapiro et al., 2005). Taken together, the results from all of these techniques make it possible to provide a comprehensive crustal model for the whole Earth, as well as higher-resolution regional models.

1.11.3 Seismic Techniques for Determining the Structure of the Crust and Uppermost Mantle

Seismic techniques provide the highest-resolution geophysical measurements of the structure of the crust and uppermost mantle. These techniques may be divided into those using active sources versus passive sources. Active sources are man-made seismic sources such as vibrators, air guns, and borehole explosions. Passive sources are derived from naturally occurring seismicity, including P- and S-wave body waves, Love and Rayleigh waves, and scattered waves. We discuss active and passive seismic techniques in turn.

1.11.3.1 Active-Source Data

Active-source seismic measurements of the structure of the crust have been conducted on a worldwide basis (Meissner, 1986; Mooney et al., 2002; Percival et al., 2012; Prodehl and Mooney, 2012; Soller et al., 1982). Seismic studies of the deep continental crust that utilize man-made sources are classified into two basic categories, seismic refraction/wide-angle reflection profiles and near-vertical incidence seismic reflection profiles, depending on their field acquisition parameters. Seismic refraction/wide-angle reflection profiles provide reliable information regarding the distribution of seismic velocities within the crust and are very effective in mapping crustal thickness (**Figure 3**). In contrast, seismic reflection data provide an image of the crust at a finer scale (50 m in the vertical and horizontal dimensions). As a result, seismic reflection and refraction/wide-angle reflection data have complementary strengths: reflection data provide a detailed structural image of the crust, whereas refraction data provide a robust estimate of the seismic velocity distribution in the crust for both V_p and

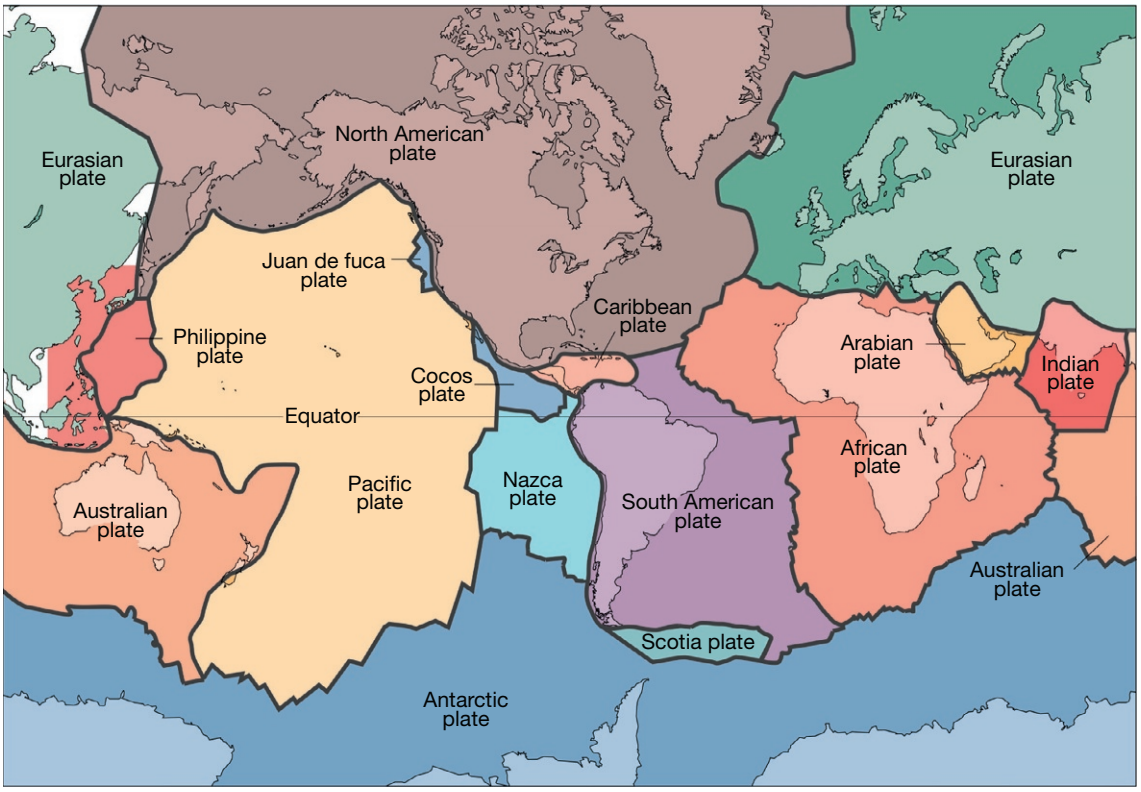

Figure 1 The 15 major tectonic plates on Earth, and the boundaries between these plates (Simkin et al., 2006). New oceanic lithosphere is constantly being produced at mid-ocean ridges (divergent plate boundary) and later subducted back into the mantle at convergent plate boundaries (**Figure 2**). Plate motions led to the recycling of oceanic crust, arc volcanism, and compression at convergent boundaries. This chapter describes the complex and laterally variable deep seismic structure of the Earth's crust.

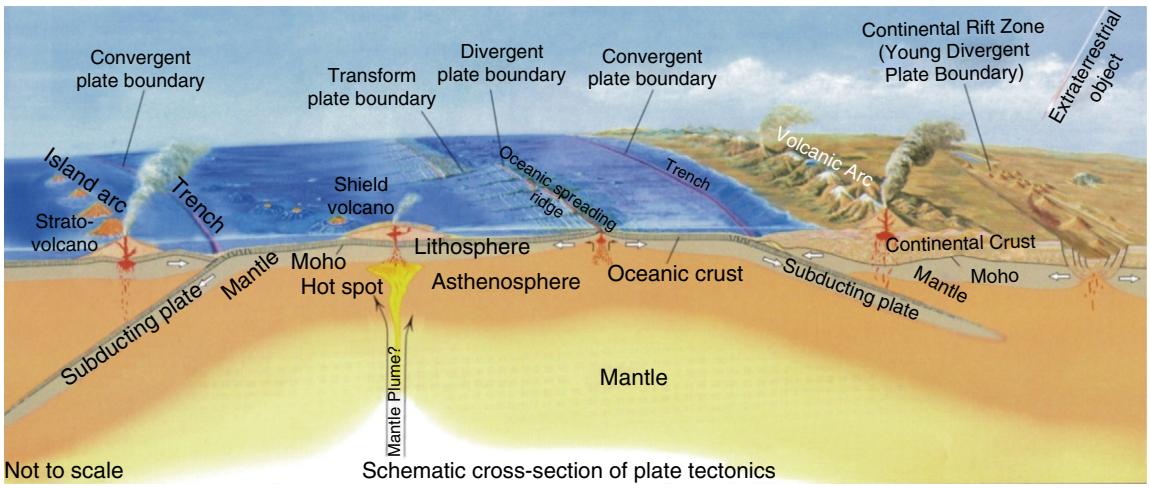

Figure 2 A cross section of the Earth's surface, indicating divergent (oceanic spreading ridge) and convergent (subducting plate) plate boundaries (Simkin et al., 2006). Active magmatic arcs at convergent boundaries increase the volume of continental crust and continental rift zones led to crustal thinning. We summarize the deep structure of these and other features of the Earth's crust.

V_s (shear-wave velocity). Key papers that describe the acquisition and analysis of active-source data are provided in Table 2.

The most common sources used in land profiles are chemical explosions and mechanical vibrators. Chemical explosions are generally composed of ammonium nitrate compounds that are detonated in a borehole at a depth of 20–50 m in the ground. In contrast, a vibrator truck weighs several tons and has a heavy steel plate that is pressed against the ground that vibrates at increasing frequencies (5–60 Hz) for up to 30 s. This method requires cross correlation of the recordings with the

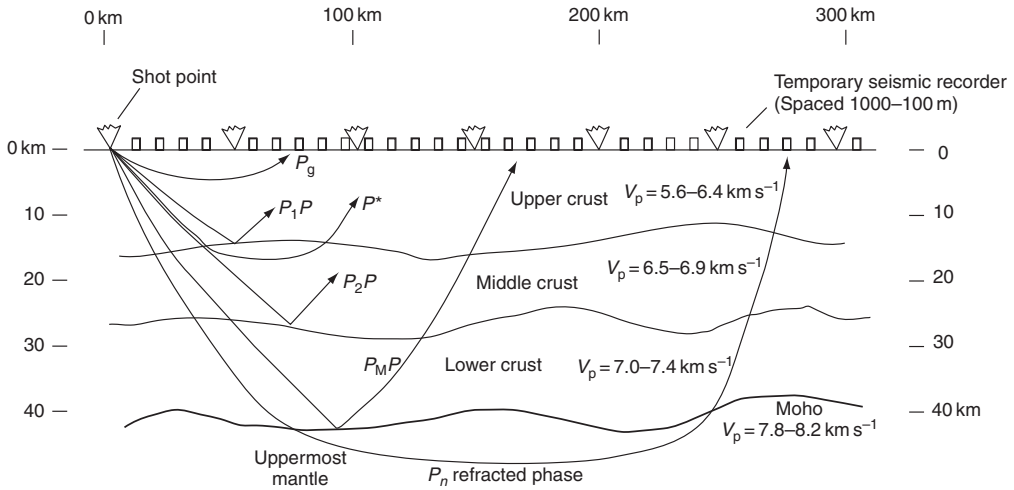

Figure 3 Ray paths for a continental seismic refraction/wide-angle reflection profile for crust with a typical seismic velocity structure found beneath a stable craton. The crust–mantle boundary (Moho) is a continuous feature, but intracrustal boundaries may be discontinuous laterally and several kilometers wide vertically. Commonly, shot points are spaced 50 km apart (or closer for higher resolution); temporary seismic recorders are spaced 1000–100 m apart.

source signal in the data processing stage. The most common sources in marine profiles are the air gun, in which a bubble of very high-pressure air is released into water, and, prior to modern environmental concerns for marine life, explosive charges. Long-range seismic refraction data have also been recorded from nuclear sources, particularly in the former Soviet Union (Egorkin et al., 1987; Pavlenkova, 1996). Due to the strength of these nuclear explosions, such long-range profiles probed not only the crust but also the entire upper mantle to a depth of 660 km (Mechie et al., 1993; Morozov et al., 1998, 1999; Ryberg et al., 1995, 1996).

1.11.3.1.1 Seismic refraction/wide-angle reflection profiles

Seismic refraction/wide-angle reflection profiles are recorded with relatively widely spaced (100–5000 m) geophones (typically with vertical component seismometers) and long offsets (100–500+ km) between sources and receivers (Figure 3). The data from these seismic profiles commonly contain strong wide-angle reflection phases (Figure 4) and provide excellent constraints on seismic velocity within the lithosphere.

Profiles with sources all to one side of the receivers are referred to as unreversed refraction profiles. Unreversed refraction profiles record only apparent velocities and are interpreted as if the crust was composed of flat-laying, uniformly thick layers. Split refraction survey lines, which in some ways are similar to simple reversed refraction lines, have generally been used for oceanic crust. Reversed refraction surveys are more reliable, and the technique used for interpreting them is described in Mooney (1989), Chulick (1997), Zelt and Smith (1992), Braile et al. (1995), Zelt (1999), and Prodehl and Mooney (2012). Reversed refraction profiles generally have multiple shot points that provide overlapping coverage (Figure 5). The most reliable way to determine a velocity structure from seismic refraction data is to compute detailed (two-dimensional) 2-D ray-theoretical travel times (Figure 5(b)) and synthetic (theoretical) seismograms and compare these with the observed data. This modeling must take into

account (1) the source time function, which could be from an explosion, earthquake, air gun, or vibrator; (2) the effects of transmission through the crust; and (3) the response of the detection systems, which may be seismometers, amplifiers, and filters. For trial-and-error forward modeling, an initial velocity model is constructed and is adjusted until the synthetic seismograms match the recorded seismograms to the desired degree. For inverse methods (e.g., Zelt and Smith, 1992), seismic travel times are used to obtain a best fitting model, starting from the near surface and moving down through the crust. Recent developments of low-cost, ultracompact seismic recorders that can be deployed by the thousands hold the promise of true 3-D imaging of the crust.

Seismic velocities in the crust are primarily determined by five factors: mineralogical composition, confining pressure, temperature, anisotropy, and pore fluid pressure. In order to draw inferences about the mineralogical composition of the deep crust, however, one must first estimate the contribution of the other four properties. Confining pressure is easily calculated from depth of burial, and temperature can be estimated from the surface heat flow. The quantitative effect on measured seismic velocities due to seismic anisotropy (Rabbel and Mooney, 1996) and pore fluid pressure (Hyndman, 1988; Manning and Ingebritsen, 1999) is more difficult to estimate.

1.11.3.1.2 Seismic reflection profiles

Near-vertical incident seismic reflection data provide the most detailed images of crustal structure. Data are recorded with closely spaced (5–100 m) geophones and sources that yield a high-resolution image of the internal structure of the crust and

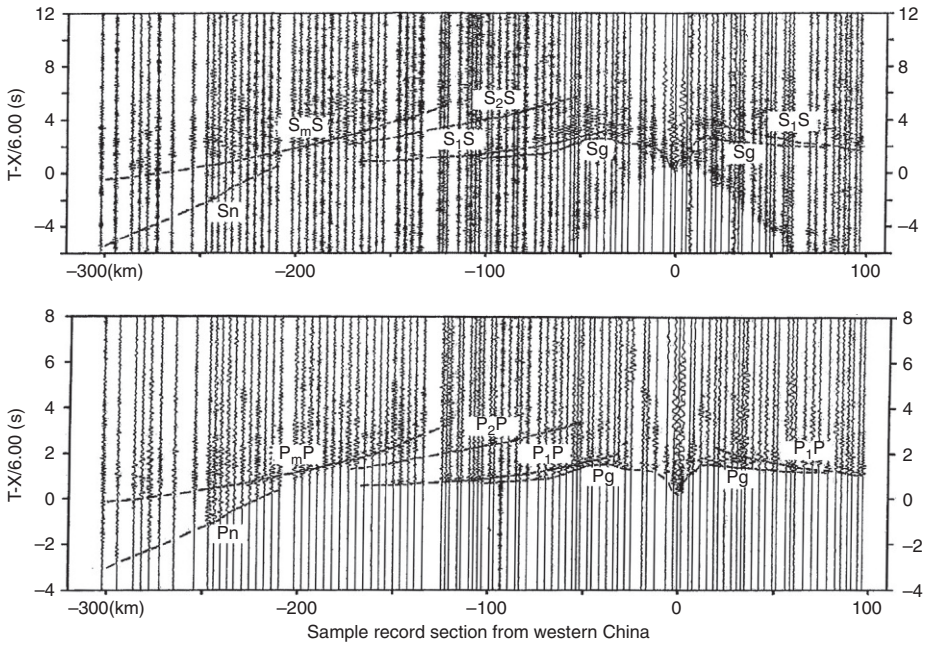

Figure 4 Sample seismic record section from western China. Top: Shear (S)-wave record section with a reduction velocity of 3.46 km s^{-1}. This is a split-spread profile, with the shot point at 0 km; seismic phases as defined in **Figure 3**; Sg, direct arrival; S1S, reflection boundary between the upper crust and the middle crust; S2S, reflection from middle crust and lower crust; SmS, reflection from Moho; Sn, refraction from uppermost mantle. Bottom: Compressional (P)-wave record section with a reduction velocity of 6.0 km s^{-1}; seismic phases as defined for S-waves above. Reproduced from Wang CY, Chen W, and Mooney WD (2003) Three-dimensional velocity structure of the crust and upper mantle in southwestern China and its tectonic implications. *Journal of Geophysical Research* 108: 2442, http://dx.doi.org/10.1029/2002JB001973; Wang XY, Mooney WD, and Yuan XC (2003) The crustal structure from the Altai Mountains to the Altyn Tagh fault, northwest China. *Journal of Geophysical Research* 108: 2322, http://dx.doi.org/10.1029/2001JB000552.

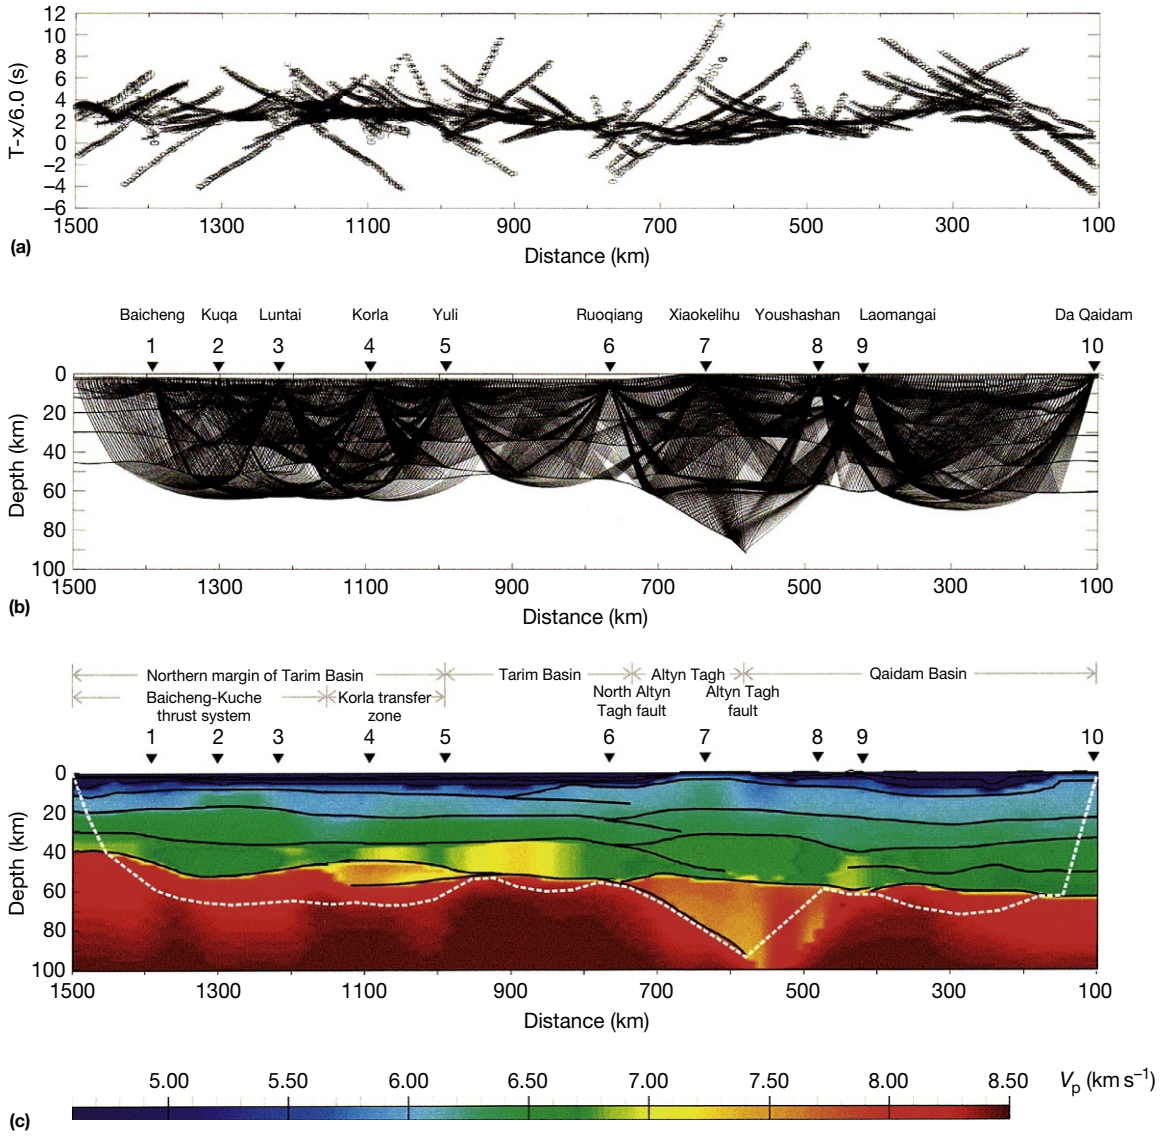

Figure 5 Modeling results along the seismic refraction/wide-angle reflection profile at the northern margin of the Tibetan Plateau. (a) Overlapping and reversing travel time curves; (b) Ray tracing through the crustal model showing dense subsurface ray coverage that provides excellent constraints on seismic velocities. (c) Crustal and uppermost mantle seismic velocity (V_p) model. Both V_p and V_s can be estimated for the crust from these data. Pn velocity ranges from 7.8 to 8.2 km s^{-1}. Reproduced from Zhao JM, Mooney WD, Zhang X, Li Z, Jin Z, and Okaya N (2006) Crustal structure across the Altyn Tagh Range at the northern margin of the Tibetan Plateau and tectonic implications. *Earth and Planetary Science Letters* 241: 804–814.

Moho, but such data generally do not constrain seismic velocities in the deeper (middle and lower) crust. P-waves from an energy source, such as a vibrator, buried explosive, or air gun, are reflected by intracrustal interfaces and recorded by geophones located close (0.1–10 km) to the source. In the data processing stage, the effects of the source and receiver are removed from the recorded seismograms through a process called deconvolution, allowing for higher-resolution images of the structure. The seismic reflection data are commonly migrated, a processing step that shifts the reflectors into their correct spatial locations.

Seismic waveform inversion exploits the full information content within the recorded wavefield (Pratt, 1999; Tarantola, 1984) and has been applied to both near-vertical incident seismic reflection and seismic refraction/wide-angle reflection data. The inversion procedure, usually in the frequency–space domain, iteratively refines a starting model to reduce the waveform misfit between observed and model data (Hu et al., 2009; Pratt, 1999; Sirgue and Pratt, 2004). The method can be applied to any wavefield that interrogates the seismic velocity structure of the crust (Aster et al., 2012; Ben-Hadj-Ali et al., 2008).

The seismic properties that are most readily obtained from reflection data are reflectivity patterns, and these correlate with distinct geologic settings. For example, the European North Sea has undergone Cenozoic extension that is evident in deep seismic reflection data as tilted horst and grabens, a shallow (30 km) distinct Moho, and a dipping shear zone (Flannan reflections) within the upper mantle (**Figure 6**). When

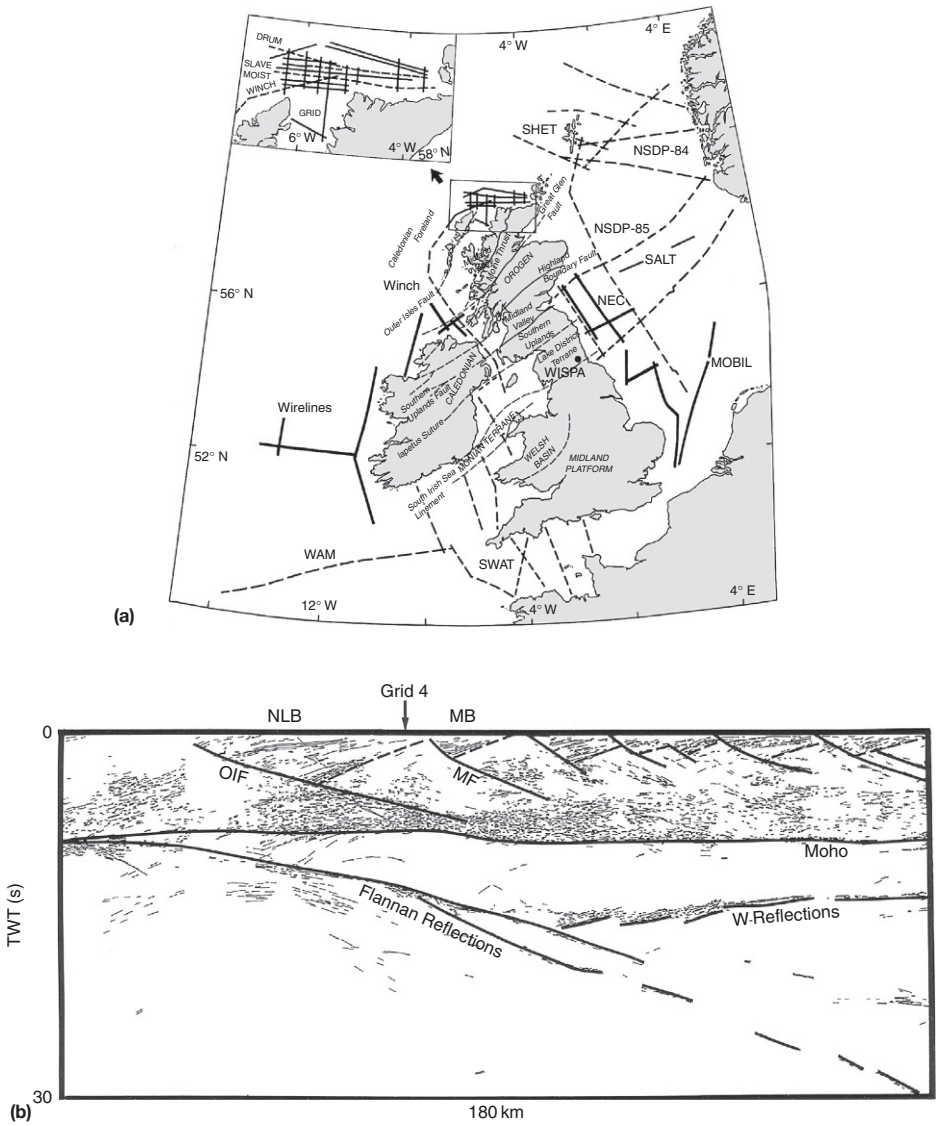

Figure 6 Deep seismic reflection imaging of crustal and upper mantle fault zones. (a) Location map for the British Isles with marine seismic reflection profile lines indicated. (b) Seismic profile DRUM located off the north coast of Scotland (see inset in panel (a)). This profile shows brittle normal faults within the upper crust that merge into a zone of diffuse ductile deformation in the lower crust. The Moho is labeled at a two-way time of 10 s (30 km depth). The uppermost mantle shows two zones of reflections, labeled Flannan and W. The Flannan reflections are interpreted as a Caledonian suture that was reactivated as an lithospheric extensional fault (Flack and Warner, 1990). Modified from Matthews DH and BIRPS Core Group (1990) Progress in BIRPS deep seismic reflection profiling around the British Isles. *Tectonophysics* 173: 387–396.

reflectivity patterns are interpreted with complementary seismic velocity and nonseismic crustal parameters (discussed in the succeeding text), inferences regarding the composition and evolution of the crust can be made (Clowes et al., 1987).

The widespread observation of crustal reflectivity suggests that common processes account for its existence. The primary cause of crustal reflectivity is compositional and metamorphic layering within the crust. Regional and global plate stresses act to enhance crustal reflectivity by inducing lower crustal ductile flow that produces subhorizontal lamination. This ductile flow requires elevated temperatures and is therefore more common in the middle crust and lower crust.

1.11.3.2 Passive-Source Data

Techniques to investigate the seismic structure of the crust and uppermost mantle using passive seismic data have seen rapid development in the past two decades (**Table 3**). These developments can be attributed to the increased availability of higher-quality, broadband data from permanent seismic networks and temporary deployments. Passive seismic techniques began with surface-wave studies (Brune and Dorman, 1963; Ewing and Press, 1954) and progressed to seismic tomography (Aki and Lee, 1976; Aki et al., 1976; Nolet, 1987a,b), seismic receiver functions (Langston, 1977; Phinney, 1964; Vinnik, 1977), and most recently seismic ambient noise inversion

(Campillo and Paul, 2003; Shapiro et al., 2005). We discuss each of these in turn.

1.11.3.2.1 Surface waves

An earthquake near the Earth's surface will generate both Rayleigh and Love seismic surface waves. The amplitude of motion for these waves decreases exponentially with depth in the Earth, with longer-wavelength waves being more sensitive to the seismic velocity structure at great depth. This wavelength dependence of seismic velocity gives rise to the dispersion of surface waves and makes them a valuable tool for studying the velocity structure of the crust and mantle lithosphere. The analysis of seismic surface waves for crustal and upper mantle structure has been applied on a global basis and is particularly effective in determining the shear-wave structure (Boschi et al.,

2004; Bruneton et al., 2004; Chimera et al., 2003; Debayle and Lévêque, 1997; Friederich, 2003; Karagianni et al., 2005; Langston et al., 2002; Lebedev and Nolet, 2003; Levshin et al., 2005; Maggi and Priestley, 2005; Okabe et al., 2004; Panza et al., 2003; Pilidou et al., 2004, 2005; Shapiro and Ritzwoller, 2002). Thus, seismic surface waves provide complimentary information to seismic refraction data that often provide information only on the compressional-wave structure of the crust. Surface-wave data can also be used to measure seismic anisotropy within the uppermost mantle (Huang et al., 2004).

1.11.3.2.2 Seismic tomography

Local and distant (teleseismic) earthquake data can be used to determine crustal structure. Local seismic tomography uses earthquake arrivals at a network of seismic stations to determine crustal and upper mantle structure by examining the arrival times of many crisscrossing paths between the earthquakes and the seismometers. This technique, which is similar to medical tomography, has the potential to provide a 3-D picture of the crust and uppermost mantle. Local studies mainly provide information about the upper crust and middle crust (Lei and Zhao, 2005; Mandal et al., 2004; Salah and Zhao, 2003; Thurber, 1993; **Table 3**), whereas regional studies have better resolution within the uppermost mantle, especially for Pn velocity (Al-Lazki et al., 2003, 2004; Bannister et al., 1991; Calvert et al., 2000; Chen et al., 2003; Hearn and Ni, 1994; Hearn et al., 2004; Liang et al., 2004; McNamara et al., 1997; Mele, 1998; Nolet, 1987a,b; Parolai et al., 1997; Ritzwoller et al., 2002a,b; Sandoval et al., 2004; Sandvol et al., 2001, 2008). A second technique uses teleseismic data and generally provides an image that extends to greater depth (100+ km) but lacks high resolution of structure within the crust (Allen et al., 2002; Benoit et al., 2003; Bijwaard et al., 1998; Lippitsch et al., 2003; Liu et al., 2005; Petit et al., 1998). Tomographic studies are also effective at determining upper mantle seismic attenuation (Gung and Romanowicz, 2004).

1.11.3.2.3 Receiver functions

Estimating seismic structure from teleseismic receiver functions is a highly effective method of exploring the crust and upper mantle since it requires only a single broadband seismic station. Crustal layering is determined by the processing of a three-component station using teleseismic arrivals P-waves. The incident P-wave will undergo multiple conversions to S-waves at seismic boundaries within the uppermost mantle and crust. The analysis of these converted waves yields the shear-wave velocity structure beneath the station (Burdick and Langston, 1977; Langston, 1977; Owens et al., 1988; Phinney, 1964; Vinnik, 1977). The method works best with nearly horizontal layers, although forward modeling may be applied in regions with 3-D structure. An informative discussion of the method is given by Cassidy (1992). Numerous local and regional studies have been reported (e.g., Owens and Zandt, 1985; Ramesh et al., 2002), including studies of the crustal thickness in North Africa (Sandvol et al., 1998), Moho depth variation in California (Zhu and Kanamori, 2000), and various upper mantle studies (Kind and Vinnik, 1988; Kind et al., 2002; Yuan et al., 1997).

Recently, the receiver function method has been extended to consider converted, precursory P-waves that arrive just prior to the direct S-wave (Angus et al., 2006; Li et al., 2004). This is known as the S-wave receiver function method. S-wave receiver functions have a lower resolution than P-wave receiver functions due to lower-frequency data involved but are effective at identifying the base of the lithosphere (Li et al., 2004; Yuan and Romanowicz, 2010; Yuan et al., 2006).

1.11.3.2.4 Ambient noise analysis

Passive seismic methods that rely on distant earthquake sources have the disadvantage of lacking high-frequency seismic information that is lost because of intrinsic attenuation and scattering during wave propagation. An alternative approach uses ambient seismic noise to recover surface-wave dispersion data by cross correlating a random isotropic wavefield between a pair of receivers (Campillo and Paul, 2003; Shapiro and Campillo, 2004). This method can obtain approximate Green's functions of Rayleigh waves propagating between a pair of stations at relatively short periods (e.g., 5–20 s), and the dispersion curves may be inverted for S-wave crustal structure. This method is advantageous for data from temporary seismic networks because it does not rely on the recording of teleseismic events, which may not occur during the operation of the temporary network. The method has seen widespread application (e.g., Shapiro et al., 2005; Ward et al., 2013).

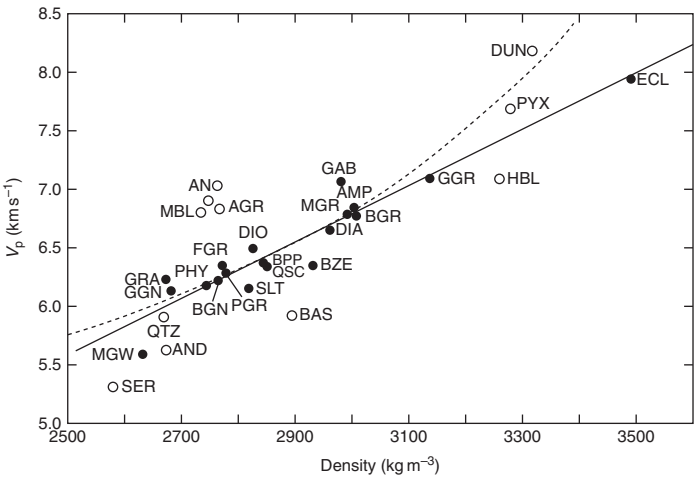
1.11.3.3 Laboratory Studies

1.11.3.3.1 Velocity–density relations

Seismic wave velocities and density are fundamental properties of Earth materials. Thousands of field and laboratory measurements have been made for V_p, but fewer measurements have been made of rock densities at depth, since these require a borehole. Compressional-wave velocity and density correlations are important because they allow estimates of crustal density for surface-wave inversions and gravity studies, and conversely, rock densities can be used to estimate seismic velocities (Christensen and Mooney, 1995). Classic studies of velocity–density relations include the Nafe–Drake curve (Nafe and Drake, 1957); Birch's (1961) law relating velocity, density, and mean atomic weight; and linear regression solutions for oceanic crust (Christensen and Salisbury, 1975). **Figure 7** presents average velocities for 29 rock categories at a depth of 20 km and a temperature of 309 °C, corresponding to an average geotherm, versus rock density (Christensen and Mooney, 1995). Two curves are drawn in **Figure 7**, a linear curve (solid line) and a nonlinear curve. The appropriate coefficients for both linear and nonlinear solutions are presented by Christensen and Mooney (1995).

1.11.3.3.2 V_p–V_s relations and Poisson's ratio

Seismic measurements of crustal structure more commonly report only V_p rather than V_p and V_s. There are several reasons for this. First, explosive or air gun sources generate primarily compressional-wave energy. Second, many field observations record on the vertical component of ground velocity. Third, shear-wave arrivals are often either weak or obscured by scattered seismic energy (coda). In the absence of measured



Abbreviation	Rock type

AGR, anorthositic granulite; AMP, amphibolite; AND, andesite; BAS, basalt; BGN, biotite (tonalite) gneiss; BGR, greenschist facies basalt; BPP, prehnite–pumpellyite facies basalt; BZE, zeolite facies basalt; DIA, diabase; DIO, dionite; DUN, dunite; ECL, mafic eclogite; FGR, felsic granulite; GAB, gabbro–norite–troctolite; GGN, granite gneiss; GGR, mafic garnet granulite; GRA, granite–granodiorite; HBL, hornblendite; MBL, calcite marble; MGR, mafic granulite; MGW, metagraywacke; PGR, paragranulite; PHY, phyllite; PYX, pyroxenite; QCC, mica quartz schist; QTZ, quartzite; SER, serpentinite; SLT, slate. Reproduced from Christensen NI and Mooney WD (1995) Seismic velocity structure and the composition of the continental crust: a global view. *Journal of Geophysical Research* 100: 9761–9788.

shear-wave speeds, it is necessary to estimate its value from V_p. A direct relation between V_s and V_p, therefore, is highly desirable for many studies. This is accomplished by using empirically derived V_p–V_s relations that are based on field borehole and seismic profiling data together with laboratory measurements. A recent study (Brocher, 2005) has derived empirical relations between V_p, V_s, and Poisson's ratio that can be used to estimate the ratio V_p–V_s or, equivalently, Poisson's ratio from a knowledge of V_p and rock type (i.e., sedimentary vs. crystalline rock). The empirical and regressional fits are only defined for V_p between 1.5 and 8.5 km s and fit the data remarkably well (Figure 8).

Conversely, the mineralogy of the crust can be estimated when both compressional-wave (V_p) and shear-wave (V_s) velocities are measured (Figures 8 and 9). The relation between V_p and V_s is commonly expressed by Poisson's ratio, which varies from 0.23 to 0.32 for most minerals, but quartz has a value of only 0.08 at room conditions (Christensen, 1996). Thus, the measurement of Poisson's ratio offers the means of distinguishing between felsic (quartz-rich) and mafic (quartz-poor) rocks.

1.11.3.3.3 Seismic anisotropy

Many minerals exhibit birefringence, which is a directional dependence of the speed of light through the mineral. This phenomenon is used by petrologists to identify minerals in a thin section ($\leq$1 mm) where a sample illuminated by polarized light is rotated under a microscope to reveal its birefringence. Likewise, elastic waves show a directional dependence in wave speed in many minerals. Perhaps, the most prominent example is the mineral olivine, which is a major constituent of the upper mantle. The discrepancy between Rayleigh and Love wave speeds was measured in the early 1960s (Anderson, 1961) and led to the recognition of seismic anisotropy in the mantle lid. At about the same time, laboratory measurements of metamorphic rocks demonstrated significant shear-wave anisotropy in the crust (Christensen, 1966b). These measurements demonstrated that seismic anisotropy is not only confined to the upper mantle but also plays a prominent role in the crust (Figure 10). Table 4 lists several key papers on the seismic properties, particularly anisotropy, of the uppermost mantle. Additional references for laboratory studies of the seismic properties of continental rocks can be found in Table 5.

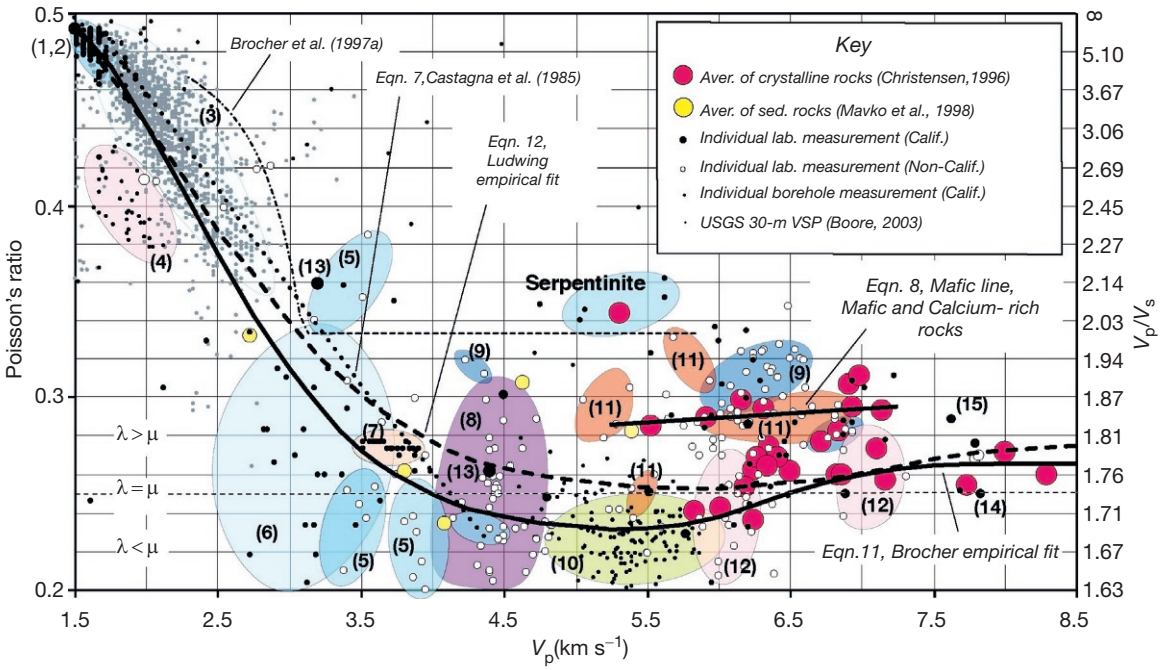

Figure 8 Poisson's ratio as a function of V_p for common lithologies. Colored ellipses highlight measurements reported by a single reference: bold numbers in parentheses link ellipses to similar studies. The thinner horizontal dashed line shows Poisson's ratio of 0.25 ($V_p/V_s = 1.73$) commonly assumed for the crust when the first Lame constant, λ, equals the shear modulus, μ. Reproduced from Brocher TM (2005) Empirical relations between elastic wavespeeds and density in the Earth's crust. *Bulletin of the Seismological Society of America*, 95 (6): 2081–2092.

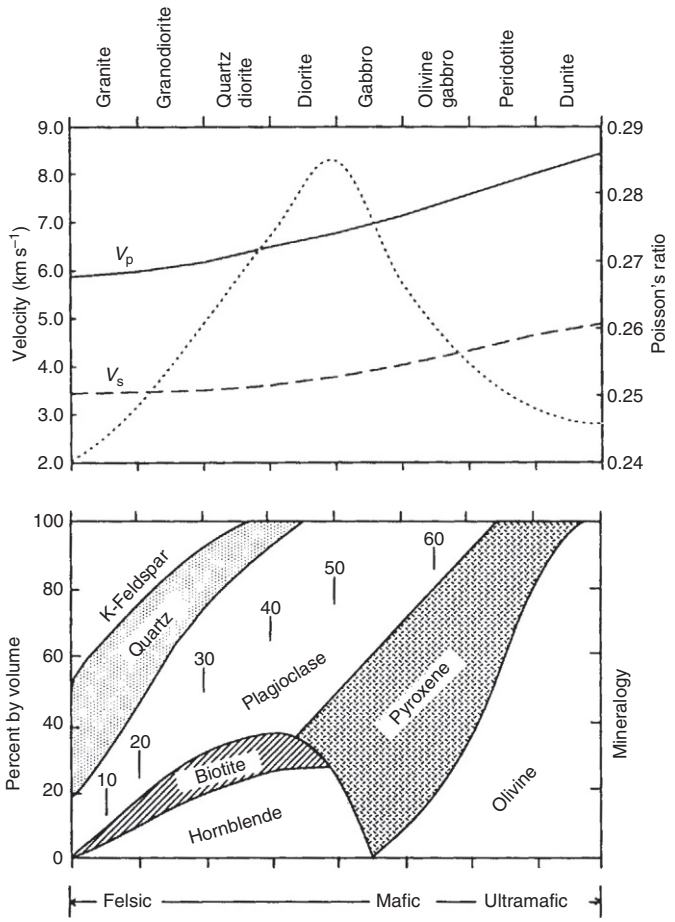

Figure 9 Variations in compressional-wave velocity (V_p), shear-wave velocity (V_s), and Poisson's ratio (σ) with mineral composition (Berry and Mason, 1959) for common igneous rock types. Anorthite content of plagioclase feldspar is shown within the plagioclase field. Reproduced from Christensen NI (1996) Poisson's ratio and crustal seismology. *Journal of Geophysical Research* 100: 3139–3156.

Reproduced from Christensen NI and Mooney WD (1995) Seismic velocity structure and the composition of the continental crust: A global view. *Journal of Geophysical Research* 100, 9761–9788.

1.11.4 Nonseismic Constraints on Crustal Structure

All rock types have a variety of distinct, albeit nonunique, physical properties that include density, magnetic susceptibility, and conductivity. Geophysical surveying techniques to measure these properties are highly developed, and it is possible to make detailed maps of lateral changes in rock magnetic properties and conductivity and to estimate density variations. Advanced digital processing of such data enhances the reliably of interpretations, although resolution typically decreases with depth. Such nonseismic geophysical studies are widely used and have the capability to distinguish between competing geologic models of the structure of the crust. Key papers on laboratory studies of nonseismic properties of rocks are provided in Table 6.

1.11.4.1 Gravity

Gravity anomalies reveal rock density variations, with the amplitude of the anomaly proportional to the density contrast and thickness of the anomalous body. Short-wavelength (<250 km) gravity anomalies are usually correlated with crustal structures, while long-wavelength (<1000 km) gravity anomalies are correlated with lateral variations of mantle densities. Kane and Godson (1989) demonstrated that long-wavelength gravity highs are correlated with high mantle seismic velocities and gravity lows with low mantle velocities. Kaban et al. (2003) showed that upper mantle density variations contribute long-wavelength gravity anomalies ranging from −250 mGal to +150 mGal. The largest of these positive anomalies over the continents were associated with the Andes, the East European Platform, the Alpine–Mediterranean fold belt, and the central southeastern part of North America. The largest negative anomalies, indicating a thin lithosphere, are associated with vast Cenozoic regions of plume–lithosphere interaction: the East African Rift and the Basin and Range Province of the western North America.

New satellite measurements of the Earth's gravity field were begun in April 2002. The data from the Gravity Recovery and Climate Experiment satellites yield a complete measurement of the gravity field to harmonic degree 160 (300 km spatial resolution at the Earth's surface) every 30 days. These observations have improved the precision of the global gravity field by two orders of magnitude (Tapley et al., 2005).

The interpretation of gravity data is nonunique because measured gravity integrates the 3-D distribution of mass around the measurement location. For this reason, it is essential that, when modeling gravity data in terms of crustal structure, additional constraints be used. The most useful constraints come from coincident seismic data that define the seismic structure of the crust. The seismic model is converted into a density model using well-established relations (e.g., Christensen and Mooney, 1995), and the final model is

1.11.4.2 Aeromagnetics

High-resolution aeromagnetic surveys can be used to define major regions of coherent structure in the Earth's crust (Kane and Godson, 1989). Since rocks commonly retain magnetism that originates from the time of their formation, magnetic anomaly data provide a unique opportunity to infer geologic processes not readily observed through other geophysical quantities. One common example of this is seafloor spreading, indicated by a series of magnetic stripes, originating from the mid-ocean ridge.

Magnetization is commonly associated with igneous rocks, but it is controlled more generally by the thermal history of the rock. The remnant magnetization of a mineral is fixed in the direction of the Earth's magnetic field when the mineral is cooled below the Curie temperature; the remnant magnetization is removed when heated above this temperature. Metamorphism can also change the magnetization of a rock, but the magnitude of the effect is usually small. So, in contrast to density, rock magnetization can range through several orders of magnitude (Kane and Godson, 1989).

Long-wavelength gravity and magnetic data are available from space-based observations (McEnroe et al., 2004; Purucker et al., 2002). The CHAMP (CHAllenging Minisatellite Payload) mission is a small German satellite designed for geoscientific and atmospheric research and applications. CHAMP will generate highly precise gravity and magnetic measurements of the Earth over a 5-year period in an attempt to create a highly precise gravity field of the Earth, in order to appropriately constrain seismic velocity models (Hemant and Maus, 2005). For additional references on magnetic studies of the crust, see Table 8.

1.11.4.3 Geoelectrical Measurements

In general, the conductivity of the Earth is correlated with salinity, composition, and temperature (Jones, 1992; Keller, 1989a). At the surface, electrical conductivity depends on the amount of salinity of the groundwater in a rock. At intermediate depths, conductivity depends on water content and composition (particularly graphite and sulfide content). At great

depths, where temperatures rise to at least 500 °C, conductivity is mainly a function of electron and ion mobility (Keller, 1989a).

Most studies of the Earth's crust are based on magnetotelluric (MT) data (Keller, 1989b). This method relies on measurements of five separate components of the time-varying electromagnetic field at the surface of the Earth. The analysis of these time series yields 1-D and 2-D models of the subsurface conductivity structure. When measurements are made for long periods (10 000 s and longer), estimates of the conductivity of the crust and upper mantle to a depth of 200 km and greater are possible (Jones, 1999). The source for electrically conductive material may be seen as high-density blocks within the crust.

Electrical conductivity profiles of the crust may be divided into marine and continental studies. Major marine studies include the RAMESSES marine experiment over the Reykjanes Ridge (MacGregor et al., 1998; Sinha et al., 1998), the PEGASUS (Pressure, Electromagnetic, Gravity, Active Source Underwater Survey) experiment in the northeast Pacific Ocean (Constable and Cox, 1996), and electromagnetic studies of the axial zone of the northern East Pacific Rise (Evans et al., 1999). On continents, electrical conductivity structure of stable regions, sutures and paleosubduction zones, regions of lithospheric extension, and orogens have all been investigated (Jones, 1992; Jones et al., 2001; Wannamaker et al., 1989). In most cases, these studies have been conducted in conjunction with active- and passive-source seismic profiles. Notable results include the correlation between low shear-wave velocity and high electrical conductivity beneath the southern Tibetan Plateau. This correlation has been attributed to the presence of either partial melts or aqueous fluids in the middle crust (Li et al., 2003; Nelson et al., 1996). Thus, electrical studies provide an important additional constraint on the composition and physical state of the crust and upper mantle. For additional references on geoelectrical studies of the crust, see **Table 9**.

1.11.4.4 Heat Flow Data

Surface heat flow data provide valuable information on temperatures within the crust. The highest heat flow values are found at mid-ocean ridges and within geothermal zones and active volcanoes. Heat flow has been measured on a global basis within oceans, continents, and their margins (Pollack et al., 1993). Surficial heat flow is the product of radiogenic heat production in the crust and heat transferred from the convecting mantle. In order for a lithospheric geotherm to be reliably calculated, crustal heat production and thermal conductivity must be estimated from laboratory measurements on typical crust rocks (Artemieva, 2011; Artemieva and Mooney, 2001; Cermak, 1993; Champman, 1986; Jaupart and Mareschal, 1999, 2011; Pollack and Chapman, 1977). Crustal geotherms can be subdivided into hot, normal, and cold geotherms. Within continental crust, these three geotherms predict temperatures at a depth of 40 km (Moho) of about 500°, 700°, and 90 °C, respectively. Thermal studies of the crust have provided valuable constraints on crustal composition and evolution (Jaupart and Mareschal, 2011; Mareschal et al., 1999; Rudnick and Fountain, 1995). For additional references on heat flow studies, see **Table 10**.

1.11.4.5 Borehole Data

Deep scientific boreholes provide exceptional data regarding the physical properties of the upper crust. The deepest boreholes are the 12 km Kola Superdeep Borehole (KSDB) in Russia (Kozlovsky, 1987), the 9.1 km Kontinentales Tiefbohrprogramm (KTB) in Germany (Emmernmann and Lauterjung, 1997), and the 6.8 km and 6.5 km Gravberg–Stenberg boreholes in Sweden (Juhlin, 1988; Papasikas and Juhlin, 1977). In addition, there are numerous scientific foreholes to depths of 3–5 km. These boreholes provide direct sampling of the composition of the upper crust, as well as measurements of *in situ* seismic velocities, density, temperature, state of stress, rock porosity, and the fluid pressure (Kern et al., 2001; Smithson et al., 2000). Evidence has also been obtained for crustal shear zones containing electrically conductive graphite and sulfides. An unexpected result is the presence of free fluid throughout the entire depth range of the KSDB and KTB boreholes.

1.11.4.6 Surface Geology, Exposed Deep Crustal Sections, Xenoliths, and Geochemical Data

Surface geology, exposed deep crustal sections, xenolith samples, and geochemical data all provide direct observations of the

composition and physical properties of the crust. The composition of the upper continental crust is, by definition, evident in global geologic maps, which are dominated by felsic intrusive rocks and low-grade metamorphic rocks, particularly shales and sandstones (Clarke, 1889; Clarke and Washinton, 1924; Taylor and McLennan, 1992). The recognition that mountain belts provided exposures of the deep crust can be traced to the work of Elie de Beaumont (1847) who studied the Pyrenees. It was, however, many years later that these observations were systematically analyzed in terms of cross sections of the entire crust (Fountain and Salisbury, 1981; Percival et al., 1992; Salisbury and Fountain, 1990). Xenoliths are samples from the deep crust (and mantle lithosphere) that have been carried to the surface by volcanic activity (Kay and Kay, 1981; Yanaqi, 2011). These samples provide excellent constraints on lower crustal composition (Fountain et al., 1992; Mahan et al., 2012; Rudnick and Gao, 2005; Yanaqi, 2011). Geochemical analysis of xenolith samples provides critical data on crustal composition (Condie, 2011; Rudnick and Gao, 2005; Taylor and McLennan, 2009).

1.11.5 Structure of Oceanic Crust and Continental Margins

Several thousand measurements of the deep seismic structure of the Earth's crust have been made. However, the geographic distribution of seismic measurements is uneven (**Figure 11**), with more results available for the Northern Hemisphere and a concentration of data in North America, western Europe, and Eurasia. In the Southern Hemisphere, Australia and New Zealand have abundant data. Oceanic data are widely available for all oceans. Here, we summarize the principal results obtained by these seismic data and then present a global model for the Earth's crust.

1.11.5.1 Typical Oceanic Crust

The seismic velocity structure of oceanic crust was first established in the 1950s, before the discovery of plate tectonics and seafloor spreading. Oceanic crust was found to be uniformly thinner than continental crust. Much of the knowledge of the structure of ocean crust has come from seismic refraction/wide-angle reflection profiles. These seismic profiles use air gun or explosive sources that are recorded by either hydrophones or ocean-bottom seismometers. Passive seismology has limited application since most receivers are on continents or islands. However, a few tomographic studies of crustal structure at mid-ocean ridges have been completed (Dunn et al., 2000; Wolfe et al., 1995).

In their pioneering studies, Hill (1957) and Raitt (1963) divided 'normal' oceanic crust into separate, uniform seismic layers, known as 'Raitt–Hill layering.' The basic construction was a 2–3 km thick upper layer (layer 2) with a velocity of 2.5–6.4 km s^{-1}, underlain by a 3–5 km thick lower layer (layer 3), with a velocity of 6.5–7.3 km s^{-1}. The total thickness of ocean crust was determined to be 6–7 km. Layer 2 consists largely of pillow lavas and dikes, while layer 3 consists of a 'sheeted' dike complex underlain by diorites and gabbros (**Figure 12**). More details regarding the structure of the crust have been obtained using modern analysis methods. The application of synthetic seismogram modeling to marine seismic refraction/wide-angle reflection data indicates that the transition from layer 1 to layer 2 is often transitional, while the transition from layer 2 to layer 3 is relatively sharp (Spudich and Orcutt, 1980).

In the late 1970s, it was proposed that layer 2 could be further subdivided into three layers: 2A, 2B, and 2C. According to Ewing and Houtz (1979), two distinct layers with seismic velocities of about 3.5 km s^{-1} (layer 2A) and 5.2 km s^{-1} (layer 2B) were consistently identified. Below layer 2B, but above layer 3, a third layer with a seismic velocity of 6.0–6.2 km s^{-1} (layer 2C) was detected. Orcutt et al. (1976) and White et al.

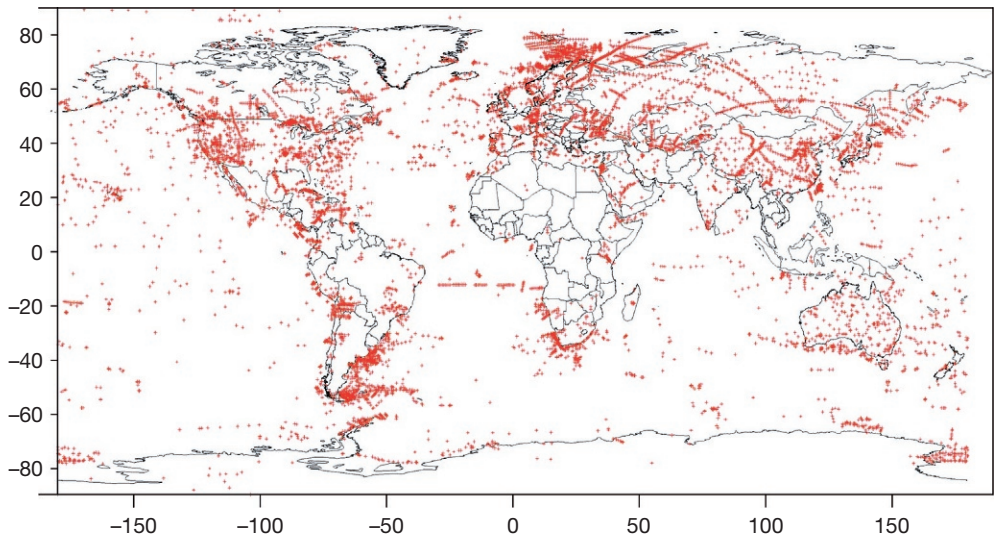

Figure 11 Locations (solid triangles) of individual seismic velocity–depth measurements made within the Earth's crust, 1920–present. Up to 1980, the majority of these measurements were made using the seismic refraction/wide-angle reflection technique. Since 1980, a great many determinations have been made using receiver function analysis of teleseismic arrivals and local earthquake tomography (see text).

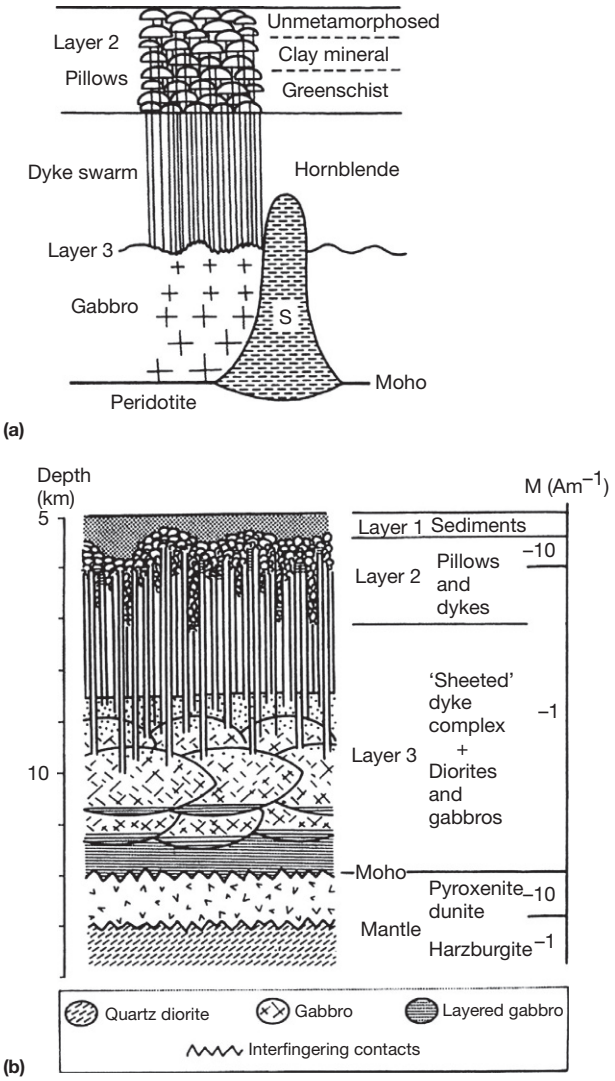

Figure 12 Compositional models of the oceanic crust derived from seismic measurements and exposed crustal sections: (a) after Cann (1970) and (b) after Vine and Moores (1972). Traditionally, the oceanic crust is described as being composed of three layers, termed seismic layers 1–3. According to model (b), layer 1 is sediments; layer 2 is made up of basaltic pillow lavas and their feeder dikes, unmetamorphosed in their upper parts; layer 3 is composed of sheeted dikes underlain by massive plutonic diorites and gabbros. Seismic velocities within these layers are shown in **Figure 13(b)**.

(1992) reviewed previous work and provided a modern synthesis of the seismic structure of typical oceanic crust. Layer 1 lies beneath an average 4.5 km of seawater and is composed of sediments (pelagic sediments, silts, muds, and sand) and is approximately 0.5 km thick, with a seismic velocity of 1.5–2.0 km s^{-1}, increasing with depth as the sediments consolidate. Layer 2A–C, the volcanic layer, is 2.11 ± 0.55 km thick, with a seismic velocity of 2.5–6.6 km s^{-1}. Layer 3, sometimes called the oceanic layer, is 4.97 ± 0.90 km thick, with a seismic velocity of 6.6–7.6 km s^{-1}. The upper mantle has an average seismic velocity of 7.9–8.1 km s^{-1}. See **Table 11** for additional references on oceanic crust studies. **Table 12** lists selected papers on the composition of oceanic crust.

1.11.5.2 Mid-Ocean Ridges

The concept of seafloor spreading from mid-ocean ridges (**Figure 2**) was first proposed in the early 1960s by several workers, including most prominently the American geologist Harry H. Hess (Hess, 1965). Its major tenets gave great support to the theory of continental drift and provided a conceptual base for the development of plate tectonics.

Mid-ocean ridges can be separated into three categories: fast spreading, intermediate spreading, and slow spreading. Fast-spreading ridges have a spreading rate of 8–16 cm year^{-1}, with eruptions of 1–5 million m^3 of magma occurring every 5 years. Meanwhile, intermediate-spreading ridges have a spreading rate of 4–8 cm year^{-1}, with 5–50 million m^3 of magma erupting every 500 years. Slow-spreading ridges erupt 50–1000 m^3 of magma every 5000 years, yielding a spreading rate of 1–4 cm year^{-1} (Perfit and Chadwick, 1998).

The seismic structure of a fast-spreading ridge shows that the intrusive zone is only 2–3 km wide, and normal oceanic crust is found 5–6 km away from the ridge axis (**Figure 13**). Directly beneath the ridge axis, an upper crustal low-velocity zone exists that corresponds to a zone of partial melting. This seismic structure is in contrast to the earlier hypothesis that anomalous oceanic crust extends for tens of kilometers away from the axis of a mid-ocean ridge. The seismic structure of the fast-spreading East Pacific Rise has also been examined using seismic P-wave tomography (Dunn et al., 2000). The spreading ridge is characterized by a seismic low-velocity volume that is 5–7 km wide within the crust and three times broader (c. 18 km) in the mantle. Magma accumulates at two levels: at a shallow crustal depth (the top of the magmatic system) and at the Moho transition zone (Dunn et al., 2000). Measurements of seismic anisotropy within the shallow mantle beneath the ridge indicate a mismatch between the locus of mantle melt delivery and the morphological ridge axis. The geometry of this mismatch governs the segmentation of the ridge and controls the intensity of ridge crest processes (Toomey et al., 2007).

1.11.5.3 Oceanic Plateaus and Volcanic Provinces

Oceanic plateaus are one type of the large igneous provinces that cover portions of the oceans and continents (i.e., flood basalt provinces; Coffin and Eldholm, 1994; Ernst and Buchan, 2003). While continental flood basalt provinces were recognized in the early twentieth century (Holmes, 1918), regions of unusually thick oceanic crust were not identified until the 1970s. Edgar et al. (1971) originally discovered an overthickened region within the Caribbean plate, and when a number of similar features were documented, they were called 'oceanic flood basalt provinces' (Donnelly, 1973; **Figure 14**). The term 'ocean plateau' was suggested by Kroenke (1974) when the Ontong Java Plateau (OJP) in the western Pacific was explored using seismic refraction/wide-angle reflection profiles. More than a dozen oceanic plateaus have been identified (**Figure 14**), and these have anomalous crustal structure in comparison with normal oceanic crust.

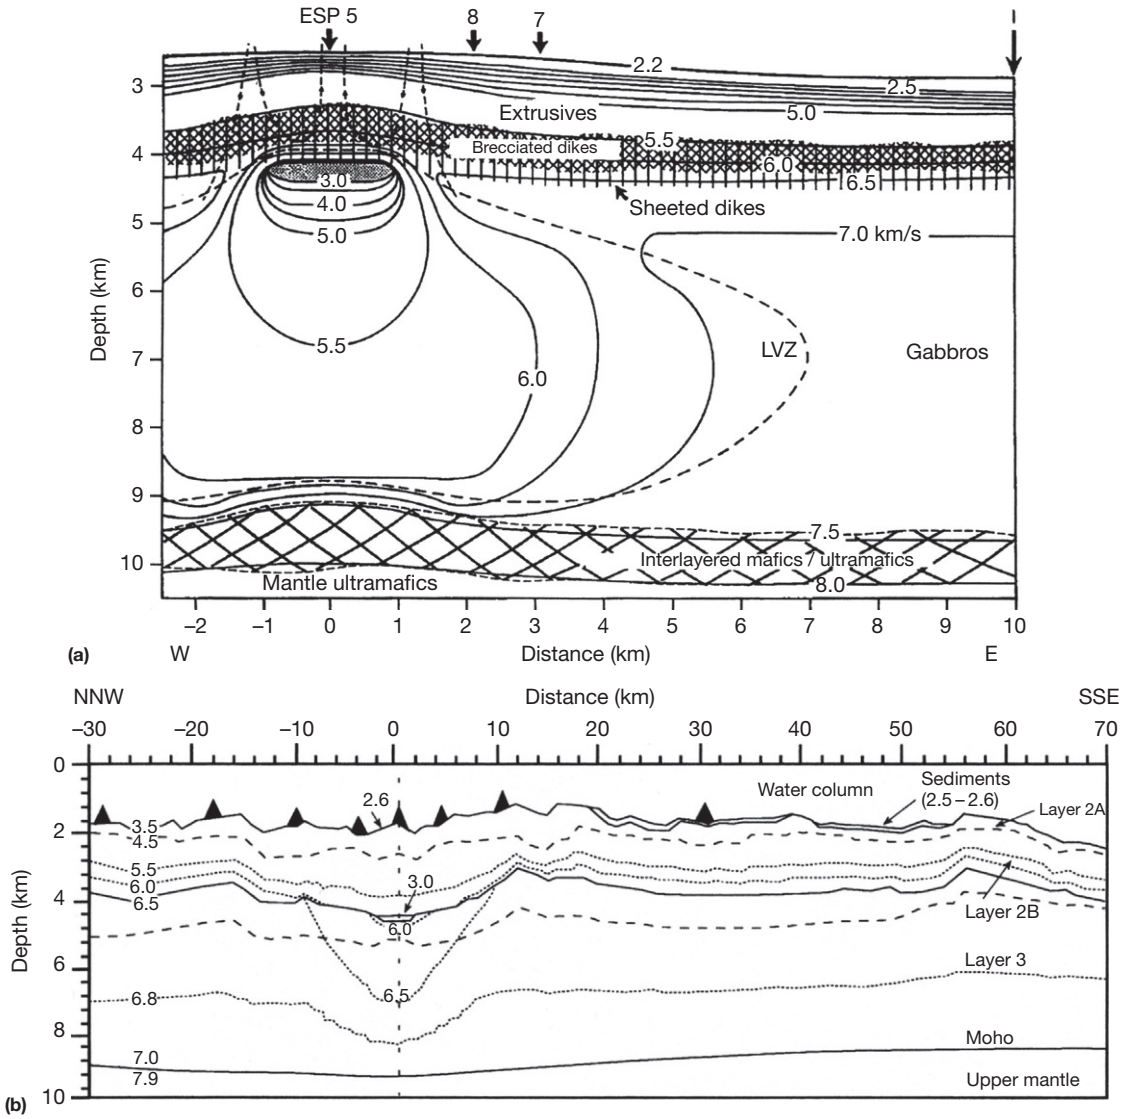

Figure 13 Top panel (a): P-wave velocity model and interpretation, based on expanding spread profile and multichannel reflection data, of the fast-spreading East Pacific Rise axis at 9°N. Arrows mark ESP locations. (b) P-wave velocity model and interpretation, based on OBS and seismic reflection data, of the slow-spreading Reykjanes Ridge axis at 57°45′N. Triangles mark OBS locations and dashed lines mark changes in velocity gradient. (a) Redrawn from Vera EE, Mutter JC, Buhl P, et al. (1990) The structure of 0–0.2-m.y.-old oceanic crust at 9°N on the East Pacific Rise from expanded spread profiles. *Journal of Geophysical Research* 95: 15529–15556. (b) Redrawn from Navin D, Peirce C, and Sinha MC (1998) The RAMESSES experiment-II. Evidence for accumulated melt beneath a slow spreading ridge from wide-angle refraction and multichannel reflection seismic profiles. *Geophysical Journal International* 135: 746–772; Minshull TA (2002) Seismic structure of the oceanic crust and rifted continental margins. In: Lee WHK, Kanamori H, and Jennings PC (eds.) International Geophysics Series 81 A: International Handbook of Earthquake an Engineering Seismology, pp. 911–924. San Diego, CA: Academic Press.

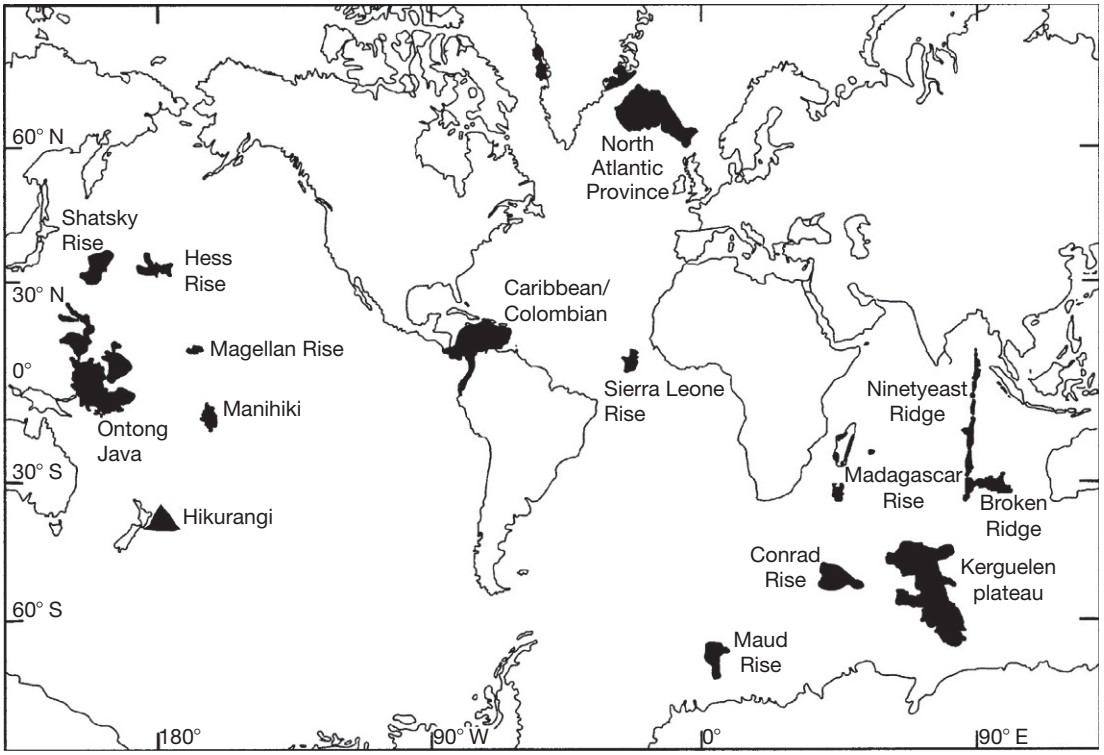
The crustal structure of several ocean plateaus has been resolved using seismic and gravity data, including recent studies on the Kerguelen and OJP. Farnetani et al. (1996) and Gladczenko et al. (1997) presented models for the OJP that show high seismic velocities (7.1 km s^{-1}) throughout most of the crust. These high velocities are likely due to the presence of basalt and olivine–pyroxene cumulates, with high-velocity garnet granulite in the lower crust. Gladczenko et al. (1997) suggested that these garnets may have formed from the deformation and hydrothermal alteration of lower crustal cumulates.

More recently, measurements of upper mantle shear-wave splitting and shear-wave velocity have suggested the presence of a 300 km thick, long-lived, rheologically strong, and chemically depleted root beneath the OJP (Klosko et al., 2001). Further proposed that this chemically depleted root originated from mantle melting processes, which would contribute lower-density material to the base of the plateau, increasing the overall buoyancy of OJP.

At the present time, the process of ocean plateau formation is not well understood. There are a number of models for how



Oceanic plateau	Mean age (Ma)	Area (10^6 km^2)	Thickness range (km)	Volume (10^6 km^3)
Hikurangi	Early-mid Cretaceous	0.7	10–15	2.7

Caribbean	88	1.1	8–20	4.4
South Kerguelen	110	1.0	~22	6.0
Central Kerguelen/ Broken ridge	86	1.0	19–21	9.1
Sierra Leone rise	~73	0.9	>10	2.5
Maud rise	~>73	0.2	>10	1.2

Figure 14 Map showing all major oceanic plateaus and other large igneous provinces discussed in the text (after Saunders et al., 1992; Eldholm and Coffin, 2000). These plateaus have measured crustal thicknesses of 10–32 km and an average thickness (22 km) that is twice that of typical oceanic crust.

large volumes of mafic magmas are generated and emplaced by processes unrelated to 'normal' seafloor spreading and subduction (Campbell et al., 1989; Farnetani and Richards, 1995; Griffiths and Campbell, 1990; Loper, 1983; McKenzie and Bickle, 1988), but it is not understood why these eruptions occur in such a rapid, concentrated period of time. Most ocean plateaus were formed in a short time, less than 2–3 Myr (Coffin and Eldholm, 1994), which may raise important questions about mantle processes and source regions (Hart et al., 1992; Stein and Hoffman, 1994). During the most recent phase of Large Igneous Province (LIP) formation, in the mid-Cretaceous, the Ontong Java, Manihiki, Hess Rise, and Caribbean–Colombian plateaus were formed in the Pacific, while the Kerguelen Plateau formed in the Indian Ocean (Kerr, 2003).

If the plateaus are accreted adjacent to continental margins or island arcs, they may eventually significantly contribute to the growth of existing and new continents (Abbott, 1996; Albarede, 1998). Due to their increased thickness relative to normal oceanic crust, plateaus are especially buoyant, preventing them from completely subducting at active margins (Ben-Avraham et al., 1981; Cloos, 1993; Kimura and Ludden, 1995) and allowing the top layers to be 'peeled off' and merge with the continental crust (Kimura and Ludden, 1995).

Ideas about hot spots and mantle plumes have been around for more than 40 years (Wilson, 1963), but the deep structure of these features remains controversial. Currently, there are two different models for the crust and upper mantle beneath Iceland, one of the two most prominent hot spots on the planet (the other being the Big Island of Hawaii). The 'thin-crust model' is based on MT data, heat flow from shallow wells, petrogenetic models, and seismic data. It suggests a ~10–15 km thick crust under the main rifting axis of Iceland, with

a 25 km thick, older crust in eastern, western, and north-central regions of the island. There is also a thin, highly conductive, molten basaltic layer. The 'thick-crust' model is based entirely on seismic receiver function data and suggests a Moho depth of 35–40 km (Du and Foulger, 2001; Foulger et al., 2003). Much of the ambiguity regarding the crustal thickness can be attributed to the presence of melt in the lower crust and the absence of a sharp seismic discontinuity at the base of the crust. Figure 15 is a schematic cross section across the center of Iceland compiling all available seismic, MT, heat flow, and viscosity data (Bjőrnsson et al., 2005). A unique and prominent feature beneath this hot spot is the continuous good conductor above the underlying asthenosphere. Bjőrnsson et al. (2005) suggested that a 20–40 km deep discontinuous reflector does not necessarily represent the Moho; these authors instead support the 'thin-crust' model. Further data are needed to resolve this controversy.

1.11.5.4 Ocean Trenches and Subduction Zones

Geophysical studies of oceanic trenches can be traced to gravity measurements made by Vening Meinesz (1887–1966) in the Indonesian archipelago. These negative gravity anomalies were interpreted by Vening Meinesz (1948) as being due to pronounced downbuckling of the oceanic crust. The detailed structure of oceanic trenches was clarified from marine seismic profiles that were made 30 years after Vening Meinesz's pioneering gravity measurements. One of the best studied trenches is the Nankai Trough, eastern Japan. Two crustal models derived from seismic refraction/wide-angle reflection and gravity data collected across the Nankai Trough (Figure 16) show the geometry of the subducting oceanic crust as it descends beneath the Japan volcanic arc (Figure 16). These models define the geometry of the thick sedimentary basins that are located between the Nankai Trough and continental Japan. These results are typical of many subduction zones, including the Cascades region of western North America. Due to the pronounced lateral variations across oceanic trenches and subduction zones, studies that combine multiple seismic and nonseismic data have been the most successful at determining the deep structure (Wannamaker et al., 1989).

1.11.5.5 Oceanic Island Arcs

Oceanic island arcs are created at ocean–ocean subduction systems. Examples include the Aleutian Arc, the Scotia Arc, and the numerous island arcs of the southwest Pacific Ocean. They are distinguished from continental magmatic arcs, such as the Andes of western South America, that are the product of ocean–continental subduction. Oceanic island arcs are commonly identified as accreted terrains within continental crust (McLennan and Taylor, 1982) and have attracted widespread interest among Earth scientists.

The deep crustal structure of several island arcs has been investigated using controlled source seismology (Calvert, 2011). Prominent study areas include the Aleutian Arc (Holbrook et al., 1999; Shillington et al., 2004), the Izu–Bonin arc (Kodaira et al., 2007), the northern Izu arc (Suyehiro et al., 1996), and the Mariana arc (Takahashi et al., 2007, 2009). Measured P-wave seismic velocities beneath arcs are generally higher than found at the same depths beneath continents: beneath the Aleutians, midcrustal velocities of 6.5–7.3 km over depths of 10–20 km indicate andesitic to basaltic compositions, while lower crustal P-wave seismic velocities of 7.3–7.7 km s^{-1} over a depth range of 20–35 km indicate mafic–ultramafic cumulates and/or garnet granulites (Schillington et al., 2004). A seismic profile across the Izu–Ogasawara arc (Figure 17) also shows high lower crustal

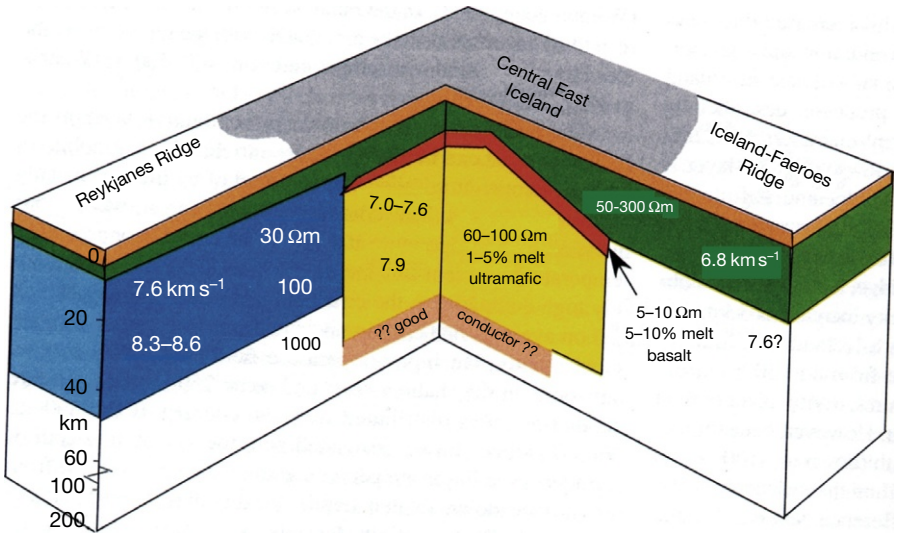

Figure 15 Simplified cross section showing the main structural features of the Icelandic crust and mantle. The left part of the figure shows a profile parallel to the Reykjanes Ridge and east of the ridge approximately along the Reykjanes Ridge Iceland Seismic Experiment seismic profile. The right part of the figure shows a profile running from central Iceland into the Iceland–Faroe Ridge. Numbers are P-wave velocities (normal type) and resistivities (italic type). Reproduced from Björnsson A, Eysteinsson H, and Beblo M (2005) Crustal formation and magma genesis beneath Iceland; Magnetotelluric constraints. In: Foulger GR, Natland JH, Presnall DC, Anderson DL (eds.) *Geological Society of America*, *Special Paper 388 Plates*, *Plumes*, *and Paradigms*, 665–686. Boulder, CO: Geological Society of America.

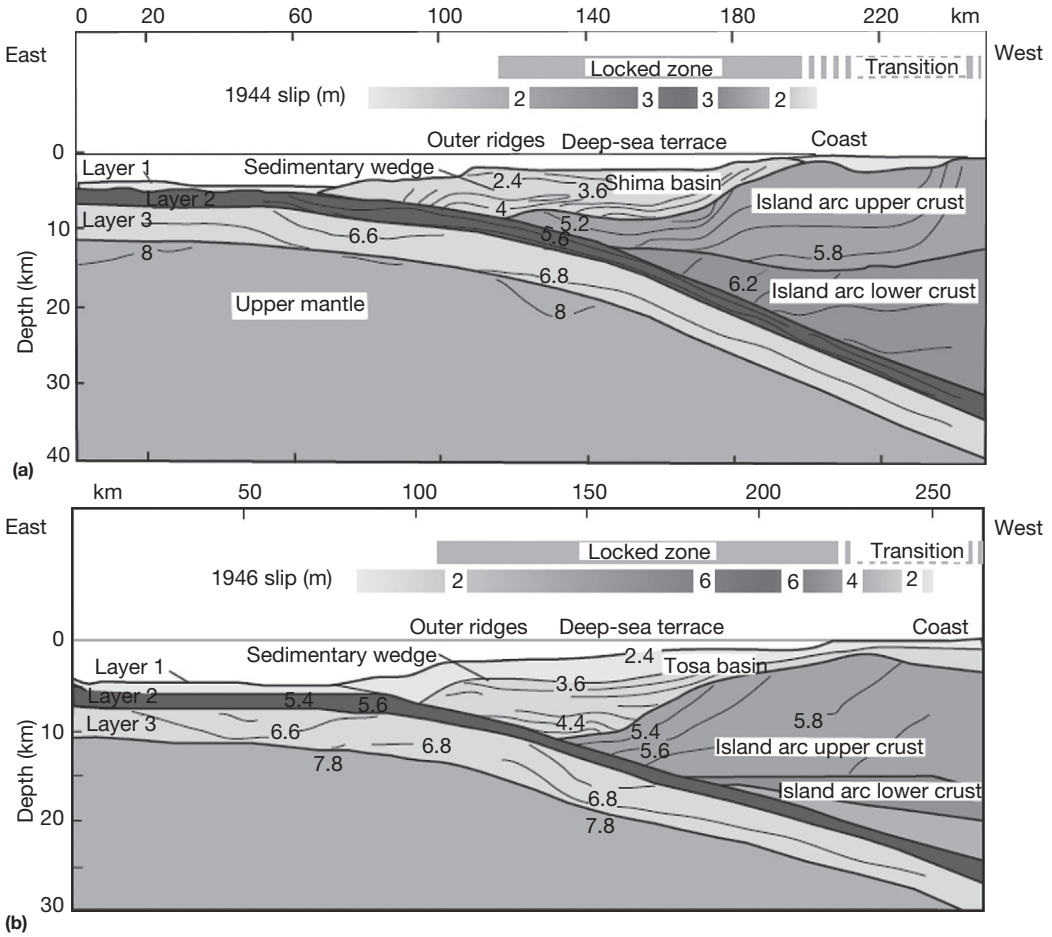

Figure 16 Seismic velocity structure of (a) the Tonanki subduction zone, site of the 1944 earthquake, and (b) the Nankai subduction zone, site of the 1946 earthquake. The relationship between the crustal structure and the locked zone is indicated (Hyndman et al., 1995; Sagiya and Thatcher, 1999; Kodaira et al., 2000; Nakanishi et al., 2002). The crustal structure is typical of many subduction zone complexes and includes a prominent low-seismic velocity sedimentary wedge and the higher-velocity igneous crust of the island arc. After Wells RE, Blakely RJ, Sugiyama Y, Scholl DW and Dinterman PA (2003) Basincentered asperities in great subduction aone earthquakes: A link between slip, subsidence, and subduction erosion? *Journal of Geophysical Research 108 (B10)*: 2507 (http://dx.doi.org/10.1029/2002JB002072).

velocities of 6.8–7.4 km s^{-1} (Takahashi et al., 2009). Such high seismic velocities are inconsistent with the concept that continental crust can be created simply by accreting island arcs. Instead, the lower crust of the arc is likely to be subducted and the middle crust remelted to form felsic melts that rise to form the juvenile continental crust (Condie and Kröner, 2013).

1.11.5.6 Passive Continental Margins

As the name implies, passive continental margins are boundaries between oceanic and continental regions where neither collisional deformation nor subduction is taking place. Despite their present-day tectonic quiescence, the crustal structure of passive continental margins is diverse and complex since they are formed by continental rifting that accompanies the breakup of a supercontinent, such as Pangaea (200 Ma) or Rodinia (1.0 Ga). Prominent examples include the eastern seaboard of North America, the Gulf Coast, the coasts of Antarctica, and the east, west, and south coasts of Africa. Tectonic activity is minimal and erosional or weathering processes dominate, forming low-relief geography and increased sedimentary debris. These sedimentary basins are economically and scientifically valuable due to their large reservoirs of hydrocarbon and their recorded history of the rifting between two continents.

Passive margins are my be divided into two primary types; volcanic margins and nonvolcanic margins (Eldholm et al., 2002; Holbrook and Kelemen, 1993; White and McKenzie, 1989). The North Atlantic Margin formed during early Tertiary lithospheric extension between Europe and Greenland, involving the Iceland hot spot, and is one of the world's largest volcanic margins (Eldholm and Grue, 1994). The US Atlantic volcanic margin was formed in the Mesozoic but apparently without the involvement of a hot spot (Holbrook and Kelemen, 1993). The extensive volcanic rocks of these margins were formed by excess melting associated within a wide, hot zone of asthenospheric upwelling present during rifting (McKenzie and Bickle, 1988). In many cases, a high-seismic-

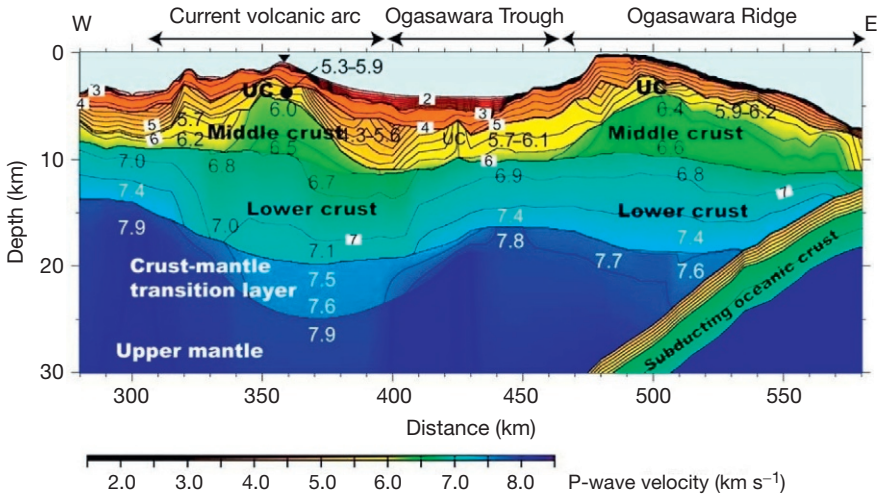

Figure 17 Crustal structure of the Izu-Ogasawara arc system (Takahashi et al., 2009). Crustal thickness varies from 10 km west of the current volcanic arc to 24 km beneath the current arc (taking 7.9 km s^{-1} as the top of mantle). Key: UC, upper crust. The lower crust is 5–10 km thick and has a relatively high P-wave velocity of 6.8–7.4 km s^{-1}, indicative of a mafic (gabbroic) composition. The crust-mantle transition layer reaches a thickness of 5 km, has a P-wave velocity of 7.5–7.6 km, and is likely composed of interlayered mafic and ultramafic rocks. The accretion of island arcs as depicted here will not yield typical continental crust because the arc crust is more mafic that continental crust which has a more intermediate crustal composition.

velocity (7.3 km s^{-1}) lower crust is also present. Nonvolcanic passive margins are formed where asthenospheric temperatures remain lower during rifting. An example is the nonvolcanic margin of the Labrador Sea of northeastern Canada.

The passive boundary zone between continental and oceanic plates is sometimes characterized by a sharp drop in elevation over distances less than ~30 km, as indicated by several gravity anomaly and wide-angle seismic studies (Delhinger et al., 1970; Faleide et al., 1990; Jones and Mgbatogu, 1982; Todd et al., 1988). A velocity profile of the margin off the Ghana coast can be seen in **Figure 18**. This ocean–continent transition indicates the absence of underplating beneath the continental basement, due to the lack of high velocities in the lower crust. See **Table 13** for additional references on continental margins.

1.11.6 Structure of Continental Crust

1.11.6.1 General Features

Continental crust above sea level comprises 29% of the Earth's crust, but when submerged continental crust is taken into account, continental crust amounts to 41% of the total crust. Since some 75% of continental crust is covered by either sediments or water, geophysical measurements are a very important source of information about the properties of the continental crust. The deep structure of the continental crust has been investigated for more than 100 years, beginning with the landmark study of Mohorovičić (1910) that defined the crust–mantle boundary. The locations of the presently available seismic refraction/wide-angle reflection profiles on continental crust are shown in **Figure 11** and amount to several thousand profiles. **Table 14** lists many key papers on continental crust studies. **Table 15** lists selected papers on the global composition of continental crust.

Studies of the continental crust using active (explosive) sources began in earnest in the late 1950s and 1960s (James and Steinhart, 1966; Pavlenkova, 1973; Steinhart and Meyer, 1961; Tuve, 1951, 1953; Tuve et al., 1954; **Table 1**). These early studies provided the first clear evidence that the seismic structure of the crust varied in a systematic way with geologic setting. They also showed that the crust can be described as consisting of several layers that are separated by either sharp or transitional boundaries. The existence of crustal layers, which have a heterogeneous fine structure, can be viewed as the product of igneous differentiation of the crust, whereby silicic melts rise into the upper crust and middle crust, leaving behind a mafic lower crust. Igneous differentiation thus leads to a heterogeneously stratified crust, with granitic to dioritic plutons forming the upper layer.

The evidence for distinct layers within the continental crust depends almost exclusively on the interpretation of second-arriving phases (wide-angle reflections). Whereas some regions display clear secondary phases, in other regions, the seismic velocity may increase gradually with depth, producing no distinct intracrustal reflections (Levander and Holliger, 1992).

1.11.6.2 Principal Crustal Types

Seismic measurements of continental structure are best described in terms of the local geologic setting. The distribution of the primary crust types is illustrated in **Figure 18**. In stable regions, the continental crust is generally 30–50 km thick. Compressional-wave seismic velocities in the upper crust are 5.6–6.3 km s^{-1}, corresponding to granitic and metasedimentary rocks. At a depth of 10–15 km, the seismic velocity commonly increases to 6.4–6.7 km s^{-1} (the middle crust), corresponding to intermediate composition plutonic rocks and amphibolite-grade metamorphic rocks. This discontinuity is sometimes referred to as the Conrad discontinuity (Conrad, 1925; **Table 1**), a term that is now out of date, as it came into

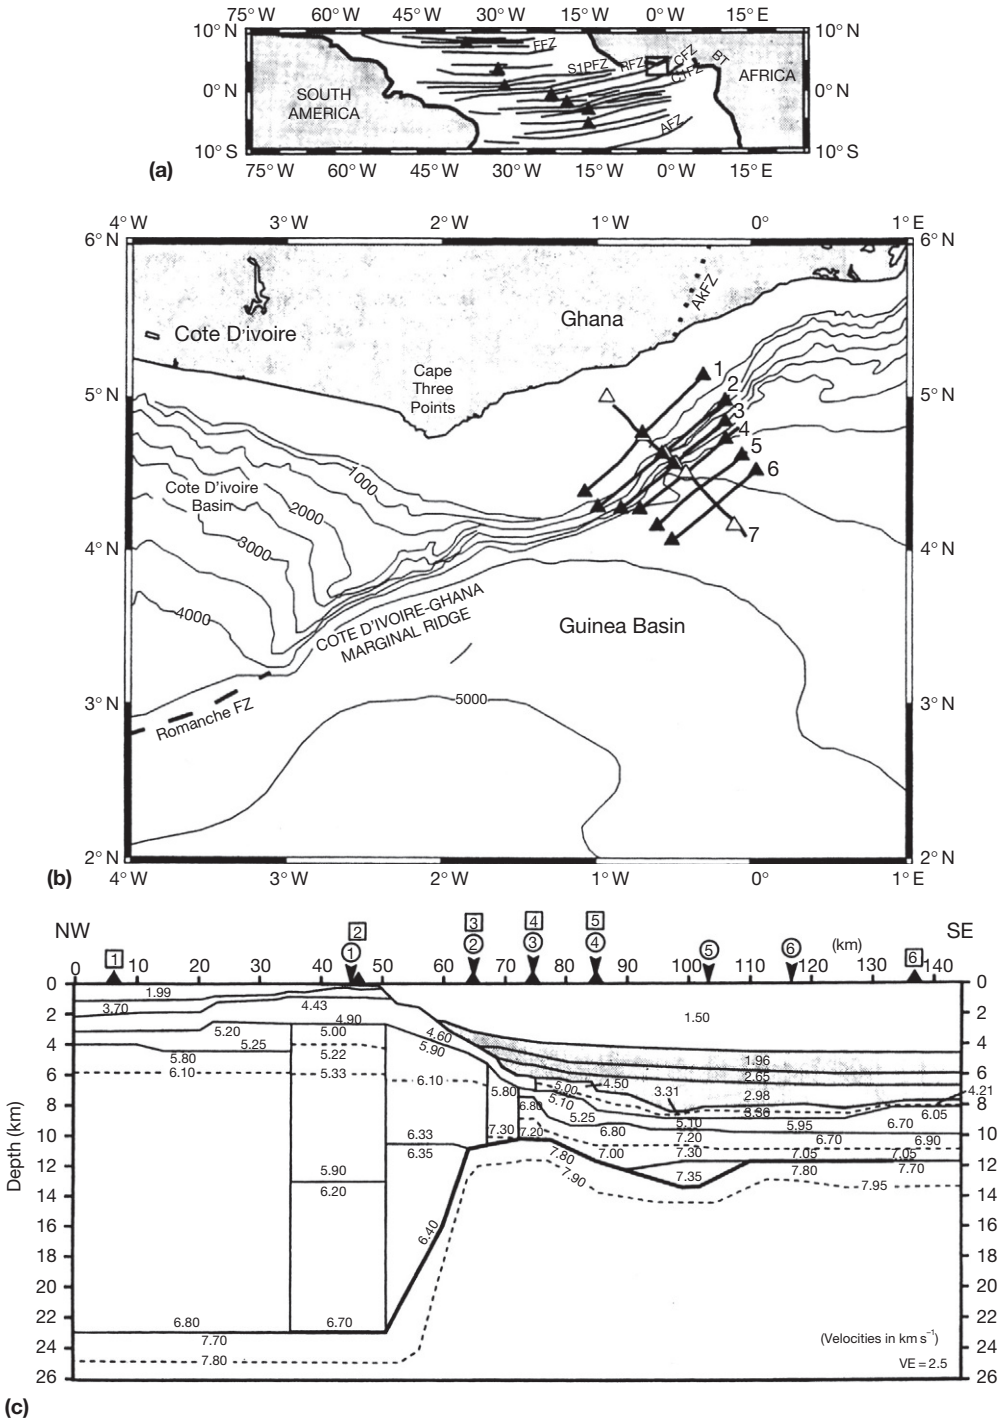

Figure 18 Example of an oceanic-continent transition zone from Ghana, west Africa. (a) Atlantic fracture zones. (b) Positions of wide-angle seismic profiles. (c) Model of seismic velocities. The crust thins over a remarkably short distance from 23 km on the continental shelf to 10–12 km beneath the oceanic crust. The igneous oceanic crust is covered by 3–4 km of low density, low-seismic velocity sediments. use at a time when the crust was believed to consist of only two layers, an upper granitic layer and a lower basaltic layer. We now know from direct observation of exposed crustal sections and numerous seismic measurements that the crust is much more complex than this term implies. The lower crust of stable continental regions commonly has a seismic velocity of 6.8–7.3 km s^{-1}. The seismic velocity below the Moho, known as the Pn velocity, is 8.1 ± 0.5 km s^{-1}. The Moho is generally clearly observed in active-source seismic profiles due to the large seismic velocity increase (0.5–1.5 km s^{-1}) at this boundary.

Seismic measurements do not have a uniform global distribution (Figure 11), which affects attempts to calculate average crustal properties. The proportions of continental crust by area are 69% shield and platform (cratons), 15% old and young orogens, 9% extended crust, 6% magmatic arc, and 1% rift (Christensen and Mooney, 1995). Using these statistics, we calculate a weighted average for crustal thickness and average crustal velocity. This procedure corrects for the overrepresentation of crustal measurements in regions of extended crust, such as western Europe and the Basin and Range Province of western North America, and the relative scarcity of measurements from Africa, Greenland, and Antarctica. The weighted mean crustal thickness and average crustal velocity are 41 km (s.d. 6.2 km) and 6.45 km s^{-1} (s.d. 0.21 km s^{-1}), as compared with the simple arithmetic average of 39 km (s.d. 8.5 km) and 6.45 km s^{-1} (s.d. 0.23 km s^{-1}; Christensen and Mooney, 1995). The weighted average is more representative of the average continental crust.

Seismic measurements of the deep crust from around the world provide a firm basis for defining the characteristics of primary crustal types associated with specific geologic settings (Figure 19). The thickest continental crust (~80 km) is found beneath the Tibetan Plateau and the South American Andes, both of which are young orogens. Continental crust with an elevation above sea level has an average thickness of 39 km, with a standard deviation of 8.5 km. Thus, 95% (two standard deviations) of the crust has a thickness of between 22 and 56 km. The higher value of this range (56 km) is well below the 70–80 km thickness of some orogens, which indicates that crustal thickness may not follow a strictly normal distribution. The thickest crust is usually a young (late Cenozoic) crust and undergoes rapid uplift and erosion that results in crustal thinning.

Continental crust thinner than 30 km is generally limited to rifts and highly extended crust, including continental margins. The process of crustal extension rarely results in uniform stretching of the crust. Instead, the brittle upper crust fractures and rotates along normal faults, and the middle crust and lower crust undergo pure shear extension. Nonuniform crustal extension over a large region gives rise to Moho undulations, which in turn drive lateral lower crustal flow (creep). Thus, tectonic processes can give rise to significant changes in the distribution of crustal materials. Lower crustal flow is not limited to extending crust; the gravitational forces associated with the high (4–5 km) topography of young orogens also drive crustal flow. A prominent example is the hypothesized southeast crustal flow of the northern and central Tibetan Plateau into the adjacent continental crust (Tapponnier and Molnar, 1975).

The deep structure of orogenic crust has been studied in nearly all the mountain belts of the world, including the South American Andes, Tibetan Plateau, Western Cordillera of North America, Urals, and European Alps (Figure 20). Orogenic crust is commonly characterized by a highly thickened, low-density, low-seismic-velocity upper crust combined with strong folding and thrusting (Figure 20). In some cases, it appears that the lower crust is being subducted into the mantle, possibly aided by a phase transformation of the mafic lower crust to the dense eclogite facies (Rudnick and Gao, 2005). Due to the complexity of the crustal and upper mantle structure, multiple seismic and nonseismic techniques are needed to reliably determine the deep structure of orogens.

1.11.6.3 Correlation of Crustal Structure with Tectonic Provinces

Shields and platform occupy by far the largest area (69%) of continental crust (Figure 21). These regions have an average

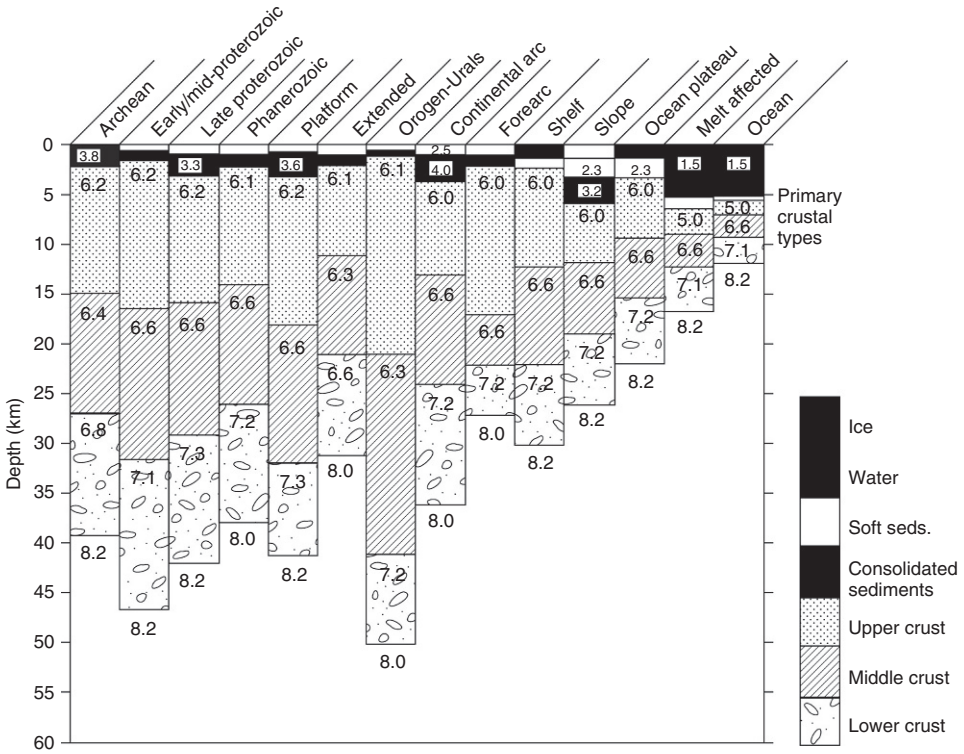

Figure 19 Fourteen primary continental and oceanic crustal types (Mooney et al., 1998). Typical P-wave velocities are indicated for the individual crustal layers and the uppermost mantle. Velocities refer to the top of each layer, and there commonly is a velocity gradient of 0.01–0.02 km s^{-1} km^{-1} within each layer. The crust thins from an average value of 40 km in continental interiors to 12 km beneath oceans.

crustal thickness of 41.5 km, very close to the weighted global average continental crustal thickness of 41 km. Orogens, young and old, show a wide range of thicknesses, from 30 to 75 km. Extended crust, as the name implies, has been thinned and shows an average thickness of 30.5 km. Rifts, both active and inactive, show a broad range, from 18 to 46 km. The broad range in crustal thickness for a tectonic province is sometimes present within a single tectonic province. For example, the Tibetan Plateau ranges in thickness from 55 to 75 km, and the Kenya rift from 20 to 36 km. Thus, significant variations sometimes occur within a single tectonic province. A second important observation is that there are numerous regions with anomalous crustal thickness. For example, southern Finland consists of a Proterozoic shield that is nearly at sea level. Global statistics would predict a crustal thickness of 41.5 ± 6.2 km. In fact, in southern Finland, the crust reaches a maximum thickness of 65 km due to the persistence of an ancient crust root at a Precambrian suture zone. This example attests to the considerable variability of continental crustal properties.

1.11.7 Global Crustal Models

The studies of the Earth's crust that have been summarized in the previous sections are sufficient to form the basis for a global model of the Earth's crust. One simple representation is a contour map of global crustal thickness (Figure 22). This map shows several interesting features. Continental interiors have a crustal thickness of 35–45 km, with much thicker (70–80 km) crust beneath the high topography of the Tibetan Plateau and South American Andes. Most continental margins have a thickness of close to 30 km, and the vast ocean basins are underlain by approximately 10-km-thick crust, including the water layer. Such a contour map, while presenting the main variations in crustal thickness, lacks information regarding lateral variations in compressional- and shear-wave velocity and density. These physical properties vary strongly within the uppermost mantle as well. For this reason, it has proved valuable to create global crustal models that quantify not only crustal thickness but also seismic velocities and density for the entire crust and uppermost mantle.

Global models of the seismic velocity and density structure of the crust have numerous applications in geophysics. Such models provide regional travel time to determine accurate earthquake locations and provide 'crustal corrections' to improve mantle seismic tomographic models. Also, lateral variations in mantle density may be inferred from long-wavelength gravity data when the density structure and thickness of the overlying crust are known. In addition, the crustal contribution to lithospheric stress and crustal isostasy can be calculated from crustal thickness, density, and topography (Mooney et al., 1998; Tesauro et al., 2012).

The earliest 3-D seismic velocity model of the Earth's crust dates back to Soller et al. (1982) who assembled one of the first compilations of global Moho and upper mantle velocity. A $2° \times 2°$ cell model called 3SMAC followed more than a

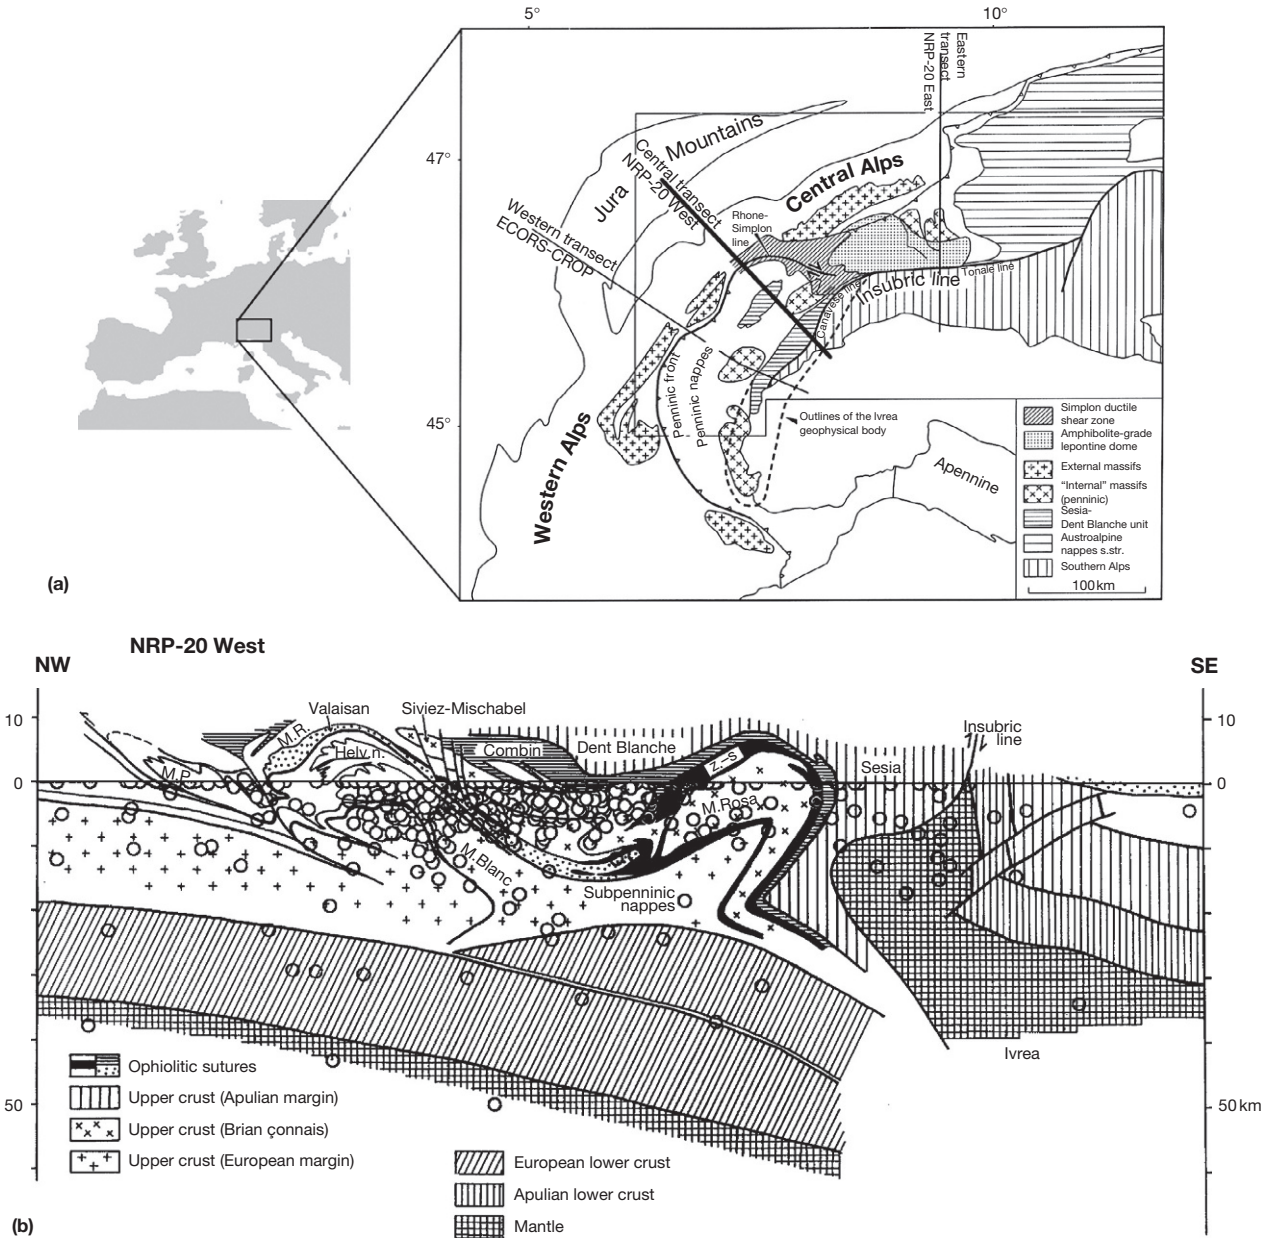

Figure 20 Synthesis of the deep structure and seismicity of the central Alps along the profile NRP-20 West (Schmidt and Kissling, 2000). (a) Location map showing the location of the seismic profile. (b) Crustal cross section (1:1 exaggeration) showing far-traveled nappes, crustal seismicity, and deep structure. Surficial faults are rooted in the middle crust. Seismicity (open circles) decreases dramatically below a depth of 10–15 km, but some earthquakes are located in the lower crust and even the upper mantle. Reproduced from Mooney WD, Beroza GC, and Kind R (2007) Fault zones from top to bottom: A geophysical perspective. In: Handy MR, Hirth G, and Hovius N (eds.), Tectonic Faults: Agents of Change on a Dynamic Planet. Cambridge, MA: MIT Press, pp. 9–46.

decade later (Nataf and Ricard, 1996). The 3SMAC model was derived using both seismological data and nonseismological constraints such as chemical composition, heat flow, and hot spot distribution, from which estimates of seismic velocities and the density in each layer were made. Two years later, CRUST 5.1 was introduced (Mooney et al., 1998) incorporating twice the amount of active-source seismic data than 3SMAC. Statistical averages were calculated for the different tectonic regions (Figure 23), and these average models were used in regions with no direct seismic measurements. However, the $5° \times 5°$ resolution was still too coarse for regional studies. In 2000, CRUST 2.0 updated the ice and sediment thickness information of CRUST 5.1 at $1° \times 1°$ resolution while basically redistributing the crustal thickness data onto a $2° \times 2°$ grid (Figure 23). In addition, several high-resolution regional compilations of depth-to-Moho values have been developed for Europe (Dèzes and Ziegler, 2001; Geiss, 1987; Meissner et al., 1987; Ritzmann et al., 2002; Tesauro et al., 2008), the Middle East, and North Africa (Seber et al., 2001), and new models have been presented for South America

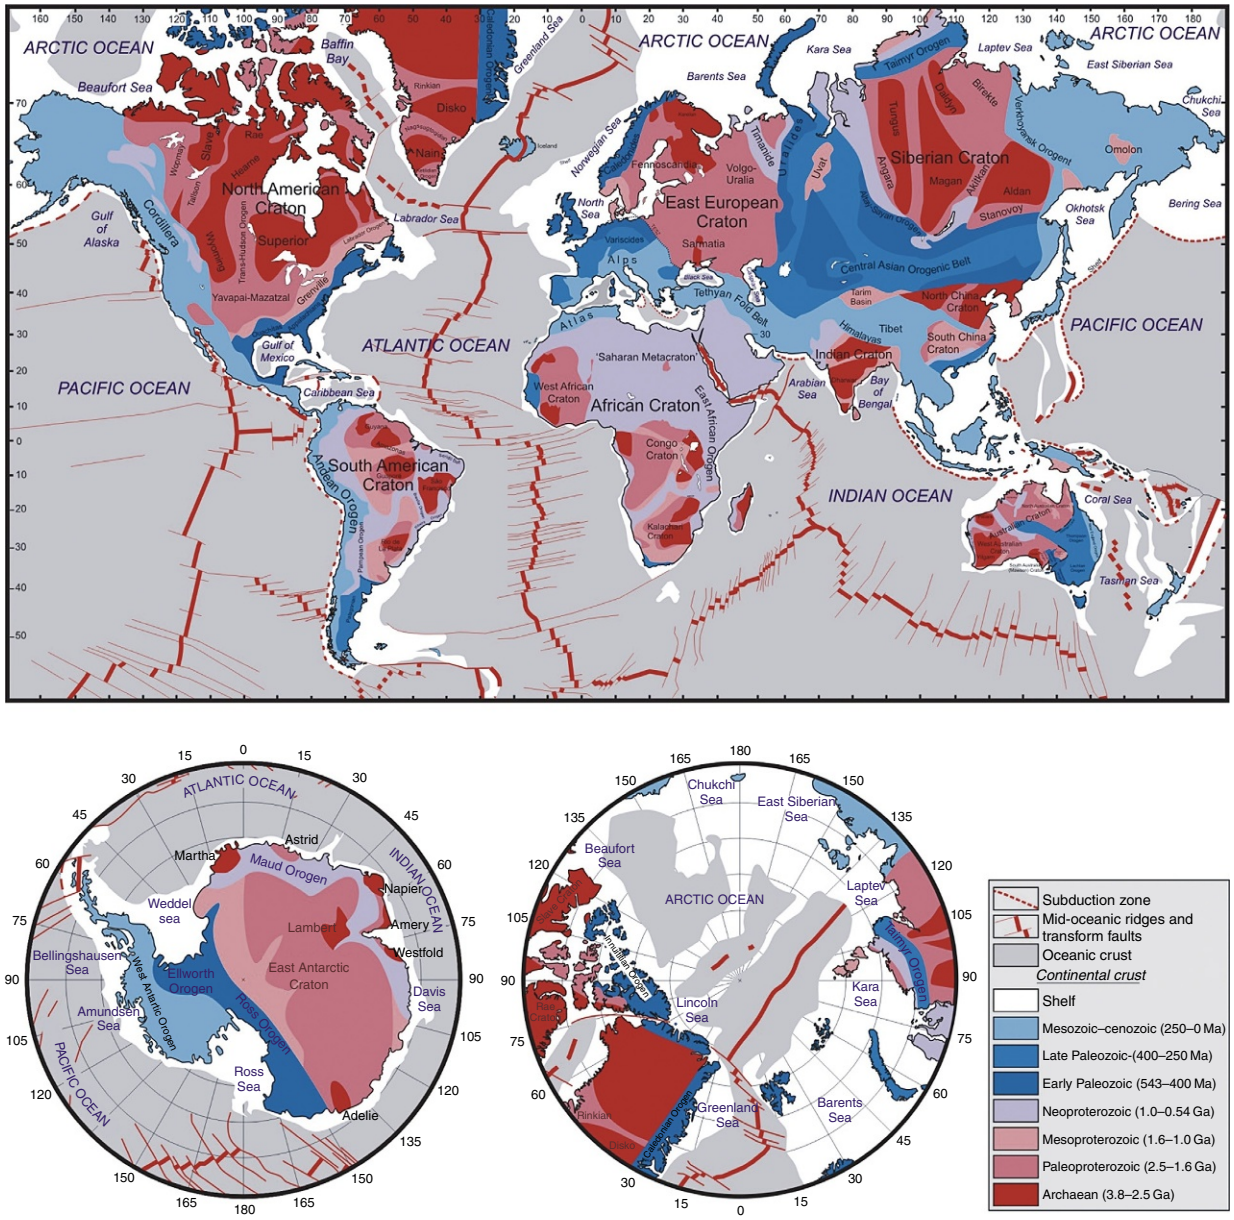

Figure 21 Geology of the continental crust. The crust is composed of six principal types, including the Precambrian platforms and shields, old and young orogens, extended crust, magmatic arcs, and rifts. Continental shelves are an additional important type. Basement age of the continental crust and distribution of mid-ocean ridges, oceanic crust, and continental shelf. The crust is subdivided by age. Precambrian shields and platforms comprise 69% of the continental crust by area. Seismic measurements cover much of the Earth's crust, but gap in coverage still exists (c.f. **Figure 11**). Statistical averages and their standard deviations make it possible to estimate crustal thickness and velocity structure in unmeasured regions, as is required to make complete global crust models. Reproduced from Mooney WD, Laske G, and Masters TG (1998) CRUST 5.1: A global crustal model at $5^{o} \times 5^{o}$. *Journal of Geophysical Research* 103: 727–747.

(Chulick et al., 2013; Lloyd et al., 2010) and Asia (Stolk et al., 2013).

Other published crustal models include WINPAK3D (Johnson and Vincent, 2002) and WENA 1.0 (Pasyanos et al., 2004), which provide an estimate of the velocity and density structure of the upper lithosphere (i.e., whole crust and uppermost mantle, Pn and Sn velocity) for specifically defined geophysical regions. These models are based on independent compilations of sediment, crust, and mantle models and data previously constructed or collected within these regions. Complete crustal models can be used to compare a variety of empirical observations over large geographic areas, to test the propagation of seismic waves, and to serve as starting models for tomographic inversion techniques. **Tables 16** and **17** list select references on global and regional crustal models, respectively.

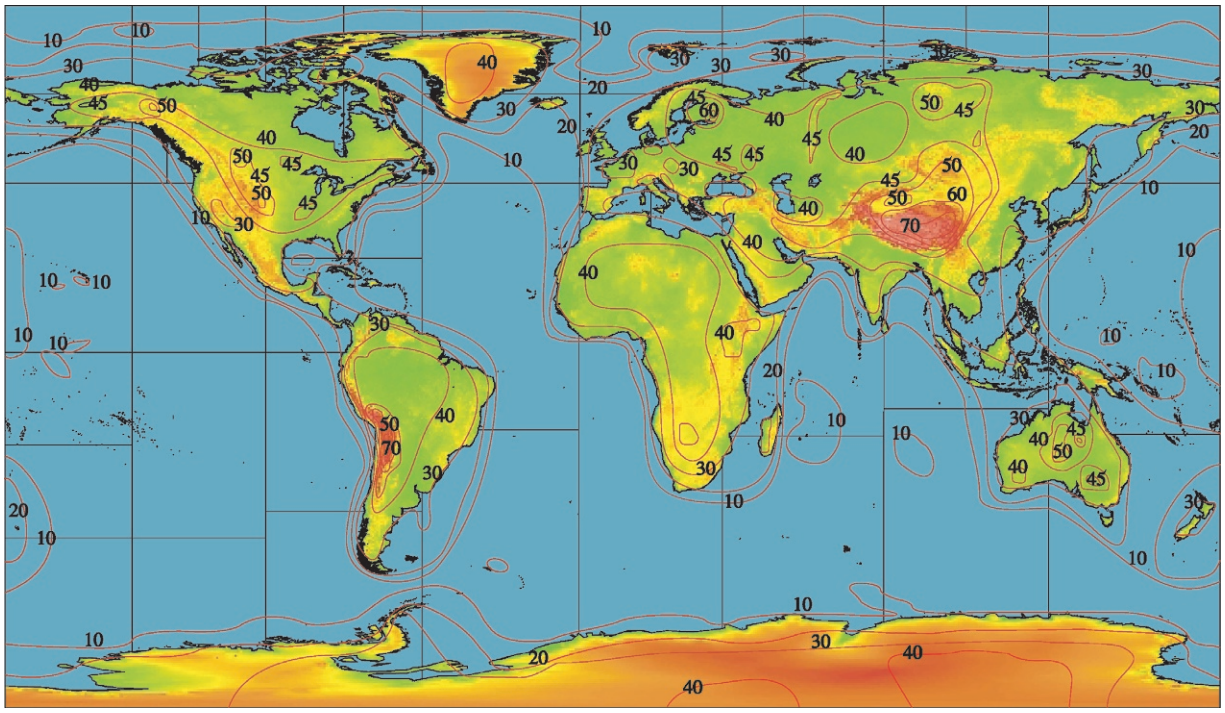

Figure 22 Global contour map of crustal thickness. Red lines indicate 10 km contour intervals.

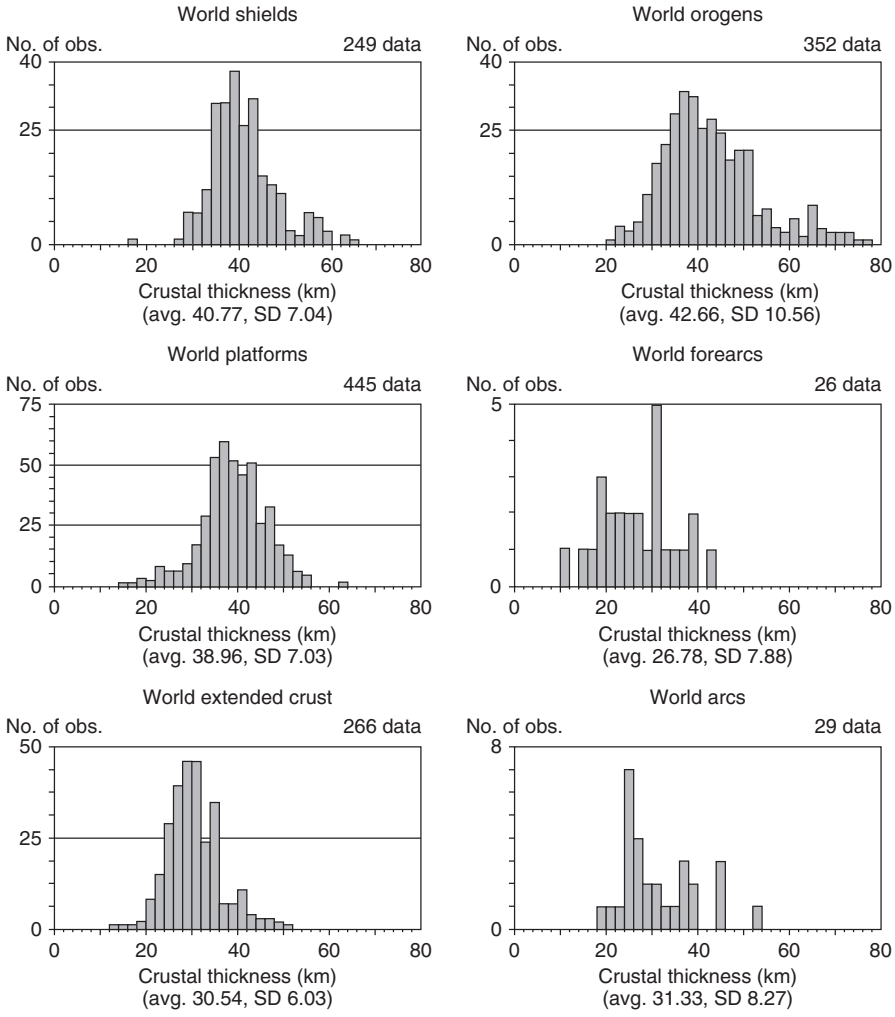

Figure 23 Histograms of crustal thickness for six continental tectonic provinces calculated from the individual point measurements (**Figure 11**). Average and standard deviations are indicated. These histograms indicate systematic differences among tectonic provinces and provide a basis for extrapolating crustal thickness into unmeasured regions.

1.11.7.1 The Sedimentary Cover

The sedimentary cover plays an important role in global crustal models because these materials have low seismic velocities and low densities. Thus, the sedimentary cover can have a large influence on travel times of seismic body and surface waves, as well as on the global gravity field.

Although sedimentary rocks cover most of the ocean floor and nearly three-quarters of continental surfaces, they are estimated to constitute only 5% of the upper 16 km of the crust by volume (Prothero and Schwab, 2004). This volumetric estimate is based on a variety of sources: (1) direct calculation from exposed stratigraphic sections or boreholes, (2) seismic reflection and refraction surveys, and (3) geochemical analyses including dissolved sodium or potassium in seawater than can be traced to total sediment–sedimentary rock volume. Taylor and McLennan (1985) and Prothero and Schwab (2004) used geologic data to estimate the abundances of common sedimentary rocks. The average abundances from these authors are 75% shales, 12% carbonates (limestone and dolomite), 10% sandstones, and 3% evaporates. Sedimentary rocks, especially fine-grained shales or mudrocks, are subject to postdepositional processes such as diagenesis, metamorphism, and alteration by oceanic water (Rudnick and Gao, 2005). These processes increase rock density and seismic velocity.

1.11.7.2 The Crystalline Crust and Uppermost Mantle

A complete global P- and S-wave crustal (and upper lithospheric) model for the globe is based on three types of information: (1) synthesizing existing models, such as WENA 1.0, the new Barents Sea model, and WINPAK; (2) seismic wave tomography data; and (3) an ongoing compilation of published seismic models for the crust, based on active- and passive-source seismology (**Figure 11**). Thus, in addition to the results from controlled sources, the model also incorporates the results from receiver function analysis, surface-wave dispersion analysis, and seismic tomography.

After compiling all of the existing regional models, the models are then compared and evaluated based on their technique and data quality. Separate databases are constructed for each technique, for example, (1) active-source models, (2) surface-wave models, (3) seismic tomography models, and (4) receiver function models. Integration of such varied models requires some discrimination of data and model quality, and a suite of models emerges from which a 'best fit' composite model is developed. Discrepancies between input models are resolved based on the best available data, which must occasionally be decided subjectively.

In the $2^\circ \times 2^\circ$ model CRUST 2.0 (**Figure 24**), the Earth's crust is divided into eight layers: (1) ice, (2) water, (3) soft sediments, (4) hard sediments, (5) crystalline upper, (6) middle crust, and (7) lower crust, and (8) uppermost mantle (Pn and Sn). The first seven layers are required so that one can accurately model the thickness of the crust and, therefore, obtain accurate Pn/Sn results for travel time analysis purposes. Both P- and S-wave velocities are specified in each layer.

Layers 1 and 2 are the easiest to determine. Ice is only found near the poles and in high regions such as the Himalayas. Efforts to determine its thickness are straightforward and relatively expeditious. Water depth is also relatively easy to interpret at $2^\circ \times 2^\circ$ using the ETOPO 2 model of the National Geophysical Data Center (2001). Both soft and hard (unconsolidated and consolidated, respectively) sediments are determined as these represent two distinct layers (3 and 4) in the model.

Layers 5–8 are determined from the compiled global crustal structure database and regional models. At present, the largest global crustal structure database of active- and passive-source measurements of the structure of the upper lithosphere includes more than 9200 data sets (almost ten times the number available for CRUST 5.1). This is more than sufficient to build a $2^\circ \times 2^\circ$ crustal block model.

Using the criteria set forth in the construction of CRUST 5.1 and other similar models, one of a series of primary crustal 'types' is assigned to each cell. There are approximately 400 different crustal model 'types' used in the $2^\circ \times 2^\circ$ global model. Once the global crustal structure model has been compiled, the model must be evaluated. Model testing is generally based on a comparison of Pg (Sg) and Pn (Sn) travel time predictions, with some empirical observations. **Tables 16** and **17** list the currently available global and regional crustal models. Updates to these models appear on a regular basis; Laske et al. (2012) presented a $1^\circ \times 1^\circ$ global model.

1.11.8 Discussion and Conclusions

Seismological studies of the crust and uppermost mantle began in the first decade of the twentieth century (Mohorovičić, 1910). Over the next 60 years, a wide range of studies (**Table 1**) defined the gross properties of the crust. The past 40 years have seen a pronounced increase in crustal and lithospheric studies, with the development of such techniques as seismic reflection studies of the deep crystalline crust, receiver function analysis, earthquake tomography, high-resolution surface-wave inversions, and seismic ambient noise analysis. These advances have been matched by extensive laboratory

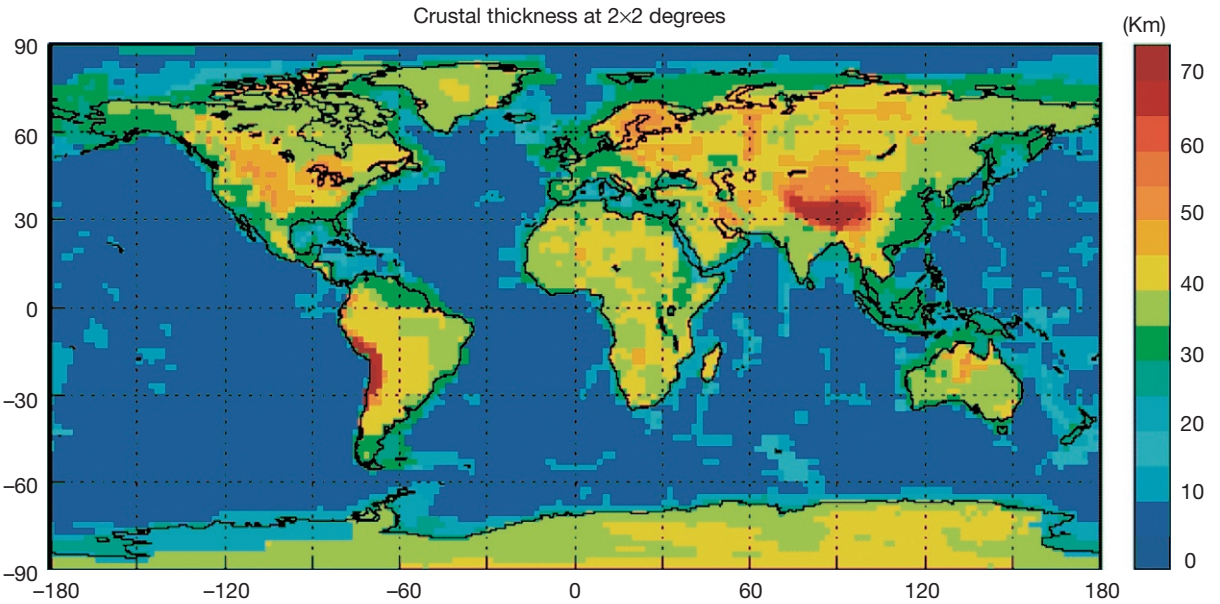

Figure 24 Crustal thickness provided by the $2^\circ \times 2^\circ$ CRUST2.0 model (Bassin et al., 2000). The locations of seismic profiles used to make this model are shown in **Figure 11**. Typical crustal velocity models are summarized in **Figure 21**. The crustal structure is estimated in regions with no seismic measurements using the statistic average illustrated in **Figure 23**. This crustal model is useful to make crustal velocity (P- and S-wave) or density correction in many types of geophysical models.

studies of rock velocities and densities and nonseismic geophysical studies using gravity, magnetic, and geoelectrical methods. Geophysical studies of the crust and subcrustal lithosphere have become so numerous that it is difficult for any individual or research group to keep abreast of all recent results. This suggests a need for a searchable data bank of results, where it would be possible to sort by technique, location, depth of penetration, or geologic setting.

The process of synthesizing global studies of crustal structure is more than 30 years old (Soller et al., 1982), and numerous regional and global models have become available (**Tables 16** and **17**). Until recently, these models have been largely based on seismic measurements of compressional-wave speeds (V_p), with the shear-wave speed (V_s) and density estimated using empirical relations. Future models should be able to rely more heavily on measured shear-wave velocities. Estimating deep crustal density will continue to be a challenge but is greatly aided by borehole and laboratory measurements. The use of multiple seismic data sets in constructing regional and global crustal models will be aided by the use of inverse techniques (e.g., Pasyanos et al., 2004). As high-resolution surface-wave models become available, particularly from ambient noise data (Campillo and Paul, 2003; Shapiro and Campillo, 2004), it will be possible to directly compare regional models derived from body-wave studies with models derived from surface waves. Likewise, nonseismic methods are rapidly developing, including satellite observations of long-wavelength gravity and magnetic fields. The synthesis of all of these methods promises to provide ever-increasing resolution on the global structure of the Earth's crust and subcrustal lithosphere.

Acknowledgments

Discussions with my scientific colleagues at the USGS and elsewhere over the past decade have aided greatly in preparing this chapter. Thanks to Claus Prodehl, Nina Pavelnkova, Shane Detweiler, Gary Chulick, Rolf Meissner, Gary Fuis, Gabi Laske, and Guy Masters for sharing their thoughts and insights. Susan McDonald, Martina Strakova, Honglei Wong, and Shane Detweiler provided valuable assistance in preparing this report.
